Cell at Half Price

One of the indispensable journals of modern biology, Cell is now available at a greatly reduced rate to individual subscribers. Why not join the many others who have taken advantage of this offer to gain immediate access to the seminal research papers published in Cell without waiting in turn for library copies? (It can be a long wait; Cell is famous—perhaps infamous—for its unavailability in the library due to excess demand.)

An international journal edited from MIT and England, Cell is published as 13 issues per year, containing the work of leading institutions in molecular biology, cell biology, virology, genetics, developmental biology and immunology. The range of subjects contained in Cell is too great to list, but papers of critical importance have already been published this year on the topics listed opposite. With all this, plus reviews of rapidly developing topics and critical book reviews, can you afford to miss a personal subscription to Cell?

A personal subscription may be taken for $85 per year (compared with the usual rate of $185). The only restrictions are that payment should be made direct to the publisher by a personal check (no invoice or receipt can be sent), and the subscriber should certify that the copies are for his personal use only. The more personal subscriptions taken, the lower the price in future years—so help us and help yourself. A subscription to start the eighties can be obtained with the form below.

Cell in the Eighties

- location of promoters in the middle of genes
- switching in the splicing pathway for immunoglobulin production
- presence of circular RNA in yeast mitochondria
- role of RNA in splicing
- discovery of new embryonic and pseudo-globin genes
- roles of new classes of enzymes in translocation and catenation of DNA
- cis dominant locus responsible for plasmid partitioning
- translocation specificities of Tn elements
- new loci involved in lambda integration
- initiation of DNA synthesis at non-origins
- action of src protein
- phenotypic control of SV40 gene expression
- mechanism of SV40 integration
- RNA virus expression and cell phenotype
- sequences of flu hemagglutinin genes
- dependence of poliovirus replicase on host protein
- association of DNA methylation with cell differentiation
- role of phorbol esters in differentiation
- fibronectin and cell growth
- nature of mouse t antigens
- segregation of developmental potential of nematodes
- role of the fv2 locus in erythropoiesis
- fate of the nuclear lamina in mitosis
- identification of cell-cell adhesion glycoprotein
- control of RNA virus expression by adjacent cellular DNA
- differences in dye binding of normal and leukemic cells
- colchicine-resistant mutants of tubulin
- recycling of cell surface receptors
- inclusion of LDL receptors in coated vesicles

Cell Discount Order Form

To: The Journals Department
The MIT Press
28 Carleton Street
Cambridge, Massachusetts 02142
USA

I should like to subscribe to Cell for 1980 and I enclose a personal check for $85. (Overseas subscribers please add $10 for postage.) The subscription is solely for my personal use.

Introduction to NUCLEAR REACTIONS

G. R. SATCHLER

– Research staff member, Oak Ridge National Laboratory, Tennessee.

Spring 1980; £25; 336pp; ISBN 0 333 25907 6.

Contents include – Some Background; Introduction to Nuclear Reactions; Elementary Scattering Theory; Models of Nuclear Reactions.

This book presents a summary of our present understanding of the Scattering and Reactions that occur in collisions between nuclei and is an introduction to the theoretical formalisms used to describe them. It is aimed primarily at readers in the undergraduate and beginning graduate student level but many others will also find it useful. The specialist from another field will find that this book is excellent background reading and the established nuclear physicist will find reading it to be helpful in refreshing the memory about areas in which he or she is not currently working.

For further details contact Francis Roach, Scientific and Medical Division, Macmillan Publishers Limited, Houndmills, Basingstoke, Hampshire, RG21 2XS.

Getting down to the finer details of microelectronics

As a leading manufacturer, and user, of microelectronic technology, Philips is constantly searching for techniques that will improve the production process, or the product, or – ideally – both. This objective has now been achieved with the development of the 'Beamwriter' vector scan lithography system. In fact, it's the only production-oriented vector scan electron beam writing system available in the world.

Compared to conventional optical lithography techniques, vector scanning produces significant savings in the time taken to produce a set of masks or reticles; hours instead of days. It is also much more efficient than the raster scan E-beam method because the writing beam is directed only to points where exposure is required. The Beamwriter also generates an exposure dosage twenty times greater than other

Fast, convenient, safe

^{32}P-nucleotides — straight from the bottle

You can add our [α-^{32}P]dNTP's or [γ-^{32}P]ATP's in stabilized aqueous solution* at 10mCi/ml directly to your reaction mixture in most cases. Elimination of the evaporation step

- saves time
- minimizes handling
- reduces possibility of decomposition or spillage

Extensive trials have shown that you can expect the same high stability and performance from these products as you obtain from the solutions in 50% aqueous ethanol that make us the world's leading supplier.

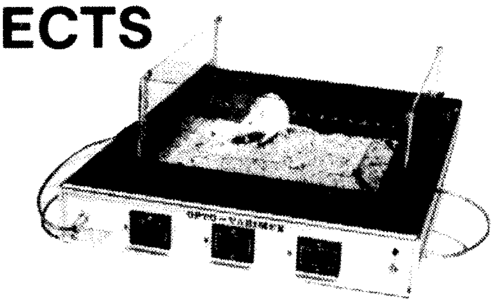
ANIMAL ACTIVITY METER

FOR RODENTS, FISH OR INSECTS

MEASURES TRAVELED DISTANCE, PLOTS PATTERN OF MOVEMENTS.

Measures Animal Respiration and Tremors



★ Measures horizontal activity by interruption of invisible infrared beams criss-crossing animal cage 1" above the bottom.
★ Measures rearing and jumping activity by means of two adjustable light curtains.
★ Plots pattern of animal movements on X-Y chart recorder by decoding position of animal from interrupted IR beams.
★ *Completely* insensitive to urine bedding or feces as IR beams cross the cage 1" above bottom.
★ Large 15" x 15" transparent plastic cage—not attached to the instrument.
★ Measures tremors and respiration by proximity sensor.

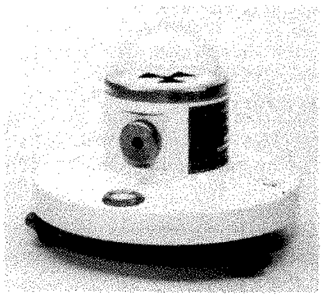
SOLAR RADIATION MEASURING INSTRUMENTS & SYSTEMS

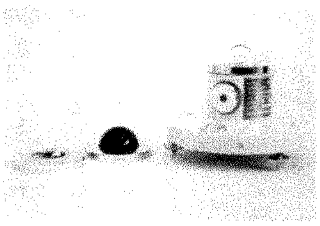
EKO, having 50 years' experience in manufacturing meteorological instruments, offer various and precise radiation instruments and systems. Consultation and instrumentation for special measuring requirements are available.



Neo Pyranometer
MS-42

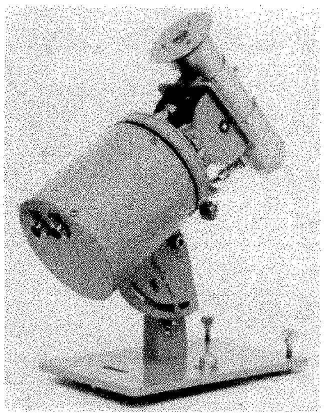
Serves for precise and stable measurement of global radiation from sun and sky. The detector is thermopile with the black hot-junction receivers and the white cold-junction receivers.
Secular fluctuations are free.

Measures with high accuracy sun and sky radiation in defined wavelength bands. Delivered with a polished hemisphere of a quartz glass in the inside and a filter in the outside which can readily be replaced by other filter (cut-off filters WG-305, GG-395, RG-695 available).

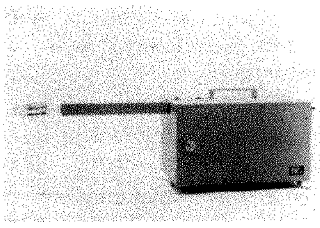


Precision Spectral Pyranometer
MS-800

Measures precisely and continuously the intensity of direct solar radiation. The opening angle, slope angle and limit angle of Pyrheliometer tube (permanently mounted on a power driven equatorial mount) are according to WMO recommendation (opening angle 3.98°).

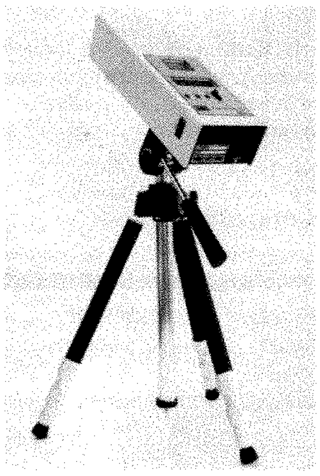


Pyrheliometer
MS-52



Net Radiometer
CN-II

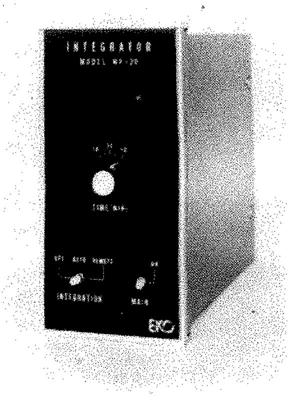
Newly designed net radiometer having characteristics of both wind through type and wind protection type. Wind through system protects polyethylene hemispheres against frost and homoginizes the temperature of the hemispheres. The built-in fan and dryer keep the shapes of upper and down hemispheres round constantly and prevents them from freezing.



Sunphotometer
MS-120

Latest new development based on WMO recommendation for measurement of atmospheric turbidity, eliminating disadvantages of same measurement with pyrheliometer with broad band filters or traditional sunphotometer in respects of accuracy and handling.
MS-120 has high spectral purity and stability against temperature fluctuation.

Connectable to all kinds of mV output type detector such as solarimeter, thermometer, radiometer, anemometer, hygrometer and other instruments of meteorological and engineering fields. Minus signals can also be integrated. By using with multi-points recorder, the integrated and the time dependent values are recorded on a same chart.



Analogue Integrator
MP-20

OTHER AVAILABLE SENSORS

- Tube Type Solarimeter
- Pyranometer + Shadow Band Stand (for measuring diffuse sky radiation)
- Various Heat Flow Measuring Sensors
- Alhedometers
- Dew Detector

RECORDERS & INTEGRATORS

- Electronic Self-Balancing Recorders
- DC Mini-Recorders
- Digital Integrator
- DC Portable Integrator
- Data Logger

Nature manuscripts

The Articles and Biological Letters in this issue are the last to be seriously affected by an industrial dispute that has been delaying the typesetting of manuscripts in the past 3 months.

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp(a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

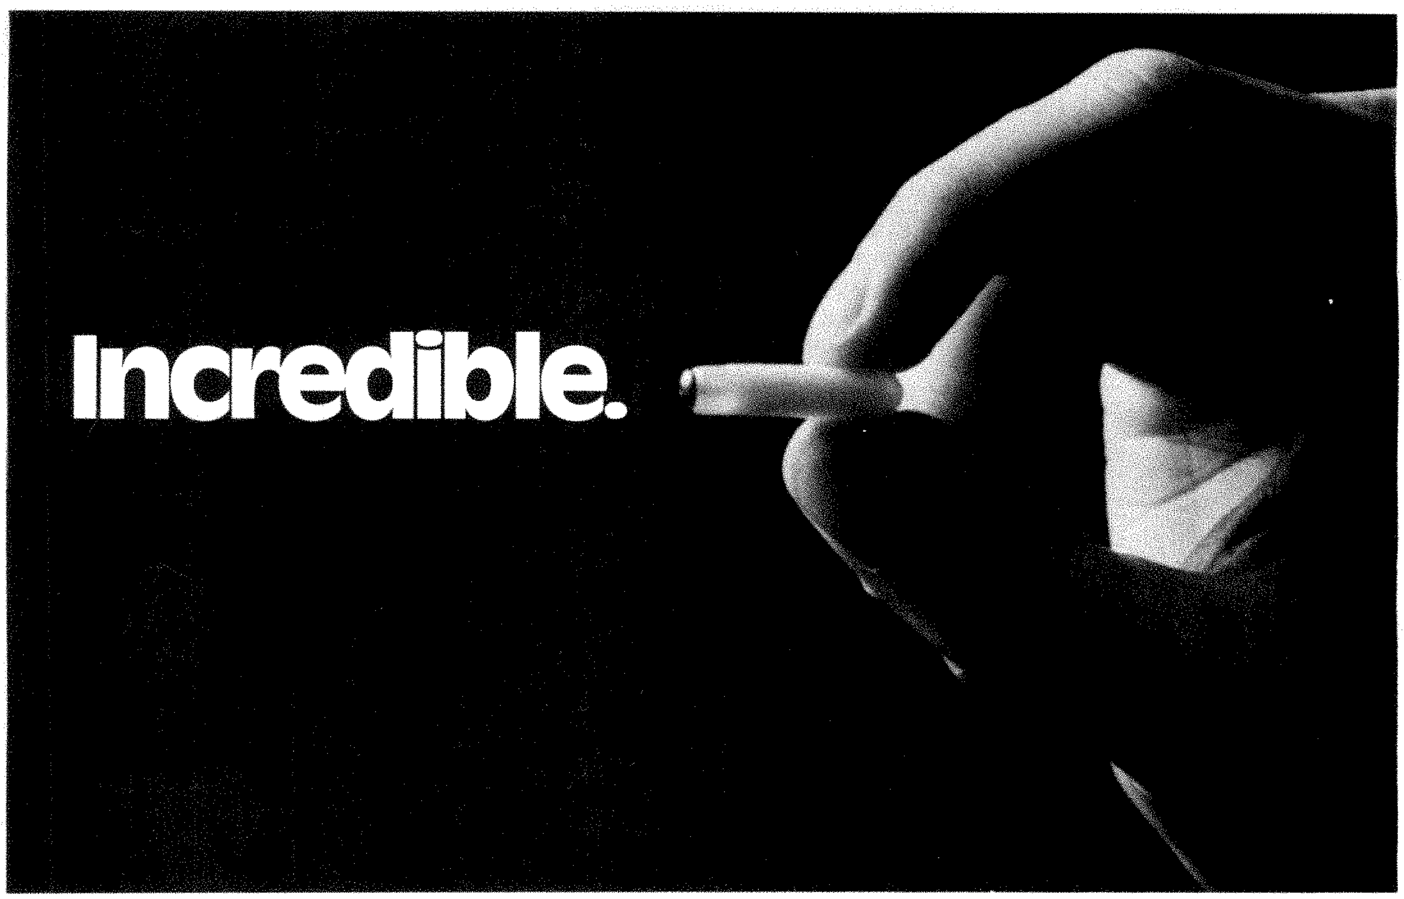
(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).



This tiny, completely self-contained pump provides continuous, unattended delivery of test solutions for one or two weeks.

It's called the Alzet® osmotic minipump.

It is a self-contained pump that is implanted subcutaneously in animals as small as mice or rats and that delivers your test solution to the animal at a controlled, continuous rate of 1µl/hr for one week, or .5µl/hr for two weeks.

And, while the Alzet® osmotic minipump frees you and your staff from the burden of dosing the animal several times a day, it can free the animal from the trauma of multiple injections.

With this pump, you can expect to produce sustained biological effects, more reproducible than with injections. The animals are unrestrained and do not undergo the continual stress of being externally catheterized.

The Alzet® osmotic minipump is ideal for compounds with short half-lives, since its constant infusion maintains steady state plasma levels of the agents. And the constant, continuous delivery assures you that there are no missed or late doses.

Steady state biological effects in unrestrained animals . . . that's what the incredible Alzet® osmotic minipump can offer you.

For technical information, call 415/494-5323. To order, call 800/227-9953 or write to Alza, Dept. Y, 950 Page Mill Road, Palo Alto, California 94304.

Fast, convenient, safe
^{32}P-nucleotides — straight from the bottle

You can add our [α-^{32}P]dNTP's or [γ-^{32}P]ATP's in stabilized aqueous solution* at 10mCi/ml directly to your reaction mixture in most cases. Elimination of the evaporation step

- saves time
- minimizes handling
- reduces possibility of decomposition or spillage

Extensive trials have shown that you can expect the same high stability and performance from these products as you obtain from the solutions in 50% aqueous ethanol that make us the world's leading supplier.

British Journal of
CLINICAL PHARMACOLOGY

ESSENTIAL INFORMATION AT YOUR FINGERTIPS. EVERY MONTH!

Published monthly on behalf of the British Pharmacological Society, *British Journal of Clinical Pharmacology* is as fast-moving as the area of science it examines:

Bridging the gap between medical professions, clinical research and the pharmaceutical industry.

Containing papers and reports on all aspects of drug action in man, in both health and disease.

Providing free copies of the proceedings of selected symposia on new methods, new drugs and new approaches to treatment, to all subscribers.

To keep up-to-date in this fast-moving area of science why not join the ever-increasing number of clinical pharmacologists all over the world who rely on the *British Journal of Clinical Pharmacology* as their professional journal.

ANNUAL SUBSCRIPTIONS
UK £59.50
USA/Canada US$195 USA/Canada (surface) US$150

text books from MACMILLAN PRESS

FROM DNA TO PROTEIN: The Transfer of Genetic Information
MARIA SZEKELY

This is the first textbook which discusses gene structure on the basis of recent discoveries of overlapping and split genes and which genetic information can be encoded into the genetic material and how it can be transferred to other materials.
A perfectly up-to-date account of our present knowledge of the structure and expression of genes in prokaryotic and eukaryotic organisms and the only available text showing the correlation between the structure and function of nucleic acids.
March, £18.00, 0 333 21836 1
£9.95, 0 333 21828 8

HUMAN REPRODUCTION AND DEVELOPMENTAL BIOLOGY
D. J. BEGLEY, J. A. FIRTH and J. R. S. HOULT

An integrated approach to describe the cellular and physiological processes of human reproduction and embryological development in relation to their underlying mechanisms and to their practical applications in medicine. The book combines anatomy, biochemistry, physiology and pharmacology, making it more suitable for modern preclinical and human biology courses.
February, £20.00, 0 333 23423 5
£9.95, 0 333 23424 3

GYNAECOLOGICAL CYTOLOGY
MATHILDE E. BOON and METTE LISE TABBERS-BOUMEESTER

Dr Boon and Dr Tabbers-Boumeester have, over the past ten years, developed the course in diagnostic cytology which was first given in Leiden in 1969.
In this volume they present their insight into both the study of diagnostic cytology, and into the teaching of this increasingly important subject. To illustrate the modern concepts of cytopathology, examples of more advanced approaches are included: as well as scanning and electron microscopy there are details of DNA measurements, morphometry and immunopathology.
June, £25.00, 0 333 26117 8

text books from MACMILLAN PRESS

FROM DNA TO PROTEIN: The Transfer of Genetic Information
MARIA SZEKELY

This is the first textbook which discusses gene structure on the basis of recent discoveries of overlapping and split genes and which genetic information can be encoded into the genetic material and how it can be transferred to other materials.
A perfectly up-to-date account of our present knowledge of the structure and expression of genes in prokaryotic and eukaryotic organisms and the only available text showing the correlation between the structure and function of nucleic acids.
March, £18.00, 0 333 21836 1
£9.95, 0 333 21828 8

HUMAN REPRODUCTION AND DEVELOPMENTAL BIOLOGY
D. J. BEGLEY, J. A. FIRTH and J. R. S. HOULT

An integrated approach to describe the cellular and physiological processes of human reproduction and embryological development in relation to their underlying mechanisms and to their practical applications in medicine. The book combines anatomy, biochemistry, physiology and pharmacology, making it more suitable for modern preclinical and human biology courses.
February, £20.00, 0 333 23423 5
£9.95, 0 333 23424 3

GYNAECOLOGICAL CYTOLOGY
MATHILDE E. BOON and METTE LISE TABBERS-BOUMEESTER

Dr Boon and Dr Tabbers-Boumeester have, over the past ten years, developed the course in diagnostic cytology which was first given in Leiden in 1969.
In this volume they present their insight into both the study of diagnostic cytology, and into the teaching of this increasingly important subject. To illustrate the modern concepts of cytopathology, examples of more advanced approaches are included: as well as scanning and electron microscopy there are details of DNA measurements, morphometry and immunopathology.
June, £25.00, 0 333 26117 8

Essential information at your fingertips

Every month!

The British Journal of Clinical Pharmacology is the leading authoritative journal presenting results of clinical pharmacological research.
Published monthly on behalf of the British Pharmacological Society the journal:
★ Bridges the gap between medical professions, clinical research and the Pharmaceutical industry.
★ Contains papers and reports on all aspects of drug action in man, in both health and disease.
★ Prints letters and short communications which allow immediate discussion of urgent observations.
Subscribers to British Journal of Clinical Pharmacology receive, free of charge, the proceedings of selected symposia on new methods, new drugs, and new approaches to treatment. Some past symposia have been on narcotic antagonists and antagonist analgesics, labetalol, clobazam mianserin, temazepam and the relationship between angina pectoris and hypertension.
Why not join the growing number of clinical pharmacologists, clinicians and others who rely on the British Journal of Clinical Pharmacology as their information medium.

Biochemical Applications of Mass Spectrometry, First Supplementary Volume
by **G.R. Waller** and **O.C. Dermer**, *both of Oklahoma State University, Stillwater*

Providing a comprehensive, up-to-date treatment of the areas of biochemical and biological knowledge elucidated by mass spectrometry, the book discusses methods and results. It is a supplement to the standard work, published in 1972, covering instrumentation, interpretation of spectra, and application.

July 1980 — 1300 pages
0471 03810 5 — $187.50/£81.75

Potential Energy Surfaces
edited by **K.P. Lawley**, *Department of Chemistry, Edinburgh University*

In this volume of essays, the major aspects of molecular collisions are examined from the point of view of the potential surface. The concept of a potential energy surface underlies the whole field of inelastic and reactive collisions between molecules. Such topics as the quenching of excited atoms, the cooling of molecules in interstellar space, chemi-ionisation and the relaxation of molecular orientation in liquids are all unified by the idea of a multi-dimensional potential.

Rapid advances in spectroscopy and beam scattering now enable some aspects of these surfaces to be reliably parameterized. Our knowledge about such topics as angle dependent potentials, vibronic coupling and branching ratios in simple atomic reactions is summarised by the various authors.

Series: *Advances in Chemical Physics, Volume 42* edited by **I. Prigogine** and **S.A. Rice**

April 1980 — 618 pages
0471 27633 2 — $78.40/£27.00

Advances in Chemical Physics Vol. 41
edited by **I. Prigogine**, *University of Brussels,*
and **S.A. Rice**, *University of Chicago*

This volume reports, interprets, and evaluates progress in this field. Topics, chosen by the editors for their timeliness, have been treated comprehensively, without limitation of space, by the authors all of whom are experts in the field.

June 1980 — 552 pages
0471 05742 8 — $59.40/£25.95

Basic Chemical Kinetics
by **H. Eyring**, *University of Utah,*
S.H. Lin, *Arizona State University,*
and **S.M. Lin**, *National Chung-Shan Institute of Sciences*

This presents, in an elementary and self-contained manner, both classical and quantal treatments of chemical kinetics for comparison. Two chapters are devoted to elementary processes in photochemistry, photophysics, and photobiology. References are provided where derivations were too long to include and problems help clarify the material covered.

May 1980 — 504 pages
0471 05496 8 — $43.75/£19.15

Cell Biology
by **P. Sheeler** and **D.E. Bianchi**, *both of California State University, Northridge*

A modern interpretation of the structure, biochemistry, and function of cells, their organelles, and other constituents. The generalized microanatomical structure of cells characterizing their organelles and their primary functions; chemistry of cells; principles for modern, experimental study; and the major structural and functional elements of the cell are all covered.

July 1980 — 596 pages
0471 78220 3 — $26.50/£11.50

Diseases of Marine Animals Vol. 1:
General Aspects, Protozoa to Gastropoda
edited by **O. Kinne**, *Biologische Anstalt Helgoland (Zentrale), W. Germany*

A comprehensive and critical review of all essential information available to date on the biotic diseases, proliferative disorders and structural abnormalities of marine animals. Produced after a decade of careful literature research, this four-volume treatise brings together, for the first time, a host of data scattered over a wide array of scientific journals and books.

Topical emphasis is placed on a detailed documentation of the types and causes of the diseases of marine animals (from the Protozoa via the Invertebrata to the Aves and Mammalia), the significance of disease as an ecological and evolutionary phenomenon, and the importance of disease for organismic performance, with a special view on experimental ecology and aquaculture.

March 1980 — 482 pages
0471 99584 3 — $73.15/£25.00

Biological Principles with Human Perspectives
by **G.E. Nelson, Jr.**, *University of South Florida*

An innovative introduction to basic biological concepts that uses the human organism extensively to exemplify major points and concepts. Topics covered include: cell structure and function, energy acquisition and use (nutrition), control systems, homeostasis, nature of the gene, human genetics and evolution, and basic ecology.

May 1980 — 442 pages
0471 02194 6 — $20.50/£8.15

Hydrobiology — A Text for Engineers and Scientists
by **D. Uhlmann**, *Professor of Hydrobiology, Technical University, Dresden*
Translated from the German by **M.F. Standen, P.J. Wilkinson** and **J. Wilkinson**

This introduction to the biology of fresh waters and water installations is intended to provide both engineers already working in the field of water economy and future engineers with a knowledge of fundamental biological principles.

March 1980 — 314 pages
0471 99557 6 — $45.10/£15.00

Molecular Biology Enzymes For Synthesis

0881 RNA LIGASE (T_4 inf. *E. coli*)
RNase and DNase FREE
Applications of this product to DNA synthesis and modifications are featured in P-L Analects 7 (2) April 1979. Minimum 1000 units/mg protein.
40 μg ..... $90.00* 200 μg. $390.00*

0880 RNA LIGASE (T_4 inf. *E. coli*)
For synthesis of oligonucleotide with specified 3′ terminus and other applications, see P-L Analects 6 (2) April 1978.
New Lower Price .... 150 units $60.00*

0872 DNA LIGASE (NAD, *E. coli*)
λ lysogenic system
New technology permits 90% lower price.
New Lower Price .... 2500 units $50.00*

0916 RNA POLYMERASE (*E. coli*)
This new product with a specific activity >800 units/mg is nuclease free.
New Low Price .... 80 units .... $ 60.00*
400 units $240.00*

0870 DNA LIGASE (T_4 inf. *E. coli*)
New process yields quality product at reduced price.
25 Weiss units (500 P-L units) $55.00*

**Insulated container and refrigerant charge $10.00.*

Cover. Differentiating quail neural crest cells are revealed in a chick-quail chimaera. A formol-induced fluorescence technique is used for cytochemical detection of catecholamine (left) and Feulgen staining is used to reveal a distinctive heterochromatin DNA marker (right). The migration of developing nerve cells is reviewed on p.663.

Contents continued overleaf

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp(a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

LEITZ-WILD
MICRO 80

A welcome awaits you at stand No. 8. And a welcome sight . . . the largest display ever seen in the U.K. of Light Microscopes for all purposes, Preparation Equipment, Balances, Image Analysis, TAS and ASM, and TV Microscopy.

KEEP ABREAST OF THE LATEST DEVELOPMENTS IN ANAESTHESIA, INTENSIVE CARE AND THE ASSOCIATED BASIC SCIENCES BY SUBSCRIBING TO

BRITISH JOURNAL OF
ANÆSTHESIA

British Journal of Anaesthesia has consistently been the leading independent journal in anaesthesia, enjoying contributions from and readership in almost every country.

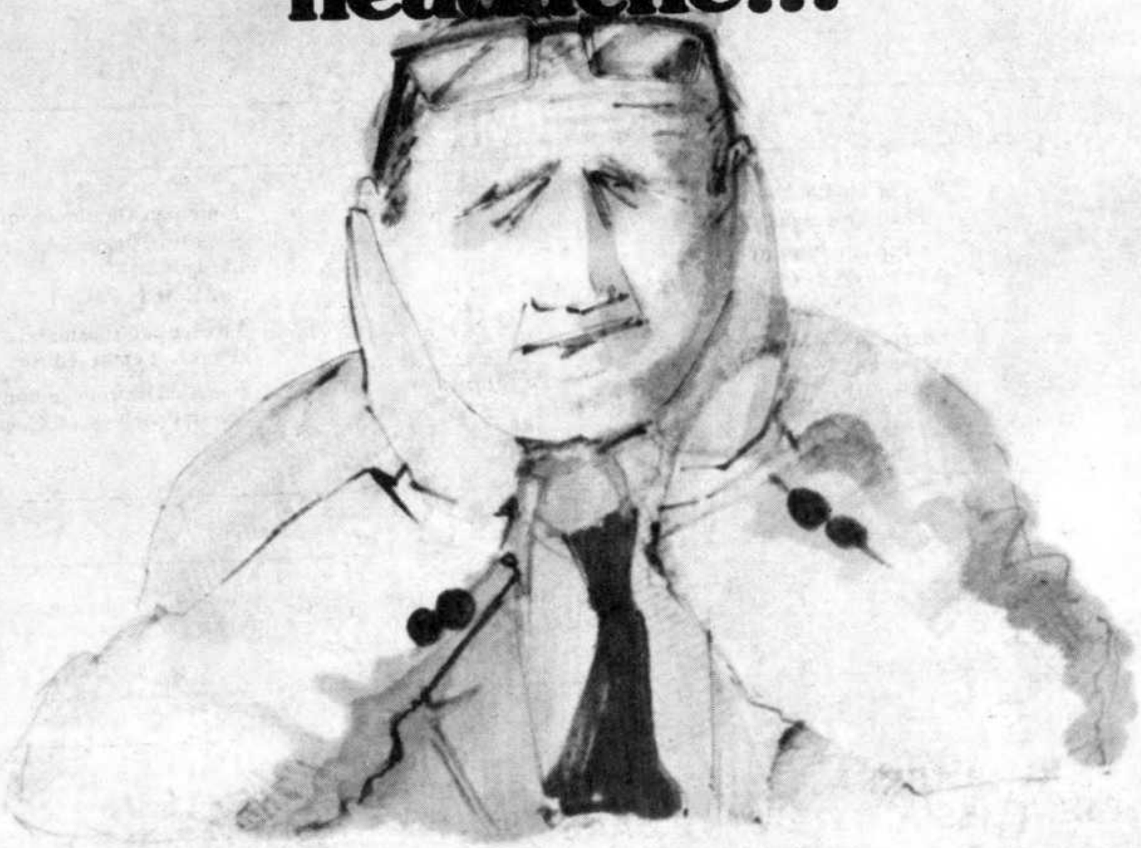
Published monthly, the journal offers:

Sections on laboratory investigations, clinical research, case reports and information on apparatus.
A correspondence section with short communications on current matters of professional interest.
Authoritative book reviews.
Twice yearly Postgraduate Educational Issues on both clinical and basic science themes.

ANNUAL SUBSCRIPTION
UK £22.50
USA & Canada US$54
Rest of the World £27.50

Orders should be accompanied by remittance, cheques made payable to Macmillan Journals Ltd.
Subscription Department, Brunel Road, Basingstoke, Hampshire, RG21 2XS, England.
Sample copies are also available from the same address.

Remembering mnemonic codes can give you a headache...



Let the EDAX 9100 remember them instead

When it comes down to Energy-Dispersive X-Ray analysis machines you must look for the one which gives *you* the least problems. With the EDAX 9100, we have designed a machine to work for you—not vice-versa. Within its compact modular construction you have a self contained operator-programmable computer with a 4000 channel memory store. The clear display gives you not only more information at a glance, visual plus numerical results on the screen, but a choice of methods in localising inhomogenious areas. Once found, our special dynastatic display feature will give you element comparison in just 5 seconds.

And when it comes to detection, Sodium right through to Plutonium are our standard range, or if you want to detect down to *Carbon*—then we can do that too—with our ECON detector.

Last but not least—the mnemonic headache. The EDAX 9100 has a unique keyboard/display which asks you which direction you wish to take your analysis—without you having to remember anything, with of course the facility to store information at any step either on floppy disc or printed on hard copy.

Perhaps the sort of thing you might rely on from the Worlds largest supplier.

BIOSIS

BIOSIS

NOTICE
To Zoologists, Librarians and Users of
ZOOLOGICAL RECORD
A Publication of the Zoological Society of London
from
BIOSCIENCES INFORMATION SERVICE
PHILADELPHIA, PA. • USA

On March 12, 1980 an agreement was signed between the Zoological Society of London and BioSciences Information Service (BIOSIS) which provides that BIOSIS assume publication of Zoological Record effective with Volume 115.

1. Under the agreement the editorial policies which have made **Zoological Record** the world's leading authority in zoological bibliography will be continued and the standard of quality of the publication maintained.

2. To assure a smooth transition, all processing of orders and delivery of publications for Volume 114 will be handled by the Zoological Society of London. It is expected that initial order processing will be completed for Volume 114 by January, 1981.

3. Order processing for Volume 115 will be initiated by BIOSIS on or about July 1, 1981. Complete delivery of all sections of Volume 115 is planned to be accomplished in 1981.

4. New computing equipment has been ordered for **Zoological Record.** It is expected that accelerated processing and delivery of **Zoological Record** will be accomplished in 1981.

For information pertaining to Volume 114 and earlier volumes please contact: Zoological Society of London, Regent's Park, London NW1 4 RY, England. Phone: 01-722-3333.

For information pertaining to Volume 115 please contact: User Services Department, BIOSIS, 2100 Arch St., Philadelphia, PA, USA 19103. Telex: 831-739 Phone 215/568-4016 or 800/523-4806 (USA only).

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

Bacterial
Cell Pastes

Escherichia coli MRE 600
The original ribonuclease free strain, buffer washed.
(Minimum quantity 3kg – £420)

Bacillus stearothermophilus NCA 1503
Grown at 60°C the source of many thermostable enzymes.
(Minimum quantity 1·5kg – £480)

Escherichia coli RY 13
Contains restriction endonuclease Eco RI and Eco RI¹.
(Minimum quantity 3kg – £420)

Thermus aquaticus YT-1
Grown at 70°C, the source of thermostable enzymes including restriction endonuclease Taq YI.
(Minimum quantity 0·5kg – £400)

Escherichia coli B
A source of ribosomes, DNA polymerase I, RNA polymerase, DNA ligase and exonuclease III.
(Minimum quantity 3kg – £420)

Micrococcus lysodeikticus NCTC 2665
A source of catalase.
(Minimum quantity 3kg – £420)

All these products can be supplied to overseas customers. 48 other types of cell paste are also available.

The listed products are offered at the quoted sterling prices, subject to availability. Prices include packing in dry ice, and delivery on UK orders, which are subject to VAT at ruling rates. Overseas orders are subject to transport charges at cost. For listed items please send your official order to:

IMMUNODEFICIENT ANIMALS IN CANCER RESEARCH

Edited by Stephen Sparrow, Pathologist at the Medical Research Council's Laboratory Animals Centre.

1980; £20.00; 208pp; ISBN 0 333 275500

CONTENTS

Immunodeficient Animals-A. J. S. Davies; Inherited immunological defects in laboratory animals -M. F. W. Festing; The importance of disease in immunodeficient mice and rats-S. Sparrow; Pathological observations on nude mice -J. P. O'Sullivan; Morphology of non-lymphatic cells in the lymph node of the nude mouse-P. Groscurth; Some aspects of immunology in the nude rat-D. I. Pritchard & R. P. Eady; Comparison of the growth of xenografts in various kinds of immunodeficient mice-S. I. Detre; Hetero-transplantation of human malignant tumours to athymic nude mice -C. O. Povelsen, M. Spang-Thomsen, J. Rygaard & J. Visfeldt; Tumour transplantation in nude rats and mice -J. C. Salomon, N. Lynch, J. Prin, V. Lascaux & A. Galinha; Transplantation of canine tumours into immunosuppressed dogs and nude mice-L. N. Owen; Human tumour xenografts in athymic nude mice: non-specific host rejection responses-R. W. Baldwin & M. V. Pimm; A prospective test for human tumour rejection antigens-M. Moore; Metastasis of human tumours implanted in immunodeficient mice -A. J. Garrett, D. Bishop, D. E. Reeson & S. Marsden; Metastatic behaviour of human colon carcinoma in nude mice-B. Sordat & E. Bogenmann; Lewis lung tumour growth and metastases in nude mice -J. C. Salomon, N. Lynch & J. Prin; Tumour metastasis in thymectomised and athymic rats -S. A. Eccles; The therapeutic response of human tumour xenografts-G. G. Steel, V. D. Courtenay, T. A. Phelps & M. J. Peckham; Cytofluorometric analysis of tumours in nude mice -P. Sordillo, H. Hansen, L. Helson & C. Helson; Identification and separation of mouse and human components of heterotransplanted human tumours-H. M. Warenius; Viral contaminants of xenografts-R. A. Weiss; The potential role of xenografts in the investigation of the clonal structure of human tumours-M. J. Peckham, P. J. Selby & G. G. Steel.

This book brings together for the first time a variety of animal models in cancer research, from the simple immunodeficient foetus to the complex genetic manipulation needed to produce the 'Lasat' mouse deficient in both thymus and spleen.
This is the first book to deal with this aspect of cancer research in such detail and it will be valuable reading for all those involved in cancer and immunological research. It will also be an important reference for students undertaking courses in Cancer Studies or Immunology.

For further details contact Ms Frances Roach, Scientific and Medical Division, Macmillan Publishers Limited, Houndmills, Basingstoke, Hampshire RG21 2XS.

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return *only the top copy* and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

M

Introduction
to
NUCLEAR
REACTIONS

G. R. SATCHLER

– Research staff member,
Oak Ridge National
Laboratory, Tennessee.

Spring 1980; £25; 336pp;
ISBN 0 333 25907 6.

Contents include – Some Background; Introduction to Nuclear Reactions; Elementary Scattering Theory; Models of Nuclear Reactions.

This book presents a summary of our present understanding of the Scattering and Reactions that occur in collisions between nuclei and is an introduction to the theoretical formalisms used to describe them. It is aimed primarily at readers in the undergraduate and beginning graduate student level but many others will also find it useful. The specialist from another field will find that this book is excellent background reading and the established nuclear physicist will find reading it to be helpful in refreshing the memory about areas in which he or she is not currently working.

For further details contact Frances Roach, Scientific and Medical Division, Macmillan Publishers Limited, Houndmills, Basingstoke, Hampshire, RG21 2XS.

Venice, Energy, Brandt and politicians

Meetings of political leaders such as that which ended in Venice on 23 June are always risky for the participants. The chief risk is simply that they fail to agree on whatever it is they have chosen to talk about, the final communique says little more than that a meeting has taken place and doubts are cast on the value of high-level consultation as such. The seven Western politicians gathered in Venice have avoided that risk. Their parting communique was at once more detailed and more constructive than for many a year. It remains to be seen, however, whether they will be able to avoid the second hazard that faces summit-goers — that having agreed on something they go back home and discover there is nothing they can do to put flesh on the bones of what they have agreed. The chances of that happening are, unfortunately, all too real. It has, after all, taken a full seven years for the heads of government to come to the belated recognition, embodied in their communique from Venice, that something must be done about the price of oil.

The argument is familiar. Increasing OPEC prices have brought about the curious blend of inflation and deflation from which the industrialized nations of the West are suffering. It has also jeopardized the future of the developing countries, which must keep on borrowing from abroad in circumstances which must throw doubt on their capacity ever to repay their debts, and which certainly diminish the chances that they will be able again to move forward socially and economically. So, the Venice communique has it, the industrialized West must diminish its own dependence on OPEC oil, must aim at making its own industry more productive and must not be seduced by the blandishments of those who argue, on narrow national grounds, for more constraints on international trade. In short, the major industrialized states appear belatedly to have recognized where their true economic interests lie, and have also made more than a passing acknowledgement of the still more serious problems of the developing countries, most recently and cogently described by the Brandt Commission (*Nature*, 21 February). So far, so good.

But why have the industrialized states not had the gumption to say all this before? That is a natural question to ask. In other less exalted contexts, in the Council of the International Energy Agency and the OECD for example, bits and pieces of the problem have been tackled. Why have the heads of government been so slow off the mark? The explication is not wholly creditable. It is only in the past year or so that all the governments represented in Venice have found themselves companions in misfortune. Both West Germany and Japan have found it possible for most of the past seven years to import oil and to pay the bills for it like men, without having to resort to their currency printing presses. It is also true that, during most of that time, several of the governments represented at Venice have been following economic policies that would have allowed inflation to bounce along at an alarming rate even if the price of oil had remained just a few dollars a barrel. The American, British and Italian governments have been the chief offenders. Readers of their communique from Venice must be forgiven the suspicion that some of the fine words are not backed by sufficient resolution. Some OPEC governments will complain, with justice, that the price of oil is being made a scapegoat for deeper ills.

The same kind of scepticism will attach to what the communique says about the steps the governments have agreed upon to lessen their dependence on OPEC oil. As these things go, the Venice document is unusually specific, replete with words such as "base-load". Plainly the world's leaders have been got at by their technical people, which no doubt is why the civil servants of the West are convinced that Venice was a "success". And, of course, it is sensible enough that the West should forswear oil-burning power stations, thereby avoiding extra demand for imported oil for the following quarter of a century. But did anybody in Venice think of asking Mrs Thatcher, the British Prime Minister, why the British nationalized utility, the Central Electricity Generating Board, is still trying to complete the oil-fired power station on the Isle of Grain (on the south bank of the Thames estuary) when the workforce of laggers (men who wrap insulation around pipes) has refused to work except at salaries which offend other workers (and their unions) on the site? The Venice declaration is also full of promises that there will be incentives, "where necessary" including fiscal incentives, to encourage the exploration for oil. Why, then, is the deregulation of United States oil prices not yet complete? Why has the British government just put up the tax on oil production in the North Sea? Why has the search for a way of taxing the "windfall profits" of the oil companies become the equivalent in the 1980s of the spate of legislation against "monopolies" in the 1920s?

The politicans at Venice can only blame themselves if some of their other specific declarations on energy policy provoke the same kind of disbelief. For the medium term, the declaration says, nuclear power, coal and conservation must bear the burden of helping to slacken external oil dependence. This, of course, has been clear for a decade. The trouble is that the governments at Venice have also known this to be the truth, but have mostly failed to make progress. The British government has only just emerged from what has been essentially a moratorium on decisions about nuclear power. (One ironical consequence is that British Nuclear Fuels Limited, which had wanted to build a prototype of a plant to vitrify nuclear waste as long ago as 1974, is now having to think of using a French process instead — see page 5.) In the United States, the Nuclear Regulatory Commission limps along with a stand-by chairman whose successor, soon to be appointed, is likely to be replaced again when the Administration changes. United States coal production, which President Nixon promised would reach 800 million tons a year at least by 1980, remains only 600 million tons a year, largely because of the endless troubles about strip-mining projects. In Britain, the National Coal Board still waits to know (after a public inquiry on the subject) whether it will be allowed to exploit a profitable reserve of coal in the Vale of Belvoir. But these, alas, are only some of the ways in which performance has fallen behind precept in energy policy. What is to be done?

Some intolerant souls, offended by this contrast, have been saying that the Venice governments should take the bull by the horns and ram what are undoubtedly sensible policies down the throats of their people. Quite apart from being a recipe for electoral disaster, such a course would risk throwing away the baby with the bathwater. The reason why it is important that the West should be freed from its dependence on OPEC oil is that money inflation is destroying valuable social institutions (educational systems, health care services, charitable institutions) while the accompanying deflation is hampering innovation. It would not however be acceptable that for the sake of being liberated from these economic shackles, people in supposedly democratic countries should be told from on high what to do and then required to put up with the consequences. Would the game then be worth the candle? Do not even self-styled and usually unqualified ecologists deserve a hearing? On nuclear power, there

0028-0836/80/270001-02$01.00

are special reasons why the professional community has a special role to play in ridding the nuclear wrangle — it is not an honest debate — of mumbo jumbo. Here and elsewhere, however, the responsibility for getting things done lies also with governments. If higher (or even higher) energy taxes are thought necessary, it is for them to persuade their voters that the benefits will be worthwhile — the chance to remain citizens of progressive yet dynamic communities. If strip mines, or ordinary coal mines, or nuclear power plants, are necessary, governments have a duty to make sure that their people know what are the stakes — the avoidance of economic debacle, to put it at its mildest; at the other end of the spectrum, the avoidance of the much more serious trouble there would be bound to be if, say, Saudi Arabia were unable to produce 11 million barrels of oil each single day.

Telling it like it is is unfortunately unfashionable. Signing communiques is easier. So too is making promises for the long term that become confused in voters' minds with solutions to immediate problems. President Carter's promise two years ago that 20 per cent of American energy production would come from the sun by the end of the century is of this kind. For the industrialized West, the question is not that of what the energy mix will be in the year 2000 but how to get from here to there. Implicitly, that is what the heads of government at Venice said. They had better now tell their people even if, as a result, they suffer the traditional fate of the bearers of bad tidings. They might make their message more palatable by seeking more imaginative ways out of their present fix — by counterbalancing the rigged OPEC market in oil with their own free market (*Nature*, 12 May). This week, for what it is worth, the spot price at Rotterdam has fallen below that charged by some OPEC countries, which can only suggest that the price would fall even more quickly if the market were assured of a regular share of the West's own oil production.

Happily, however, Venice was not entirely a recitation of familiar platitudes. Habitually, the industrialized West has collectively been shy of saying much about it obligation to the developing countries of the world for fear of giving too many hostages to fortune. At Venice, they broke cautiously with precedent and even went as far as to "welcome" the report of the Brandt Commission, promising to "study" its recommendations. They also undertook not to organize their policies on international trade in ways that would be harmful to the non-oil developing countries. That is as it should be, although it is doubtful whether the Venice signatories appreciate the magnitude of their undertaking; it implies nothing less than recreation of their industrial base at a time of perhaps indefinite recession. Such magnanimity will not come easily to the unemployed shoe-workers of New England or the unemployed workers of the British steel and motor car industries. Nor is there much hope that the industrialized West can share this burden with other states.

Why bother with school examinations?

LIKE Stratford-upon-Avon, the Changing of the Guard and the game of cricket, the British examination system is one of those characteristically British phenomena which the rest of the world knows it will never understand. Increasingly, the British are in the same plight. Now that the examinations season is at an end, when only the most diligent of those who have survived their recent trauma have begun preparing for the next, and when many of those responsible for assessing the gigantic paper output of the examination system have withdrawn temporarily from the real world, it may be safe to raise the question whether the system as a whole is worth preserving. The answer is not simple. Plainly the system cannot be entirely swept away but it is equally unthinkable that it should be preserved in its present form.

The rules of the game are worth a little effort to understand, if only for the light that understanding may throw on what must surely be one of the most pathetic of human frailties — the belief that ordinary men and women in some stratum of the academic profession can reduce any other person's quality to a number of some kind, usually between zero and 100. One of the curiosities of the recent proliferation of examinations in Britain is that in the 1950s the country was riven into the camps of those who passionately held that it is possible by means of an examination to tell at the age of eleven whether a child should have an academic or grammar school education, and the camp of those who considered the eleven-plus examination to be unjust. In the end, the abolitionists more or less won the day, comprehensive schools were invented and for a time preoccupation with school examinations seemed to have been stilled.

Alas, the wish to examine and to be examined has since reasserted itself with a vengeance. Increasing numbers of no doubt fond parents now subject their sons and daughters, often at the age of seven or eight, to the competitive examinations put up as hurdles by the fee-paying schools, knowing that their offspring will thereafter be graded once a year either by means of a number or, more elegantly, by a letter from the Greek alphabet, with pluses or minuses appended. For most British children, the first external yardstick comes at about 16, the age of O (which stands for "Ordinary") level, or alternatively of "CSE" (which stands for Certificate of Secondary Education). The word that echoes around the corridors of secondary education is that you cannot get a job unless you do reasonably well in one or other.

In ancient days (but even now in Scotland) there used to be an examination called "School Certificate" devised at least in part to meet the entrance requirements of universities. Since entry to universities was in question, universities came to dominate the committees which administered these examinations. Knowing that not every university could run its own examinations board, the universities grouped themselves into consortia, of which there at present nine, and which now administer the O-level examinations and the A (for "Advanced") equivalents, literally used by most universities as a way of telling which students should be given a chance to study something serious.

The problems of the sixteen-plus examination are unfortunately minor compared with those which crop up two years later. The rules of the game, in Britain, are that those wishing to find themselves a place in a university are required not merely to jump the hurdle of the O-level examinations but of A-level as well. They are, for practical purposes, required to elect two years in advance for what they will take an interest in at university, and then to prove (with the help of the school-teachers who happen to be around) that they can perform. Many youngsters rebel at choosing, but eventually are forced to toe the line. Others, no doubt, give up, or worse still find they have chosen wrongly. In all secondary schools, teaching A-level students is regarded as the pinacle of academic life (and in many schools it is quite remarkable how successfully the image of specialist can be created at sixteen or seventeen).

If the charge against this part of the British educational system were merely that it is farcical, it might be allowed to continue. The truth is that it is actively harmful. It ensures that young people are too narrowly prepared for the academic life, and frequently have been forced at an early age to choose the wrong disciplines to follow. In justice, and in the national interest of the British, it would be better if A-level were to be abolished. Since, however, that will not happen overnight, it would serve the same purpose if A-level were to be subverted. The way in which this might be done is easy to identify. If only universities were once again to take responsibility for their student entry, and were to select say ten per cent of intending students by some quite different method — a scholastic aptitude test, an interview or some other indicator of performance — the result would be that lots of bright young people would be found to prefer that route. If selection for the people not taking A-level were a year earlier than for the rest, but if university courses were a year longer for the early ten per cent, there would at least be a chance to tell which way was the best. Is it not time that this was tried?

New Basel director changes direction

The Basel Institute for Immunology, founded in 1971 by Hoffman-La Roche, the Swiss pharmaceutical manufacturer, is soon to have a new director, the 44-year-old chemist and geneticist Fritz Melchers. Dr Melchers, already a member of the institute, will take up his appointment with effect from 1 October.

Melchers will succeed Dr Niels Jerne, the first director, who has helped to give the institute its now outstanding reputation in basic immunology. During his tenure of the post, Jerne has also fought strongly for the independence of the institute from the company which finances it, insisting on the freedom of the members of the institute (who have no other titles) to pursue whatever research appears appropriate, to publish in the scientific literature and to pay no more attention than they wish to the research interests of their parent company.

Inevitably there is now some concern that the old arm's length policy will be changed. Melchers agreed on the telephone last week that his policy may be "more friendly" than that of Dr Jerne. The new director says, however, that he intends to maintain the role of the institute as a centre for fundamental research in immunology, cell biology and molecular genetics. Applied work will have no place at the institute, he says, and researchers will be completely free to publish their results.

Melchers says that he would not have taken the job unless these conditions had been satisfied. The future of the institute has also been underwritten by the company "for a considerable period". The implication is that the integrity of the research programme will not be compromised by short-term money problems.

The institute has a small tenured staff, but provides facilities for a much larger number of visiting scientists. It was originally set up by Roche for a limited period of ten years, although Jerne has said that Roche told him it would keep the institute going "so long as the Western world did not change drastically". Jerne took this to mean that the laboratory would continue at least as long as the world took Valium, one of the company's most successful products.

Some change in the relationship between the institute and the company is nevertheless on the cards. Melchers said last week, for example, that the role of the scientific board of the institute, as well as the mechanism for providing scientific advice to Roche, are under consideration. The function of the board has been to advise the company on the scientific work of the institute and "all matters relevant thereto". Melchers said last week that "we want a board of independent scientists who will help in the exchange of ideas with the firm while maintaining the scientific integrity of the institute". The company, he said, "has a growing interest in molecular biology and its applications", and correctly feels that the subject should be part of its research effort. Roche, said Melchers, spends a lot of money on the institute and deserves some return from it.

This does not imply that the institute will become a wing of Hoffman-La Roche research, however, Melchers says, but rather that communications between the institute and the company should be improved. He cites the setting up of a hybridoma research group at Roche with the institute's help as an example of the improved communications he has in mind.

One present member of the board, Avrion Mitchison of University College, London, greeted Melcher's appointment with delight. "He is an able scientist, decisive, and can deal with the company."

Sitting-in in Spanish labs

DEMONSTRATIONS of scientists are uncommon events, even in Spain. On 27 May, however, more than five hundred scientists of the research centres of the CSIC (*Consejo Superior de Investigaciones Científicas*) marched through the streets of Madrid to the Ministry of Universities and Research in one of the most spectacular events in three weeks of protest by Spanish researchers.

Hopes of a change in government policy towards science were aroused by the establishment of a democratic regime in Spain. The experience of the past three years has, however, been disappointing, despite some beneficial changes in the structure of the CSIC and universities.

It now seems that the creation of the Ministry for Universities and Research has not brought the benefits expected. In fact, the 1980 budget for research has increased by only 7.2 per cent, a figure far below the inflation rate. As a consequence, financial support for research has decreased in real terms compared even with the past level.

Thus the budget for one of the main sources of grants, *Fondo Nacional de Ayuda a la Investigación* (FNAI), was withheld for more than a year and afterwards fixed at only 2,500 million pesetas ($35 million), one-eighth of the applications.

This may be too late to avoid the interruption of the research in certain cases. At the same time, another important source of support for research — the programme for predoctoral fellowships — has been cut by a half. This means that an average university may receive fewer than 30 fellowships — and this at a time when unemployment among young graduates is reaching dramatic proportions.

To add to these uncertainties, the abolition of the CSIC has been considered within the government and publicly discussed. A new Universities Bill (*Ley de Autonomía Universitaria*) has been presented unchanged to parliament in spite of criticism from many sections of the scientific and university communities.

Against this background, the staff of the Institute of Astrophysics and the Experimental Station of El Zaidín in Granada recently decided to sit in as a protest against "the chaotic situation existing in the CSIC". A manifesto was issued denouncing the worsening condition of Spanish research and proclaiming that the trouble stemmed from the absence of a coherent science policy, the inadequacy of the funding for research and the low salaries and lack of promotion for scientists and technicians. Shortly afterwards, a meeting was held in Madrid by scientists and technicians and that was followed by the demonstration ending at the Ministry for Universities and Research with the reception of a delegation by the minister.

On 2 June, the minister attended the first session in Madrid of a National Congress on Science Policy after a request by the Association of Research Personnel, which consists mainly of CSIC workers. In his speech, the minister acknowledged the absence of a science policy in Spain and conceded that the present situation was caused by the low level of funding.

The day the Congress on Science Policy ended, the Ministry of Universities and Research issued a statement promising that the CSIC will not be dismantled but radically reorganized. In another statement, the ministry announced the publication of a White Paper on research and a Three-Year Plan for research. The publication of a White Paper was said to be imminent in August 1979, and a Three-Year Plan has already been promised for more than three years.

Pedro Puigdoménech

Correction

The report on 26 June of the views of the Astronomy II Committee of the Science Research Council appears to be substantially incorrect. The committee did not decide to ignore SRC policy on the appointment of postdoctoral fellows; did not offer advice to senior researchers on how best to deal with short-term appointments; and did not empower the Royal Astronomical Society to act on its behalf. The position appears to be that the Astronomy II committee did discuss the problems of short-term appointments but postponed a full-scale discussion until a meeting in October. We regret the error.

High-energy physics

LEP leaps ahead

The European Centre for Nuclear Research (CERN) last week made a firm proposal to its 12 member states for a new accelerator to be built in the 1980s. The machine, called LEP, is a 30 km circumference ring for accelerating, storing and colliding very high energy beams of electrons. The proposal already bears the mark of CERN's firebrand director-general-designate, German Professor Herwig Schopper: LEP is now cheaper than in any former design — 900 million Swiss francs (£235 million) compared with 1100 million Swiss francs (£280 million).

The scientific case for LEP is considered by high-energy physicists to be outstanding, better than that for any accelerator since the early 1950s, when the Lawrence cyclotron was built to create what was then thought to be the quantum of the nuclear force-field — the pion. LEP, it is hoped, would produce the intermediate vector bosons, the Z^0 and the W^+ and W^-, the predicted quanta of the Salam-Weinberg unified theory of the weak and electromagnetic interactions. Testing this theory is now recognized to be crucial. Success will give confidence to more ambitious attempts to construct unified field theories. Failure, however, would also be suggestive.

CERN's proposal is strictly for "LEP phase 1", which involves building a tunnel so large that ultimately beams of 130 GeV could be retained (more than enough to create $W^+ — W^-$ pairs), while cutting back on accelerating cavities (which inject the energy into the beam). The result is that LEP phase 1 would reach 50 GeV per beam, enough to make the Z^0 and make the initial tests of the Salam-Weinberg theory.

LEP phase 1 also cuts back on experimental facilities: only four of the possible eight experimental halls would be equipped. And it proposes a new injection system, which makes use of existing accelerators at CERN and eliminates the need for a large electron synchrotron, which would have been the biggest in the world, merely to inject electrons into LEP. In contrast, the intersecting storage rings, one of CERN's greatest technical successes, will not now be needed for the electrons and will be devoted to experiments outside subnuclear physics.

Professor Schopper, who is at present director of the German electron physics laboratory DESY near Hamburg, said this week that it was most important that the CERN Council had recommended that LEP be built out of CERN's running budget rather than as a separate programme. A director has been appointed to act as LEP project leader, as soon as governments give approval; this is Dr Emilio Picasso, a prominent Italian physicist at CERN. The project leader, said Schopper, would be able to organize and draw on talent throughout CERN, for short and long periods, avoiding the career problems and inflexibility that would come with a new "LEP division". "We will bring the work to the people", he said.

The CERN Council has adopted a "firm" budget for 1981 of 596 million Swiss francs (£156 million), but this includes no provision for the construction of LEP. Schopper will propose a running budget which will include LEP in six months' time: he expects it to be a little larger than the 1981 budget "but we are only talking of a per cent or two". CERN staff are now working on reducing the cost of individual LEP components. The level of the budget will determine not whether, but how fast, LEP can be built.

●CERN's 25-metre-square antiproton accumulator is to receive its first particles in the next few days — less than two years after the ground was first broken. The accumulator will be tested with protons, but the intention is to use it to reduce or "cool" the transverse motions of antiprotons created in proton-target collisions. The antiprotons, a few per collision, will be accumulated and then injected into the 400 GeV super proton synchrotron countercurrent to the SPS proton beam.

Robert Walgate

Radioactive waste

Polite debate

A first attempt by the UK National Radiological Protection Board and the British Association for the Advancement of Science to stimulate public discussion on the problems of radioactive waste management was a damp squib. A meeting they organized on 18 May, attended by interested parties in the nuclear industry, government agencies and the anti-nuclear groups, did little to uncover the detailed technical problems.

Part of the reason for the low key in which the meeting was conducted appears to have been the decision of the British authorities that, even with the new nuclear programme, fresh arrangements for long-term disposal will not be needed until the end of the century.

Both intermediate and high-level waste have been stored at Windscale for 25 years and could sit there for many more without the authorities becoming unduly bothered. If anything, the intermediate waste is a more urgent problem — it accumulates fairly rapidly and storage facilities are costly. High-level waste disposal is nevertheless receiving most attention. Out of a total waste management research budget of £25 million, the UK expects to spend more than £10 million this year on one method of treating high-level waste: the HARVEST vitrification process which has been under development by the UK Atomic Energy Authority since the late 1950s. The British government plans a prototype vitrification plant operating at Windscale by 1990 if the go-ahead for the plant can be given some time this year.

The decision for British Nuclear Fuels, which runs Windscale, will not be easy, however; it will have to choose between its own HARVEST process and the French equivalent (AVM) which has been operating commercially since 1978. Officials are keen to point out that a decision to opt for AVM would not mean the end of HARVEST, which should be kept going to keep later options open.

The government plans to start producing vitrified high-level waste by the early 1990s for several years' storage and then final disposal in some sort of demonstration facility at the end of the century. There are three options for final disposal — on or under the ocean bed or in deep geological structures.

The Radioactive Waste Advisory Committee, a group of independent advisers, recommended in its first annual report, published earlier this year, that research on the first two options should be increased.

The most promising option seems to be disposal in deep geological structures . The government programme of test-drilling in various rock formations throughout the country, however, has excited considerable public opposition. The UK Atomic Energy Authority, which started the programme now under the aegis of the Department of the Environment, has so far been able to drill boreholes at only one site in Scotland.

Planning permission for three others has been refused and the authority is awaiting the results of appeals. The Institute of Geological Sciences is now making preliminary surveys of about fifteen other sites for the Department of the Environment in the hope of drilling at some of them fairly soon.

Russian language

Finns struggling

Recent cutbacks in university Russian departments, the falling off in the numbers of school-children sitting for Russian Advanced-level examinations in secondary schools and the virtually overnight decision to close down the Russian department of the University of Lancaster have caused considerable concern in British academic circles. Very different, one might think, the situation in Finland, where a recent report of the Ministry of Education urged substantial increases in the teaching of Russian.

According to a memorandum submitted last month to the Minister of Education, Paer Stenbaeck, at least one group of students is however at risk. The memorandum, drawn up jointly by the Finland-USSR Society and the Fund for the Promotion of the Study of the Russian language claims that a "worsening" of the position of Russian language teaching in Finnish secondary schools could be a

0028-0836/80/270004-02$01.00

serious handicap to university students reading mathematics and science.

The report sets a target that 30 per cent of the active population (people between 20 and 63) should have a knowledge of Russian — thus giving Russian, for the first time, parity with German in importance as a means of international communication.

Language study in Finnish schools is complicated by the existence of two national languages — Finnish and Swedish — one of which has virtually no use and the other only limited use as a means of international communication.

According to the new proposals, all school-children must learn one foreign language (at present this is usually English) and the "other national language" (Swedish for Finnish-speakers and conversely). Study of a third language is optional, and introduced in the eighth class (15 plus).

According to the 1977 figures, some 0.2 per cent of school-children learn Russian as their first language and 6.2 per cent as their third language. The committee's recommendation of a 30 per cent Russian-speaking "active population" seems, therefore, an improvement. Their recommendations, however, refer to the whole range of language teaching — including, for example, business and secretarial courses. The "pro-Russian" lobby maintains that the school timetable is now so overburdened that few science-orientated students will be able to fit in a third optional language and will, accordingly, have no access to Russian scientific literature.

To the present generation of Finnish scientists, however, a lack of knowledge of Russian seems no particular burden. They use the cover-to-cover English-language translations of Soviet journals, and have little need, they say, for spoken Russian as a medium of scientific communication.

Experimental animals

Lab invaded

The UK Agricultural Research Council's Institute of Animal Physiology at Babraham, near Cambridge, has lived under threat of physical attack by anti-vivisectionists for several years. Last weekend the expected happened when a group of demonstrators forced their way into administrative buildings and laboratories housing animals. One object of the invasion was apparently to photograph animals in the laboratory.

The cost of the damage is small — no scientific experiments were tampered with. Preliminary estimates put it at a few hundred pounds. But, says the ARC statement, the noise of the break-in and the flashing bulbs of cameras must have caused alarm to the animals, which are accustomed to good treatment.

After some reports in the press earlier this week, the ARC also said that neither "outsize" goats nor crossbreeds between goats and horses are kept at Babraham. Some demonstrators questioned on the site were apparently under the misapprehension that toxicity tests with cosmetics and cigarettes were being carried out.

The Institute of Animal Physiology has been a focus for the anti-vivisectionists for some time. The institute has pointed out before that all experiments done there are subject to licensing by the Home Office and are not exceptional in that similar experiments take place in other laboratories.

Whaling quotas

More wrangling

The 1980 general meeting of the International Whaling Commission at Brighton on 21-26 July will have on its agenda a call for a total moratorium on whaling. This is the third time that the issue has been raised; on previous occasions, however (1972 and 1979), the motion was amended to one for selective moratoria. This year, the proposal for a total moratorium is tabled, *inter alia,* by France, the Netherlands and the United States, and is felt to have an even chance of success.

As in previous years, defeat or amendment of the motion would probably result not from a change of heart by the pro-moratorium lobby but from a feeling that adoption of such a motion would push anti-moratorium countries out of the convention and therefore beyond international control.

The way in which the argument at Brighton is likely to go can be told from what opponents of a total moratorium are saying in advance. One of the strongest opponents of a total moratorium, the Soviet Union, recently made its position clear in an English-language broadcast on Moscow radio. Calls for a total moratorium, said commentator Boris Belitskii, have no ecological basis, but are based on emotional attitudes encouraged in some quarters for political reasons.

The English-language broadcast added that in the case of really endangered species and in certain limited areas the Soviet Union has cut back its whaling considerably. (In the case of the baleen whales of the Sea of Okhotsk, a 2-year total ban has restored the population from the verge of extinction.) The broadcast went on to say that, over the past few years, the Soviet Union has closed down on-shore whaling factories and has disbanded the whaling fleet based on the Baltic port of Kaliningrad, dispersing the ships to marine and ichthyological research.

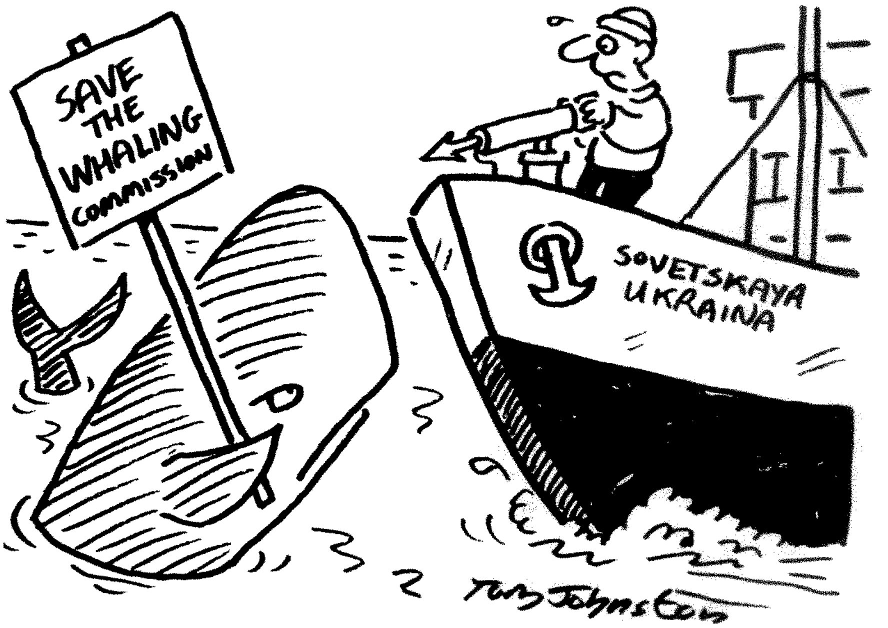
At present, Soviet whaling operation are said to be based on Vladivostok, and the two flotillas, with mother ships *Sovetskaya Rossiya* and *Sovetskaya Ukraina,* carry the necessary international observers as well as Soviet marine ecologists.

Rhetoric apart, the Soviet Union and other anti-moratorium countries such as Japan appear to have a certain case: they joined, they say, a "whaling" commission (to control and maintain the industry) not an "anti-whaling" commission.

There has been considerable speculation that, should the pro-moratorium advocates carry the day at Brighton, the Soviet Union and Japan might set up a rival commission of their own. Already the two countries have had some bilateral cooperation over quotas.

When, last year, the Soviet Union accepted the IWC's decision for a partial moratorium, in which fishing from factory ships would be confined to minke whales, it implemented this decision by ceding to Japan its North Pacific quota of 230 bryde whales in return for 300 of the less valuable minke whales from Japan's quota in the Antarctic.

Vera Rich



Big science

German doubts

WEST Germany is in the process of reviewing ten major scientific projects which would cost more than £500 million if all were funded now. They range from a continental deep drilling project which would reach the Mohorovic discontinuity at a cost of £30-75 million per hole to the possible commitment to the European proposal to build a large electron-positron ring (LEP) at CERN, Geneva at an estimated cost to Germany of £90 million.

The German research ministry, the BMFT, has set up an *ad hoc* committee of seven distinguished scientists and one journalist (to give "the people's view") which has already begun taking evidence. The cases have been heard for LEP, HERA (an electron-proton ring proposed for the DESY laboratory near Hamburg) and a relativistic heavy ion accelerator (10 GeV per nucleon) for the nuclear laboratory GSI at Darmstadt.

The chairman of the committee, Professor Klaus Pinkau of the Max-Planck-Institute für Physik und Astrophysik, Munich, said last week that he would make "a brave attempt" to finish all the hearings before August; the committee's views are not requested before mid-1981, but the sooner they are received by the new government after the October 1980 general elections, the more likely they are to affect policy, Pinkau believes.

It is not possible, says Pinkau, to make a linear list of priorities through the projects; rather the committee must "model a research landscape". The committee has been given no financial guidelines, so that it will be "a piece of artistry" to work out what the government can afford. Pinkau sees the committee as one lying between scientists and government rather than a part of government: it will make judgements among the projects on their merits, and then turn around and plead with government on behalf of those it supports.

Despite the strength of the German economy and the scale of the package of proposals now being reviewed, financial pressures are now making themselves felt. Recently, the minister for universities, Dr J Schmude, said in a speech at the Deutches Forschungs Gemeinschaft (which funds most German university research) that scientists would have to be prepared to spend less. The national budget is being pressed by the world recession, the increasing defence budget and an increased contribution to the European Community budget to offset Britain's soon-to-be-reduced subscription as negotiated by Mrs Margaret Thatcher. "Research won't be exempted" from the cuts to come, said Pinkau.

One result will probably be that the biggest projects on the list will not be funded simultaneously. And the most direct conflict now seems to be between HERA (for Hamburg) and the relativistic heavy ion accelerator (for Darmstadt). LEP is an international project which would be paid for if the current budget for CERN at Geneva can be maintained at something like its present level. Germany has said that, on terms like these, it will not object.

HERA (electron-proton) and GSI (relativistic nuclei) are, however, both national projects in closely adjacent fields. HERA would probe the structure of the proton and the quark, and the GSI device would create, for example, regions of extreme nuclear density which in principle could simulate neutron star conditions (although it would be difficult to extract the relevant information from the experiments). And, said Pinkau cryptically, "one should be aware that DESY", where HERA would go "is an internationally important laboratory". **Robert Walgate**

Major projects under review

	Cost (million DM)*	Timescale (yr)	Proposer
Spallation neutron source	400-570	8-15	Karlsruhe and Julich
BER II reactor improvement	47	2	Hahn-Meitner Inst., Berlin
Relativistic heavy ion accelerator	190	6	Darmstadt
Superconducting nuclear cyclotron, 250-300 MeV per nucleon	a) 44 b) 33	4-6	a) Julich b) Technical Univ., Munich
Ion beam fusion accelerator	100	5	Karlsruhe; *proposal withdrawn*
LEP	350 (for Germany)	6-8	CERN, Geneva
HERA	600	7	DESY, Hamburg
European synchrotron radiation source	100-230	5	European Science Foundation
Research vessel	75	2	DFG; to replace 'Meteor'
Continental deep drilling	120-300	1-5	DFG; price is per hole

* £1 sterling = 4.14 DM

Genetic manipulation

Soviet claims

On at least two occasions in the past month, the foreign services of Moscow Radio have put forward the startling claim that a team of geneticists at the Institute of Genetics and Cytology of the Byelorussian Academy of Sciences in Minsk have succeeded in manipulating the symbiotic bacteria of cereals to yield nitrogen-fixing properties.

The claimed success is surprising, especially because Minsk has no particular renown as a centre for genetic engineering, and even the most prestigious of the Comecon molecular biological establishments — Szeged — admits that its own work in this field still has a very long way to go. There is, however, a possibility that the reported discovery was not made at Minsk at all.

Indeed, the claim seems to be based on a paper by a team headed by M.A. Troicki entitled "Nitrogen fixing activity of hybrids between *Bacillus oligonitrophilus* and *E. coli*" (*Viesci Akademii Navuk BSSR, Serija Bijalahicnych navuk,* **3,** 1980). This describes a fairly routine procedure — nitrogen-fixing hybrids of *E. coli* with soil bacteria were produced at the University of Sussex nitrogen fixation unit as early as 1972, and the only novelty seems to be the use of *B. oligonitrophilus*, a name unknown to Western taxonomy, but which Troicki *et al.* state that they themselves isolated from the soil.

The authors themselves claim merely to have demonstrated the possibility of transferring nitrogen fixation genes from *B. oligonitrophilus* to *E. coli*, although the fact that their paper was published in Russian, whereas previous papers had appeared in Byelorussian, may suggest that they felt it merited All-Union rather than local attention.

Why, then, did TASS make such inflated claims? It is possible that the TASS science commentators simply misunderstood the paper, though it is difficult to see how they could do so, since Troicki's team does not mention cereal crops at all — the work reported relates to nitrogen fixation *in vitro*. It is not impossible, however, that the claim, coming at this particular time, has political overtones.

The first announcement was made on 25 May. The following day, *Pravda* published a major article on the Warsaw conference of the Warsaw Pact states entitled "Disarmament: Real Measures are Possible". Ostensibly an appeal for military detente, it contained claims that the United Kingdom and the United States are stepping up work on bacteriological weapons. In particular, said *Pravda*, the United States is working on "ethnic viruses" — bacteriological weapons which would selectively attack members of particular races or ethnic groups.

The case is cited of a black American, Eli

0028-0836/80/270007-02$01.00

Mayji, who allegedly developed a throat tumour after working as a guard at a secret US naval installation at West Oakland, where, it was alleged, Rift Valley Fever, which causes inflammation and malignant tumours, was used as a basis for an "ethnic" weapon.

Such allegations are not entirely new. Reports of alleged research on an "ethnic bomb" and other bacteriological weapons were put out by Soviet radio in 1978 (apparently in connection with the Robert Toth affair) and again earlier this year, to counter Western intelligence reports of a fatal epidemic in April 1979 emanating from a Soviet military bacteriological research station outside Sverdlovsk. (Soviet official sources said the incident was a natural outbreak of anthrax.)

Hitherto, the specific bugbear of a US "ethnic" killer has been restricted to transmissions on "Radio Peace and Progress", the Soviet service beamed to the Third World. The appearance of such charges in *Pravda*, the leading Party newspaper, is a new departure.

Vera Rich

Dioxin

ASTMS says no

The UK Health and Safety Executive came in for some sharp criticism last week from the Association of Scientific, Technical and Managerial Staffs (ASTMS). The union, with a strong following among scientists, accused the HSE of being "sluggish and ineffective" in its handling of the case of workers exposed to dioxin during an explosion at the Derbyshire plant of the Coalite and Chemical Products Company in 1968 (*Nature*, 6 March).

In 1976, after a similar accident at Seveso, Italy, the Employment Medical Advisory Service of the HSE persuaded the Coalite company to carry out studies of the workers exposed in the accident. Full reports of those studies, however, were not released to the HSE until last April in spite of several previous requests from the medical advisory service for all the information available.

In its document "Report on Coalite Chemicals", published last week, ASTMS criticizes the advisory service for not pressing harder for the earlier release of the studies. Results published in *The Lancet* early last year, it says, were sufficiently at variance with a summary of the studies released by the company to have persuaded the HSE to invoke its powers to secure the information. The HSE, however, says that increasing its pressure on the company would almost certainly have involved a lengthy legal case. Since manufacture of 2,4,5–T, of which dioxin is a contaminant, had already stopped at Coalite — indeed everywhere in the UK — the HSE did not consider release of the reports as its first priority, preferring instead to concentrate on current hazards.

The ASTMS document is also critical of the way in which Coalite conducted the studies. There was no properly matched control and not all the exposed workers were included, which means, says ASTMS, that little weight can be attached to the interpretation of the results.

The HSE is a little peeved that ASTMS appears to put the blame for these inadequacies on its shoulders, holding that Coalite must be held responsible. Both ASTMS and the HSE are agreed, however, that further studies need to be done. ASTMS is suggesting that they be carried out independently of Coalite and the advisory service under a joint union-steering committee. The advisory service is however persuading Coalite to re-do the studies, this time under tighter control.

Another specific point which ASTMS takes up is the lack of union participation at two key meetings. One was held last November to discuss the occurrence of chloracne, the disfiguring skin disease caused by dioxin and some other related chemicals, at three companies — Coalite, Stavely Chemicals and Monsanto in South Wales. According to ASTMS, the TUC medical adviser had pressed for union involvement in this meeting throughout 1979, but after some delay the HSE group finally decided that the meeting should be for "doctors only". The second meeting was held on 1 May between the advisory service and the Coalite workforce and management to discuss the preliminary assessment of the studies. ASTMS complains that the first it knew of the meeting was from that day's *Nature*.

All in all, ASTMS now says it has lost confidence in the HSE to make sure that sensible studies on workers are carried out. It asks that the HSE should compile a full report for the unions of the extent of recent contact with chloracnegenic chemicals, that the TUC and the HSE should draw up guidelines for union involvement in future studies of workers and that they should discuss what to do now about Coalite.

In the midst of these specific criticisms, the ASTMS document says that it is important not to lose sight of the most important issue, that of the inherent dangers of dioxin and the herbicide 2,4,5–T. It has now joined the growing group of unions calling for a complete ban on import into and use of the chemical in the UK. The most important thing, says Clive Jenkins, president of ASTMS, is to "get rid of the stuff".

Judy Redfearn

Arctic voyage

Swedes set out

Stockholm

The Swedish icebreaker "Ymer" sailed for the Arctic on 24 June on an expedition which has been delayed for more than a year because of Russian sensitivities about the strategic importance of the Arctic Ocean. When the ship left last week, it carried a team of biologists; it will return later in the summer to pick up a group of earth scientists.

The expedition was originally planned to celebrate the centenary of the first circumnavigation in 1897 of Europe and Asia by the Swedish explorer Adolf Erik Nordenskiöld, who began his voyage by sailing from the Atlantic to the Pacific along the Siberian coast, through the Northwest Passage. The original plan had been to retrace this route as far as the Bering Strait, and then to circumnavigate the Arctic Ocean.

Permission was asked of the Russian authorities to sail along the Siberian coast and to take sediment cores from the continental shelf there. Although the Swedish Prime Minister Fälldin took up the matter with Mr Kosygin, the Russians never replied. Reconciling themselves to Russian views about the strategic importance of the area, the Swedes changed their route.

Under the revised plan, the "Ymer" will sail through the northern Barents Sea, the deep ocean north and northeast of Spitsbergen, the sea between Spitsbergen and Greenland and the waters off northern Greenland, some never sailed before. The research is being financed by the Natural Sciences Research Council, and will involve about 80 scientists from eight countries.

One of the chief objectives will be to tell to what extent the Arctic is polluted. An increase of the lead content of Greenland snow and ferns has been recorded after the introduction of high octane petrol in the USA; but the origins and extent of other pollutants (aerosols, gases and particles) in the Arctic atmosphere, are not known. Atmospheric pollution may however affect the delicate radiation balance of the Arctic, which could in turn affect climate in neighbouring latitudes.

The expedition also plans to investigate the cooling during the Arctic summer of the lower atmosphere under the influence of the ice-pack. The formation of stratus clouds is thought to influence radiation balance and thus the climate.

The Arctic climate is also affected by the movement of huge bodies of water. Large amounts of warm, salty Atlantic water flow north along the west coast of Spitsbergen to the Arctic Ocean, while a mass of cold and less saline Arctic water flows south along the east coast of Greenland. Oceanographers with the expedition will collect information on temperature, salinity and currents down to great depths. They will be able to trace water movements in the Arctic basin by measuring concentrations of radioactive pollutants from the reprocessing plant at Windscale in the UK.

The expedition hopes to be able to determine the extent of the Quaternary ice sheet in the European Arctic. From earlier expeditions to the area, glaciologists think that an earlier Arctic ice sheet reached the Barents Sea, but they have not yet been able to tell whether it was ever joined to the Scandinavian ice sheet.

CORRESPONDENCE

Mr Arthur Frank

Sir, — The implications in Judy Redfearn's article (29 May) must not be allowed to pass unchallenged. I cannot speak for other directors but I trust that you will correct some of the misconceptions in the piece insofar as they may be thought to apply to Mr Frank's relations with the National Army Museum.

Three years ago he presented 80 optical and other instruments used by the British Army. They came free of any charges or conditions. This year the museum again benefited from Mr Frank's generosity when we received another 33 instruments. The second series came with the painless condition that they are on loan until such time as they can be put on display. They will then become the inalienable property of the museum, an invaluable addition to a section of the museum's collections which was extremely weak.

The caption "Arthur Frank with his instruments: gift horse or salesman?" is as unjust as it is clumsy. It is misleading, offensive and unworthy of a journal of the standing rightly enjoyed by *Nature*.

Yours faithfully

William Reid

National Army Museum,
London SW3, UK

Book prices again

Sir,— Dr Brindley (12 June) points out that paperbacks are published, on the average, at less than half the selling price of the cloth edition of the same title. He suggests that publishers of scientific books should make paperbacks more widely available to increase sales and perhaps profits.

The actual difference in cost between producing a paperback and cloth edition is about 65p for a book of 300 pages. What most publishers do is to subsidise the paperback edition by overpricing the cloth edition; this also happens in the pricing of journals where libraries have to pay an inflated rate which subsidises the cost of supplying copies to members. It should be understood, therefore, that where there is a dual edition the paperback is made available to individuals at an artificially low price at the expense of libraries. There is a strong feeling among publishers that this is just as most libraries are still allowing widespread photocopying which must reduce sales.

Yours faithfully,

Robert Campbell

Blackwell Scientific Publications Ltd.,
Oxford, UK

Sir, — The comparison of typical paperback and hardback book prices tabulated by G W Brindley (12 June) is illuminating, but I could hardly disagree more strongly with the conclusion which he draws from these data. The fact that paperback editions are usually much cheaper does not necessarily imply that it would be in the public interest for them to be made yet more widely available. It would surely be infinitely preferable to persuade publishers to adopt a pricing policy which honestly reflected the difference in unit costs (*ca* £1-£3) of the two types of binding.

An alternative way of looking at G W Brindley's figures is to work out, in each case, the publisher's pretended costs incurred in providing hard covers as opposed to paper: the booby prize clearly falls to Elsevier, who seek to extort from the unfortunate purchaser an astounding $45.75, merely for putting covers on their *Practical methods in electron microscopy*, followed by U California Press who price the covers of *Mezozoic mammals* at an almost equally surprising £15.25. It is admittedly unfair to make this sort of comparison without taking proper account of the comparative length, page size, quality and so on of the books in question; but this hardly alters the central conclusion, which is that the alleged cost of hard covers bears remarkably little relation to reality.

The explanation, one is told, lies in the publishers' naive belief that libraries will always purchase hardback editions, virtually regardless of cost, so that profits can supposedly be maximised by raising the hardback prices to increasingly absurd levels. The ordinary reader is then offered an edition identical in every respect except that it is bound between paper covers and carries a rather more realistic price tag. The fact that he or she would often prefer to pay an extra pound or so in order to gain the durability and convenience provided by a hard cover, is conveniently ignored.

There appears to be little justification for this abominable practice, which is a continuing source of despair for bibliophiles and of frustration for practising scientists. It is surely high time that it was brought to an end. Is there really no hope of persuading publishers to move back towards a pricing policy showing some degree of sensitivity towards the interests of ordinary book buyers?

Yours faithfully

Parkinson extended

Sir, — In his letter "Expanding on Parkinson's law" R. Moss produces the relations $I_{ai} = W^2/A + A$ where I_{ai} is the workload of a single administrator, W is the number of productive workers and A the number of administrators, for the most advanced state of any organisation. He then suggests that this relationship will lead to a limiting ratio of one administrator for each productive worker. Under some conditions, however, the relationship gives rise to a bureaucracy which expands without limit.

The workload of a single administrator, I_{ai}, falls to $2W$ as $A \rightarrow W$ and increases thereafter. If the objective of the chief administrator is to minimise I_{ai} the number of administrators will tend to W, but this will not be the case if instead the chief administrator seeks to increase the number of administrators until some aspiration level O is reached. If O is greater than $2W$, recruitment will slow down before the Moss ratio is reached. If, on the other hand, O is less than $2W$, the individual workload of an administrator will never reach the aspiration level, no matter how many administrators are employed, and recruitment will proceed at an ever more furious pace as more administrators are needed to meet the demands of an ever-increasing workload. Even if the chief administrator does attempt to minimise individual workloads, should the number of administrators ever exceed the number of productive workers the chief administrator will find himself appointing still more administrators in an attempt to regain his previous workloads.

The Moss ratio can thus be envisaged not as a limit on the number of administrators but as an event horizon beyond which a bureaucracy is doomed to expand ever more rapidly in an attempt to cope with the ever-increasing flow of minutes and memoranda generated within its own bounds. Ultimately it is unable to cope even with that function and becomes a veritable black hole of forms and minutes.

Yours faithfully

Manchester, UK.

Ethnographic DNA

Sir— Several of the articles in your issue of 26 June note that both confusion and entertainment can be had by considering DNA as selfish, ignorant or, indeed, both. Perhaps these terms are not so much anthromorphic as ethological. Competing DNA molecules are, after all, made up of four main nucleotides, the deoxyribonucleotides of that famous intratribal totem sub-group A,T,C and G. We know from previous analysis of intra-tribal totem preferences that totem clan A is matched by totem clan T, and so is totem clan G with C. Commonly called base-pairing, it is of course fully understood that neither a moral imputation is implied by base, nor sexual by pairing.

We have yet to learn what resources competing DNA molecules had thermodynamically to writhe over, but it may very well be that the totems of A,T,C and G hold secrets. For example, codons with their middle base T preferentially code amino acids with polar side chains, while those with A as centre base in the triplet preferentially code non-polar side-chain amino acids. There appears litle bias towards polar or non-polar by codons with C or G as the triplet centre[1]. Closer inspection reveals that A is replete with two amino groups and T with two hydroxy groups on the base nucleus; G has an amino and a hydroxy, so does C. As Kipling noted, there are 99 ways of making tribal lays — but in this tribe why should a totem of $-NH_2$ mean non polar coding, and -OH polar? What happens to totem loyalties when $-NH_2$ and -OH are paired, in C and G? The strong totem preference is annulled — are we seeing cultural impoverishment by mere group composition?

Since it appears that we have no answers to these questions at the anthropomorphic, ethological or any other level, it may be salutary to recall that molecular biology is about molecules — not selfish this or that. If this trend continues we can expect to see defrocked DNA and rampant tRNA.

Yours faithfully

Conversion courses

Sir, — My attention has been drawn to the reference in Robert Walgate's article on Dr Shallis (7 February) to our conversion course from arts to sciences and to the fact that it has closed. Sadly this is true; it closed seven years ago for lack of applicants. Not all our students were as successful as Mike Shallis, but a number are now active as scientists. We demonstrated that with motivated students it was possible and not too difficult to effect such a conversion, and we gained experience in the ways of doing it and the pitfalls to avoid. Although the course has closed, the experience is still there and available to anyone who wishes to start such a course again. There is surely need for it as long as our schools force children into choices at an age too early for them to know their minds.

Yours faithfully

NEWS AND VIEWS

Cell cycle control — both deterministic and probabilistic?

from Paul Nurse

ONE of the basic questions of cell biology is what determines the rate at which cells undergo division. Currently there are two models of cell cycle control which provide answers to this question. The first is the deterministic growth controlled model which developed mainly from experiments with microbial cells, and the second is the transition probability model which developed to explain the behaviour of mammalian cells.

The basic postulate of the growth controlled model is that the rate of division is determined by the rate of growth of the cell[1]. Some cell cycle event cannot take place until the cell has attained a critical cell size, and as a consequence the rate at which cells grow to that size determines the rate at which they divide. The model very simply explains why in steady state populations of exponentially growing cells, size at division remains constant and the rate of division parallels the rate of increase in cell mass. It is further supported by observations that the occurrence of certain cell cycle events, such as the initiation of DNA replication in *Escherichia coli*[2], traverse of 'start' as marked by bud emergence in budding yeast[3], and cell division in fission yeast[4], are well correlated with the attainment of a particular cell size.

In the original form of the Smith and Martin transition probability model, the cell cycle is composed of an A-state and B-phase[5]. In the A-state the cell does not progress towards division but it has a constant transition probability of entering the B-phase. The B-phase is made up of most of the conventional cell cycle and is completed in a constant period of time. Therefore the rate of division is determined by the time a cell takes to undergo the random or probabilistic transition from the A-state and to the complete the constant time period in the B-phase. The main evidence in favour of the model is that the distribution of cell cycle times includes an exponential component which reflects the probabilistic transition from the A-state. This evidence is particularly strong if it is assumed that the B-phase is identical for sister cells, since the differences in cell cycle times between sister cells can be described solely in terms of an exponential[6]. The deterministic or growth controlled model cannot easily explain such a distribution[7], although with further assumptions it can do so (for example see reference 8).

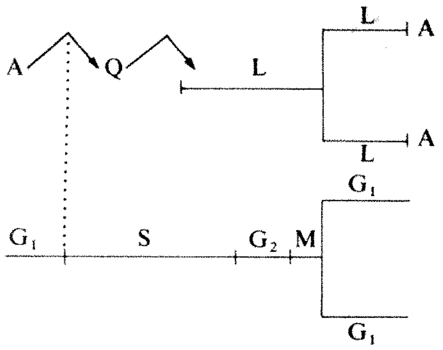
Brooks *et al.*[9] have recently modified the transition probability model to account for the identical B-phase in sister cells, and to deal with the behaviour of cells stimulated from quiescence. In the modified model, cells begin their progress towards division by a random transition from a Q-state to commence a process L. This process takes a constant time period to be completed after which the cell enters the A-state. Exit from the A-state is at random and leads to DNA replication and subsequently cell division, and, in addition, to entry into the next Q-state. In the modified model the time take to complete the two random transitions and constant time period of the sequence Q→L→A determines the rate of cell division. The model explains why the differences in cell cycle times between sister cells can be described solely in terms of an exponential since the Q→L part of the sequence occurs in the mother cell and thus is common to the two sister cells. Consequently the differences between sister cell cycle times are due solely to the random A-transition which results in the exponential distribution. The B-phase does not feature in the modified model, but its duration is equivalent to the Q→L sequence accounting for the identical B-phases of sister cells. The modified model also explains why there were two points of control in stimulated quiescent 3T3 cells[10], since one control was acting at the Q-state transition and the other at the A-state transition. Brooks *et al.*[9] have also suggested that the behaviour of the mitotic centres organising the spindle poles could act as an analogue of the Q→L→A sequence[9]. The initiation of duplication of the centres could correspond to the Q-state transition, their maturation to the L-process, and their separation to the A-state transition. This suggestion is interesting, since centrioles are likely to provide a convenient marker for the behaviour of the less tangible mitotic centres[9], and centrioles or their equivalents have been implicated in cell cycle control of both 3T3 cells[11] and budding yeast cells[12].

Paul Nurse is in the School of Biological Sciences, University of Sussex, UK.

The modified transition probability model is an advance on the original form of the model but suffers from one or two difficulties. In rat hepatoma cells van Wijk *et al.*[13] have found that most of the variability in cell cycle times between sister cells is due to variability in the duration of G_2. This is difficult to reconcile with the A-state transition occurring before S-phase. In addition, the duration of the B-phase (equivalent to the Q→L sequence) is more similar for cells of rat hepatoma which share a common grandmother (cousins), than for unrelated cells[14]. The modified transition probability model predicts that sister cells should have identical B-phases, but that cousin cells should be as dissimilar as any pair of unrelated cells within the population. Finally, centriolar behaviour may not be such a good analogue of the Q→L→A sequence, since the model predicts that quiescent cells in the Q-state should only have a single centriole, whereas Tucker and Pardee[11] have shown that 3T3 cells in such a state have a pair of centrioles.

The deterministic growth controlled model and the transition probability model give apparently different answers to the question of what determines the rate at which cells divide. One explanation for this may be that the cell cycle controls are quite different for microbial and mammalian cells. However, some experiments suggest that this may not be the case. The rate of bud emergence has been followed in cells of

0028-0836/80/270009-02$01.00



After an indeterminate period of time in the A state, a cell makes the transition to the Q state and at the same time starts synthesizing DNA (S phase). The cell remains in Q for an indeterminate period before making the transition to L. If the transition occurs during S (as shown here) or G_2, the L state, which has a fixed time span, will last until after mitosis (M) and division. Therefore both sister cells will start their own A state simultaneously.

budding yeast that have been released from a block at 'start'[13]. The distribution of times to bud-emergence within the population includes an exponential component as would be expected from the transition probability model. To explain this observation and the cell size correlation with bud-emergence mentioned above, Shilo *et al.*[15] suggested that traverse of 'start' requires growth of the cell to a critical size followed by a random transition which 'started' the cell cycle. A rather similar conclusion has been arrived at by Shields *et al.*[16] from investigations of the role of cell size on cell cycle time in mouse fibroblasts. Quiescent small cells take longer to enter S-phase than do large ones, and cells born of small mother cells have longer cell cycle times than those derived from larger mothers. The distributions of the times required before S-phase and cell division took place were found to include exponential components. The authors proposed that cell size affects the length of the B-phase acting before G_1, and within the framework of the modified transition probability model, that cell size affects the length of the L-process[7]. These experiments are suggestive that there is a size related element and a probabilistic element in the cell cycle control of both microbial and mammalian cells. Therefore it is possible that the deterministic and probabilistic models are describing different aspects of a single cell cycle control. In microbial cells the probabilistic transition occurs very rapidly, and the deterministic size element is more important in controlling the rate of division. In mammalian cells the probabilistic transition is much slower, and the deterministic size element is of less importance in controlling the rate of division.

In this context it is of interest that some mechanisms for monitoring cell size and controlling the cell cycle include both deterministic and probabilistic elements[17]. For example, in one mechanism a structure is built up at a rate proportional to the size of the cell. Smaller cells will build up the structure slower than larger ones and consequently cells will tend to complete the structure at the same cell size. This is the deterministic size related element of the mechanism. Once completed, the structure then has to interact with some site within the cell to become active. Since there is only a single copy of the structure its interaction with the site will be a random process and forms the probabilistic element in the control. If the building of the structure takes a long time then the control will appear deterministic and size related as in microbial cells, and if the interaction between the structure and site takes a long time then the control will appear probabilistic as in mammalian cells.

The possibility that the deterministic and probabilistic models describe different aspects of a single cell cycle control common to both microbial and mammalian cells, and that both aspects are important for determining the rate of division is at present based on few experiments. What is required are more kinetic investigations of the distributions of cell cycle times coupled with measurements of cell size. It would also be of interest to follow the behaviour of centrioles or their equivalent in the same experiments, to see if a firmer link can be established between these structures and the more abstract elements of the cell cycle control models. □

Can comets become asteroids?

from David W. Hughes

COMETARY nuclei, kilometric sized dirty snowballs, obviously evolve as the comets age. At each perihelion passage the nucleus will lose about a metre or so of dust and ice, producing the coma and the tail and also a large collection of meteoroids which feed the meteor stream. This process can continue until the nucleus has completely disintegrated into gas and dust but there are other possibilities. The nucleus could disrupt into a number of boulders which quickly outgas. The core of the nucleus could be slightly more compact than the outer regions and could remain when all the ice has sublimated. Or an insulating crust could develop which reduces the heat flow in towards the centre of the nucleus and thus stops the sublimation and the loss of volatiles. The last two possibilities lead to an apparent transformation of the comet into an asteroid. The Solar System would then contain active comets, asteroids and a third class of objects, extinct cometary nuclei which looks like asteroids but have the orbits of comets.

The problems of this evolutionary transformation have been discussed recently in two papers published in *The Moon and the Planets*. These are by Ľubor Kresák of the Astronomical Institute of the Slovak Academy of Science, Bratislava (**22**, 83; 1980) and H. Rickman, Astronomical Observatory, Uppsala, Sweden and C. Froeschlé, The Nice Observatory, France (**22**, 125; 1980).

Kresák stresses the role of Jupiter. The mean of the asteroidal orbits has the same eccentricity and orientation as the orbit of Jupiter. Also there is a spherical region around Jupiter of at least 1 AU in radius which is completely void of asteroids. The system of short period comets on the other hand is aligned with the line of apsides of the jovian orbit and the immediate environment of Jupiter is filled with an overabundance of comets some of which even become jovian satellites for a time. Added to this fundamental difference in orbital characteristics is the problem of observational selection. In the case of comets we are dealing with a class of objects which have a potential lifetime very much shorter than the age of the Solar System. So the comets that *are* observed today are either the last, abnormally long lived survivors of a much more abundant original population or they must be a late generation of an evolutionary sequence.

The first of these hypotheses is unlikely. The second implies that we are observing an evolved state of equilibrium between source and sink and consequentially short lived objects are underrepresented.

It would also be very presumptious of us to believe that all the types of asteroids and comets have been discovered. For example, asteroids were known for over a century before the Trojans (which follow Jupiter's orbit and have a mean elongation of 60° ahead and behind Jupiter) and the Apollo's (perihelian distance less than 1 AU) were

---

0028-0836/80/270010-02$01.00

discovered. In the last few years certain new classes of objects have been found, one with inclinations over 60°, another with periods less than a year. Chiron (asteroid number 2060) has an orbit between the orbits of Saturn and Uranus and considering the immense effect of distance dependent observational selection it is difficult to tell how many others there are in Chiron's class. One asteroid 1978 SB has been found to have an orbit similar to that of Comet Encke.

Observational bias is even stronger for comets because the brightness decreases drastically with heliocentric distance. Comets can only be seen if they get close enough to the Sun to display outgassing phenomena and to do this they have to get to within 0.0001 of the radius of the distant cometary reservoir known as the Oort cloud. Even considering temporal variations it is interesting to note that dependable astronomical observations have only been going on for about one ten-thousandth the average revolution period of a 'new' comet. At best we can only have seen 0.00001% of the whole comet population. A great number of long period comets must exist with perihelia beyond the orbit of Jupiter. Only five have been discovered so far, the first in 1974.

Even bearing these problems in mind Kresák concludes that very few of the asteroids could have been comets and none have been definitely identified as such. There are only two possible paths between the two orbital classes. Both require a complicated sequence of planetary capture by Jupiter or Saturn followed by strong non-gravitational forces to vary the aphelion distance thus pulling the comet away from Jupiter or Saturn into a more stable orbit undisturbed by planetary encounters. On attaining this stable orbit the non-gravitational forces have to cease.

The possible (even if non probable) ex-comets among the asteroids are Chiron, Hidalgo, Thule, members of the Trojan, Hilda and Grigua groups and the Apollo and Amor objects (the Amor's have perihelia between the orbits of Earth and Mars).

Rickman and Froeschlé specifically discuss the possible cometary contribution to the Apollo-Amor population. In 1963 Öpik suggested (*Adv. Astron. Astrophys.*, **2**, 219) that the perturbations of Mars on the inner boundary of the asteroid belt were too weak to account for the observed numbers of Apollo and Amor asteroids. A cometary origin was thus proposed for most of them. Rickman and Froeschlé consider the steady state where all the Jupiter family of comets (aphelion distances between 4 and 8 AU) is a possible source, this family being fed by capture and depleted by deactivation. The deactivated comets are also in a steady state, their loss mechanism being expulsion from the inner solar system by Jovian perturbation. The number of Mars crossing deactivated comets is estimated by means of a Monte Carlo simulation of the orbital evolution of the Jupiter family under the influence of Jovian pertubations.

The authors conclude that no more than five percent of the short period comets can develop orbitally into Apollo-Amor asteroids after loosing their activity. Also no more than five percent of the nuclei of comets can contain sizeable asteroidal cores.

So even bearing in mind the problems of observational selection it seems that comets are comets and asteroids are asteroids. Even though it is possible in rare cases to perturb a comet's orbit into an orbit similar to that of an asteroid, there are no obvious dead comets amongst the asteroid population. This seems to favour the hypothesis that comets do not have asteroidal cores and decay completely into meteor streams. □

The strong coupling constant is measured

from Mary K. Gaillard

THE initial evidence for hard gluon radiation by quarks came from the high energy electron-positron annihilation data of PETRA (*Nature* **281**, 104; 1979). The continued accumulation of data has permitted quantitative measurements of this process, thus providing a direct determination of the strong coupling constant. In analogy with electric charge (which determines the interaction between electrons and photons), this constant determines the interaction between quarks and gluons.

According to the widely accepted quantum chromodynamic (QCD) theory of the strong forces, the dominant mechanism for hadron production is via quark-antiquark pair creation (Fig. 1a):

$$e^+e^- \rightarrow \text{virtual photon } (\gamma) \rightarrow \bar{q}q$$

However since quarks carry color charge they can radiate gluons, i.e. quanta of the color field. This is completely analogous to the well established quantum electrodynamic (QED) theory of electromagnetic forces where, e.g., the primary mechanism for μ-pair production

$$e^+e^- \rightarrow \text{virtual photon} \rightarrow \mu^+\mu^-$$

is dressed by photon radiation. The difference is that while photons and leptons can be detected in the laboratory, quarks and gluons materialize as clusters ('jets') of hadrons, and sophisticated analyses must be performed in order to uncover the elementary QCD processes underlying what is actually observed.

The dominant component of gluon (or photon) radiation is soft or collinear with the quarks and its effects are submerged by the (so far) uncalculable angular spread inherent to the confinement mechanism governing the conversion of a quark or gluon into a jet of hadrons. Therefore most events should appear as two back-to-back jets (Fig. 1b), and this is indeed what was inferred from analyses of event configurations at SLAC several years ago, and directly observed more recently at PETRA where the higher energies produced jets sufficiently collimated to be recognized as such at a glance. Again there is an analogy with QED, where the dominant, very soft or collinear, component of photon radiation escapes detection through an inherent limit on measurement precision — except that for QCD the limiting precision is furnished by the dynamical effects of confinement.

However, sometimes in QED hard, large angle photons are emitted, but with emission rates suppressed by a factor of the fine structure constant $\alpha = e^2/4\pi$ for each such photon. In the same way, hard large angle gluons should be radiated by quarks with a suppression factor per gluon given by the strong coupling constant $\alpha_s = g_s^2/4\pi$, which is believed to be smaller than one. Therefore one expects some fraction of events to appear as three distinct jets of hadrons, a smaller fraction as four jets, and so on. Only at very high energies where jets are highly collimated can one hope to seperate visually the clusters of hadrons in a multi-jet event, and the first three jet event, presented by the TASSO collaboration at the Bergen neutrino conference in June 1979, was obtained at a center-of-mass energy of about 30 GeV. A statistically significant sample of three jet events was presented by the TASSO group at the EPS conference in Geneva. By the Fermilab conference in August, the PLUTO and JADE groups had collected samples of three jet events where neutral as well as charged hadrons were measured, and the MARK J group also presented evidence for gluon radiation.

The relative production rate for three jet events provides a direct measure of the strong coupling constant α_s. Previous determinations of α_s were based primarily on the analysis of highly inelastic lepton-nucleon interactions where the dependence of observed phenomena on the strong coupling constant is considerably more

Mary K. Gaillard is in the Laboratoire d'Annecy le-Vieux de Physique des Particules, France.

0028-0836/80/270011-02$01.00

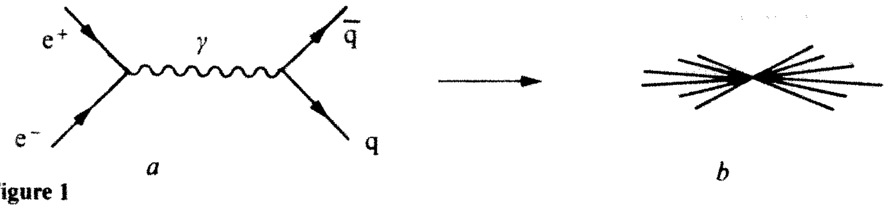

Figure 1

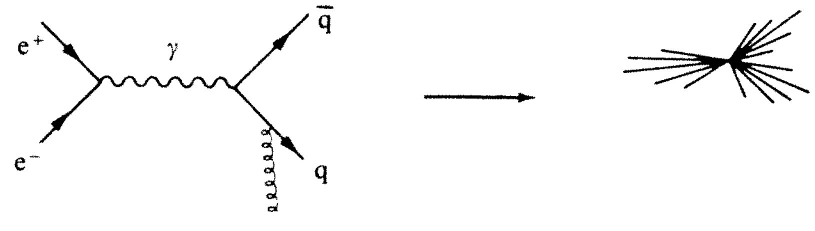

Figure 2

subtle. The method has been somewhat controversial as it requires measurements over a large energy range, including lower energies where the interpretation of the theory is somewhat problematic. On the other hand, a measurement of the rate for radiation of hard wide angle gluons at high energies is in principle straightforward and its interpretation is intuitively simple. However, a meaningful measurement of α_s requires substantial statistics, and since gluon (like photon) radiation prefers collinearity, even large angle radiation will most often produce events intermediate between Figs 1b and 2b, with two jets merged to form a single broadened jet.

The first task of the experimenters was to convince themselves that the collection of phenomena characterizing deviations from the two jet process of Fig. 1 could indeed be attributed to hard gluon radiation. There are various tests of this hypothesis, among them: a) the rate of jet broadening with increasing center-of-mass energy; b) coplanarity (up to the limited jet spread due to confinement effects) of the final state hadrons which are supposed to arise from a primitive 3-quanta final state; c) asymmetric jet broadening — since the dominant deviation from two jet events is a single hard gluon emission, only one quark jet, the one with an accompanying gluon, should appear broadened. All four groups from PETRA presented analyses supporting these features at the Fermilab conference in August.

Since then more data has been taken, providing sufficient statistics for the first quantitative analyses published by the MARK J and JADE groups. The analysis of the MARK J group, based on the angular pattern of energy flow, rather than on an event by event reconstruction of jets, showed a statistically significant excess of oblate planar events which, when projected on the event plane and oriented so as to align the axes of maximum energy flow, displayed a three lobed structure which reproduced the "antenna pattern" expected from single hard gluon radiation. From the size of the effect they reported the first evaluation of α_s based on gluon radiation. This was soon followed by a value quoted by the JADE group based on detailed analysis of event shapes. More recently the TASSO group has extracted a value for α_s from a careful study of event topologies including various checks that their result is insensitive to the uncalculable confinement effects. The result of these analyses are consistent within their estimated errors of 20% or so and yield a value for α_s of about 1/5.

What does this number mean? Even without the complications of confinement effects which arise in QCD, one never really measures a fixed coupling constant, but rather the effective strength of some coupling among field quanta of specified energy and momenta. One then extracts a momentum dependent effective coupling; the momentum dependence reflects the effects of a higher order 'dressing' of the coupling through the exchange of virtual quanta. In QED these effects are tiny because the coupling is very weak, but in QCD they are appreciable, albeit calculable. A value $\alpha_s \simeq 0.2$ for processes characterized by the PETRA energies where gluon radiation has been measured is quite consistent with expectations based on analyses of lepton-nucleon interactions mentioned earlier. More theoretical work, specifically addressed to higher order effects in electron-positron annihilation into hadrons, as well as more experimental work, allowing a determination of the momentum dependence of hard gluon radiation, are still needed for precision tests of the theory. Further studies are also needed to pin down the spin of the gluon and to measure the self-coupling of three gluons, a predicted feature of QCD which has no analogue in QED. ☐

Extra-pituitary actions of LHRH and its agonists

from Richard M. Sharpe

SINCE the origination of the concept of hypothalamic control of the anterior pituitary gland, it has been an accepted dogma of endocrinology that the releasing factors from the hypothalamus act solely on the pituitary to regulate the release of the appropriate trophic hormone. The vast number of animal experiments and clinical studies with LHRH since its structural characterization 9 years ago, have consolidated this belief. Now, a spate of recent results appears to have demolished this idea by demonstrating extra-pituitary inhibitory effects of LHRH or its agonistic analogues. The latter are considerably more potent *in vivo* that native LHRH, principally because of their resistance to enzymatic breakdown (Clayton *et al. Endocrinology* **104**, 1484; 1979), and this has been an important factor in permitting the demonstration of peripheral sites of LHRH action.

There have been numerous reports in the last 3 years demonstrating inhibitory effects of LHRH and its agonists on gonadal growth and function in intact animals, and LHRH agonists have exciting potential as new contraceptive methods in women, as luteolytic agents (Casper & Yen *Science* **205**, 408; 1979; Lemay *et al. Fertil. Steril.* **32**, 646; 1979) or, more probably, as inhibitors of ovulation (Bergquist *et al., Lancet*, **ii**, 215; 1979). As it was already established that similar 'down-regulatory' effects could be achieved by overstimulation of the gonads with exogenous gonadotrophins (see Catt *et al. Nature* **280**, 109; 1979), it was thought logical that LHRH and its agonists exerted their inhibitory effects via the pituitary.

But in fact, there was already published evidence to show that LHRH agonists could have extra-pituitary effects, as Rippel and Johnson (*Proc. Soc. Exp. Biol. Med.* **152**, 432, 1976) had reported inhibition by an LHRH agonist of human chorionic gonadotrophin (hCG)-induced ovarian and uterine weight gain in hypophysectomized rats. This brief challenge to one of the bastions of endocrinological thinking seems to have gone largely unnoticed. But in 1979 the walls began to crumble when Hsueh and Erickson demonstrated inhibition by LHRH of the follicle-stimulating hormone (FSH)-induced increase in oestrogen and progesterone secretion by rat ovarian granulosa cells *in vitro* (*Science* **204**, 854, 1979), and followed this with a similar report concerning the male (*Nature* **281**, 66; 1979). In this they showed that concomitant treatment of hypophysectomized immature male rats with FSH and

---

0028-0836/80/270012-03$01.00

LHRH agonist prevented the increases in testicular weight, LH-receptor numbers and steroidogenic responsiveness induced by the FSH treatment alone.

Confirmation of the extra-pituitary actions of LHRH and its agonists has been readily forthcoming. Ying and Guillemin (*Nature* **280**, 593; 1979) demonstrated a dose-dependent inhibitory effect of an LHRH agonist on gonadotrophin-induced ovarian weight gain in hypophysectomized female rats and also prevented ovulation, findings which a smaller study by Mayar *et al.* (*Proc. Soc. Exp. Biol. Med.* **161**, 216; 1979) confirmed. A preliminary report also suggests that LHRH agonists may directly influence ovum development following induction of super-ovulation (Erickson & Hsueh, *U.S.A. Soc. Gynec. Invest.* Abstract 371; 1980). In the male, Arimura and colleagues have shown that treatment with an LHRH agonist can reduce LH-receptor numbers in the testes of both immature and adult hypophysectomized rats (*Biochem. Biophys. Res. Commun.* **90**, 687; 1979). Outside of the gonads, inhibition by LHRH of progesterone production by human placental tissue *in vitro* has been reported (Wilson & Jawad *Fertil Steril.* **33**, 91; 1980), and preliminary work in baboons by McRae, Vickery and Stevens (*Endocrinology* Supp. in the press), suggests that LHRH agonists can suppress chorionic gonadotrophin secretion by the placenta. However, such effects may not be straightforward, as LHRH agonists do not impair the placental secretion of hCG and progesterone *in vivo* in women (Casper *et al. Proc. of P.A.R.F.R. Workshop on Fertility Regulation* Harper & Row; 1980). Gonadal or placental effects of LHRH are presumably important in explaining the local abortifacient action of LHRH on the pregnant rat uterus (Jones *Contraception* **20**, 569; 1979) and the termination by LHRH of pregnancy in rats hypophysectomized on day 12 (Bex & Corbin *61st. Endocr. Soc. Meeting, U.S.A.* Abstract 435; 1979).

The two most impressive aspects of the above findings are, firstly, that all but one of the extra-pituitary effects of LHRH and its agonists are inhibitory and, secondly, that the effects (particularly those on the gonads) are almost identical to those reported following similar treatment of intact animals. This raises the question as to whether all of the inhibitory effects of LHRH agonists in intact animals, including the contraceptive effects in women, are the result of extra-pituitary action? Although any answer must at this stage be qualified, the weight of evidence suggests this is not the case. To obtain the direct gonadal effects reported above, the investigators have used doses of LHRH agonists at least 10-times and, in most cases, over 1,000-times greater than those used in intact animals. Moreover, the direct effects reported have often been the inhibition of rather specialised changes which may not be directly relevant to the intact adult animal. Thus the acute steroidogenic responsiveness *in vitro* of Leydig cells from untreated rats is unaffected by LHRH or its agonists (Badger *et al. Endocrinology* **106**, 1149; 1980), although Clayton and colleagues (*Nature* **282**, 90; 1980) found a small decrease in the sensitivity of rat luteal cells to hCG-stimulation *in vitro* in the presence of 10^{-7}M LHRH agonist.

However, there is the very real possibility that some proportion of the inhibitory effects of LHRH and its agonists in intact animals is the result of extra-pituitary action. Indeed, the recent demonstration of specific, high affinity ($K_A = 10^9 M^{-1}$) receptors for LHRH and its agonists on luteal cells in the ovary (see last ref. above), and on Leydig cells in the testis (Labrie *et al. Int. J. Fertil.* in the press; Sharpe & Fraser *Biochem. biophys. Res. Commun.* in the press), must mean that LHRH has some role to play at the gonadal level, particularly as these receptors have almost identical properties to LHRH receptors in the pituitary (see Clayton *et al. Endocrinology* **105**, 1369; 1979). There is also persuasive evidence that the direct effects of LHRH agonists on the gonads are mediated through such receptors, as Hsueh and Erickson (*Life Sci.* **25**, 1223; 1979) have shown that the inhibitory effects of LHRH agonists *in vitro* can be prevented in a dose-dependent manner by a structurally similar, but antagonistic, analogue of LHRH. There is also immunohistochemical evidence for LHRH receptors in mouse adrenal cells (Bernardo *et al. J. Histochem. Cytochem.* **26**, 613; 1978).

Because of the specialized portal blood system, which transports LHRH from the hypothalamus to the pituitary, and because of the rapid degradation of LHRH, it seems certain that LHRH secreted from hypothalamic neurones can never reach peripheral tissues in effective concentrations. Are there, therefore, extra-hypothalamic sites of LHRH production? Two pieces of information suggest that there are. First, there is some evidence for the placental production of LHRH (Khodr & Siler-Khodr *Science* **207**, 315; 1980), and secondly, Guillemin and colleagues

---

NATURE

100 years ago

The *Times* Geneva correspondent writes under date June 20 that a remarkable electrical phenomenon occured at Clarens on the afternoon of Thursday last. Heavy masses of rain-cloud hid from view the mountains which separate Fribourg from Montreux, but their summits were from time to time lit up by vivid flashes of lightning, and a heavy thunderstorm seemed to be raging in the valleys of the Avants and the Alliaz. No rain was falling near the lake, and the storm still appeared far off, when a tremendous peal of thunder shook the houses of Clarens and Tavel to their foundations. At the same instant a magnificent cherry-tree near the cemetery, measuring a metre in circumference, was struck by lightning. Some people who were working in a vineyard hard by saw the electric "fluid" play about a little girl who had been gathering cherries and was already 30 paces from the tree. She was literally folded in a sheet of fire. The vine-dressers fled in terror from the spot. In the cemetery six persons, separated into three groups, none of them within 250 paces of the cherry-tree, were enveloped in a luminous cloud. They felt as if they were being struck in the face with hailstones of fine gravel, and when they touched each other sparks of electricty passed from their finger-ends. At the same time a column of fire was seen to descend in the direction of Chatelard, and it is averred that the electric fluid could be distinctly heard as it ran from point to point of the iron railing of a vault in the cemetery. The strangest part of the story is that neither the little girl, the people in the cemetery, nor the vine-dressers appear to have been hurt; the only inconvenience complained of being an unpleasant sensation in the joints, as if they had been violently twisted, a sensation which was felt with more or less acuteness for a few hours after. The explanation of this phenomenon is probably to be found in Prof. Colladon's theory of the way in which lightning descends, as described in Nature, vol. xxii. p.65. The Professor contends that it falls in a shower, not in a perpendicular flash, and that it runs along branches of trees until it is all gathered in the trunk, which is bursts or tears open in its effort to reach the ground. In the instance in question the trunk of the cherry-tree is as completely shivered as if it had been exploded by a charge of dynamite.

Amongst the peculiar institutions of Paris are the street astronomers, who exhibit through their telescopes the moon, sun-spots, comets' tails, and other celestial objects, according to circumstances. Their charges vary from 1*d*. in the suburbs to 5*d*. on the Place de la Concorde or the Place Vendôme, where the instruments are not unworthy of a regular observatory. At the last monthly meeting of the scientific journalists M. Flammarion read an address sent to him by the corporation of these itinerant teachers of the marvels of the heavens. They state that from the beginning of the publication of the "Astronomie Populaire" the number of their customers has more than doubled.
from *Nature* **22**, 1 July, 1980.

0028-0836/80/270013-01$01.00

(*Comptes Rendus* **D289**, 943; 1979; *Endocrinology* **106**, 114A; 1980) have identified a substance which is immunologically distinct from LHRH but has LHRH-like biological activity and is secreted by ovarian granulosa cell cultures and is present *in vivo* in follicular fluid.

The endocrine dogma concerning LHRH-like biological activity and is hypothalamic LHRH-producing neurones as unique and to view the portal blood supply as an insurance that LHRH reaches the pituitary without dilution in the peripheral circulation. The same was originally thought for somatostatin, which is also produced by hypothalamic neurones and acts on the pituitary, but is now known to be produced in the gut and elsewhere. It is therefore not too wild a speculation to consider LHRH as a 'transmitter' produced by nerve endings or other cells in the gonads or elsewhere. Certainly, if one accepts this possibility then the role of the portal blood system and the rapid degradation of LHRH by the pituitary can be viewed not only as an efficient local transport system, but also as a means of preventing hypothalamic LHRH from reaching peripheral target tissues.

It seems appropriate to end on another note of speculation. Before the advent of the enzymically-resistant LHRH agonists, binding studies with LHRH were plagued by hormone degradation problems, but there were at least two reports of extra-pituitary binding sites specific for LHRH (Marshall *et al. Clin. Endocr.* **5**, 671; 1976 and Heber *et al. Amer. J. Physiol.* **235**, E227; 1978), which were dismissed as unimportant because of their low affinity ($K_A = 10^5 M^{-1}$). These sites included the ovary and testis, which we now know to contain high affinity receptors for LHRH. Can we therefore expect that the other tissues identified (liver, spleen, renal cortex, cerebral cortex, lung) will also prove to have high affinity receptors for LHRH and its agonists? □

How does the mantle move?

from Geoffrey F. Davies

WHEN the kinematic theory of plate tectonics was developed over a decade ago, two kinds of questions were posed. The first kind concerned the implications of moving plates of lithosphere for geological processes and for the interpretation of the geological record. The second kind of question concerned the involvement of the underlying mantle and the dynamics of the plate mantle system: how much of the mantle is involved, what is the pattern of flow in the mantle, and which of several possible types of driving buoyancy forces are dominant? Although many parts of the system are now more clearly understood, the way in which they fit together into a working machine is still unclear. This is only partly because of the inaccessibility of the mantle to direct observation: it is also because of the extremes of mechanical and thermal states in the plate-mantle system, which pose a considerable challenge to would-be modelers of the system. Some of the current attempts being made to understand the system were illustrated by papers presented at a recent conference*.

It is usually presumed that the plates and underlying mantle comprise a thermally convecting system driven by the earth's internal radiogenic heat, but mantle convection is very different from the more familiar examples of convection in the atmosphere or laboratory. This is because the mantle has a very high Prandtl number (so that viscous forces dominate over inertial forces) and its rheology is complex. The stress-strain rate relation of mantle minerals is strongly dependent on temperature, and is strongly non-linear at high stresses; also, high stress at low temperatures can cause fracturing which will be observed as earthquakes. The Rayleigh number of the mantle is variously estimated to be between one million and one thousand million, which implies that temperature gradients are very large, notably near the top boundary. Combining the steep temperature gradient near the earth's surface with the temperature dependence of the rheology, one gets a picture of the lithosphere as a thermal boundary layer which is also a mechanical boundary layer: cold and therefore stronger, but also brittle. This rapid variation of temperature and mechanical properties in the lithosphere is an obstacle to finite-difference numerical modeling, since a prohibitive number of grid points is required. Also, the rheology of this lithosphere is not easily characterized in a manageable way. For example, simply increasing the viscosity in the lithosphere works for those parts of plates away from plate boundaries, but not near subduction zones, since brittle or quasi-plastic yielding may allow the large deformations associated with bending and subducting the lithosphere to occur at much lower stresses than would be predicted by a viscous rheology. Much of the recent work on plate-mantle dynamics has focussed on the lithosphere, either exploring and characterizing its rheology, or taking advantage of the order it imposes by being rigid most of the time.

The rheology of the lithosphere can be studied by using the constraints of bathymetric, gravity and geoid anomalies near subduction zones and volcanic seamounts. Models have evolved through simple elastic and viscous lithospheres to composites involving elastic-perfectly plastic or more complex rheologies. J. H. Bodine and A. B. Watts of Columbia University presented results showing that the current subsidence of Hawaii relative to Oahu at the rate of 4.1 mm per yr can be explained as a delayed response of the lithosphere to the load imposed by Kohala volcano on Hawaii, which was active until about 0.4 Myr ago. In their model, the initial response of the lithosphere is that of a thick elastic layer, but on longer time scales (a million years or more) the lower, hotter part of the lithosphere deforms, allowing stress relaxation. The result is that after a million years or so the effective elastic thickness of the lithosphere is two or three times less than the initial affective thickness. A. Cazenave and B. Lago of Toulouse presented results of analogous models incorporating plastic or semi-empirical rheologies, and they predict that the relaxation time of the lithosphere is about five percent of the age of the lithosphere at the time it was loaded. A. B. Watts reviewed analyses of gravity and bathymetric anomalies by himself and his colleagues showing that the long-term effective elastic thickness of the lithosphere is a strong function of the age of the lithosphere at the time of loading. The results are consistent with the elastic thickness being proportional to the square-root of age, as is predicted by a simple cooling half-space model of the lithosphere. The same conclusion was reached by analysis of geoid anomalies derived from the GEOS 3 and SEASAT radar altimeters (M. C. Roufousse, Smithsonian Astrophysical Observatory, Cambridge).

Although the lithosphere is difficult to incorporate into mantle convection models, its role as a rigid mechanical and thermal boundary layer has been exploited in several ways. P. Olson of Johns Hopkins University presented a generalization to spherical geometry of a boundary layer theory first applied to the mantle (Turcotte & Oxburgh *J. Fluid. Mech.* **28**, 29; 1967). Such a theory is ideally valid in the limit of high Rayleigh number, when the interior of the fluid is nearly isothermal and temperature gradients are concentrated in thin thermal boundary layers. Olson concluded that realistic surface velocities of several centimeters per year could be attained if convection was allowed to extend throughout the mantle (down to about half of the earth's radius), but could not if convection was confined to the upper 700 km of the mantle. However, Olson's models did not include a realistic lithosphere rheology, so this conclusion should probably be regarded as tentative at this stage.

Olson and several other speakers were concerned with testing a semi-empirical relation, based on laboratory and numerical experiments and on boundary layer theory, which states that the Nusselt number is proporational to the Rayleigh number to a small power, usually between

*The joint Spring Meeting of the American Geophysical Union and several Canadian Geophysical Societies was held in Toronto.

0028-0836/80/270014-02$01.00

one-fifth and one-third. The Nusselt number measures the efficiency of convective heat transport, and the relation has been applied to calculating thermal histories of planets (eg. Sharpe & Peltier *Geophys. J. R. astr. Soc.* **39**, 171; 1979; Reynolds & Cassen *Geophys. Res. Lett.* **6**, 121; 1979). E. R. Ivins and R. J. Phillips of the Jet Propulsion Laboratory, Pasadena, reported on numerical models with temperature-dependent viscosity in which the Nusselt number was systematically lower than in analogous constant viscosity cases. Again, their results may have been affected by an oversimplified lithospheric rheology, which did not include any stress dependence. E. M. Parmentier and J. Morgan, III of Brown University reported on numerical models which did include a moderately stress-dependent rheology. Their results implied that an initially hot, radioactively heated planet would approach a steady state about twice as fast as in the case of a stress-independent rheology, presumably because the larger buoyancy forces associated with higher temperatures would see a lower effective viscosity.

R. A. Lux and I. S. Sacks of the Carnegie Institution of Washington were concerned with the bottom boundary of the mantle, where seismologists have long suspected a layer of irregularities one or two hundred kilometers thick. If there is significant heat flow from the core, then one would expect a boundary layer at the bottom of the mantle complementary to the lithosphere at the top: the bottom layer would have higher temperatures and lower viscosities. One might further expect such a layer to be subject to strong Rayleigh-Taylor instabilities, which might then be the source of the seismic heterogeneities. Lux and Sacks presented results of numerical models which showed that the lower viscosities in the boundary layer allow faster horizontal flow, and the resulting larger velocity gradients actually stabilize the layer, at least in their two-dimensional models. If the instability occurred, it would have to be in the form of rolls or sheets aligned with the flow.

The usefulness and versatility of the rigid boundary layer concept of plates was further illustrated by R. J. O'Connell of Harvard University and B. H. Hager of the State University of New York at Stony Brook, who used it to investigate the chemical stratification of the mantle and the effect of plate motions on sea level. In a joint paper, O'Connell and Hager noted that the migration velocities of ridges and trenches are not negligible compared with expected mantle flow velocities. A consequence is that as trenches and ridges sweep around the globe, upper mantle material may be sampled more often than lower mantle material: roughly speaking, material recently subducted at a trench may be pulled back up by a passing ridge before it sinks to great depth. Thus a purely kinematic aspect of the plate-mantle system may give rise to a chemical gradation of the mantle, in which the shallower mantle is, on average, more strongly depleted in the incompatible elements which accumulate in continental crust.

Hager gave a new twist to an old problem by suggesting that changes in sea level relative to continents depend mainly on whether subducted lithosphere descends under continent or under ocean. Both the thermal contraction associated with the cold lithosphere and the deviatoric stresses transmitted from a sinking plate to the surface tend to lower the earth's surface above the plate. Thus subduction under continent would result in transgression and subduction under ocean would lead to regression. Hager estimated that the magnitude of this effect is considerably larger than that produced by changes in the volume of ridge systems (and hence of ocean basin volumes) resulting from changes in plate velocities. □

MHC restriction, self-tolerance and the thymus

from Jonathan Howard

THE phrase 'MHC restriction' was originally coined to describe a property of cytotoxic T lymphocytes, cells of the specific immune system which kill virus infected cells by a process involving direct membrane contact between the two cells. Specific receptors on the cytotoxic cell surface recognize and bind to virus-specific antigens on the membrane of the infected target cell. By an unknown mechanism this close contact results in lysis of the target. Oddly, however, the virus-specific antigens are not sufficient for the binding of cytotoxic cells: membrane molecules specified by the major histocompatibility complex (MHC) of the target cell are involved in the binding so intimately that they may be regarded as forming a component of the antigens recognized. In practice what this means is that cytotoxic T cells of a mouse of MHC type A, immunized with some virus X, will kill X-infected targets of MHC type A but not otherwise identical X-infected targets of MHC type B. That cytotoxic T cells recognize foreign antigens only in association with specific MHC antigens is the basic fact of MHC restriction. One can rationalize the involvement of membrane bound MHC molecules in this interaction by arguing that their presence in close association with virus specific molecules enables cytotoxic T cells to identify and kill virus infected cells while ignoring an excess of free virus.

Since its first clear definition in 1974, MHC restriction has become recognized as a fundamental feature of antigen recognition by many (if not all) classes of T cell and seems to be a corollary of the fact that specific T cell activities are probably mediated, like target cell killing, by cell-cell contact. Other examples of such activities are T cell induction by exogenous antigen, involving MHC molecules on antigen presenting cell surfaces at the beginning of an immune response, and T cell help for antibody production by B cells, this latter activity probably being mediated through MHC molecules presented to T-helper cells by the B cell surface.

A key question is, where and when is the dual specificity of the observed response established? At what point is the discrimination between different MHC molecules and different foreign antigens made? Until relatively recently it would have been a good bet that the critical stage for both discriminations was at the first encounter of a mature T cell with foreign antigen X. At this stage X is undoubtedly presented to the immune system by a specialized presenting cell which, in addition to trapping antigen, also carries MHC allelic products. If X and an MHC product are recognized together in some association by a subset of T cells, for example killer cell precursors carrying a receptor of the appropriate specificity, then the killer cells that are activated will kill only those targets which similarly express both the 'right' MHC allele and the 'right' X. Evidence in favour of this idea came from studies on the properties of T cells from F_1 hybrids between two strains carrying different MHC alleles, A and B. It was found that such animals carried two separate T cell populations, one able to recognize $X+A$ and the other $X+B$. Normally both populations were immunized by X, but if X was experimentally presented to $(A \times B)F_1$ T cells on cells of homozygous A origin, for example, only the $A+X$ reactive subset was activated.

Of course in all such simple MHC restriction experiments another class of recognition process could be imagined where T cell activation required that MHC antigens on the reactive cell should 'match' MHC antigens on the antigen presenting cell or

---

target. Such a like-like requirement amounting to self-recognition could be excluded by experiments in radiation chimaeras. Irradiated $(A \times B)F_1$ recipients were reconstituted with a mixture of marrow cells or foetal liver of homozygous A and B origins. T cells of A type grown up in such chimaeras could collaborate with B cells of B type for the production of antibody. Related experiments with cytotoxic T cells have also been done successfully. These results are perfectly compatible with the idea that the specificity of H-2 restriction is laid down at the moment of antigen presentation. If, therefore, 'self' recognition is involved in MHC restriction, T cells must 'learn' the MHC type of self during their ontogeny: self does not necessarily coincide with the MHC carried by the T cells themselves.

The idea that T cells in some way learn a range of possible MHC restrictions during their ontogeny before meeting antigens is now widely accepted (see *Nature* **272**, 11; 1978). T cells differentiate from their precursors in the thymus gland and experiments by Bevan[1], Zinkernagel[2] and others gave results which suggested that some learning of MHC restriction specificity occurs during this maturation. Chimaeras were established in which the thymus was of MHC type A while the differentiating T cells were of F_1 type $A \times B$. When T cells from such $A \times B \to A$ chimaeras were immunized with a variety of antigens on $A \times B$ presenting cells the resultant immune response showed a marked bias towards restriction by the thymus H-2 type A. The unique capacity of the thymus to determine the restriction bias was demonstrated by experiments using thymus grafts[4,5,6].

A great deal of emphasis has been laid on this thymic 'bias'. It seems likely, however, that the results may have been greatly overinterpreted. If thymus learning of an MHC restriction repertoire were absolute, a T cell population restricted to MHC type B should never be found in animals in which $A \times B$ T cells had differentiated in an A thymus. In fact, however, some responses restricted to the B haplotype, albeit relatively weak, are often found [5,7], and immunization of such animals with antigens presented on cells of B type seems preferentially to immunize this B-restricted reportoire to give substantial responses[8]. There is a thymic MHC restriction bias, and it clearly requires an explanation. Nevertheless it is only a bias, and can be overriden by appropriate immunization.

Another class of experiment says even more clearly that 'learning' in the thymus cannot alone be responsible for determining the range of MHC restriction. These experiments involve analysis of the immunological reactivity of cells from normal A donors. The question is whether in any circumstances these cells can produce an MHC-restricted response to an antigen presented on cells carrying only MHC type B. Such experiments are complicated by the fact that cells carrying MHC type B are strongly antigenic to normal T cells of A origin by virtue of the MHC incompatibility itself. This alloreactivity can, however, be removed from normal A T cell populations experimentally by a process resembling filtration. Cells from normal A donors are injected into the blood of irradiated $A \times B$ or B recipients. Alloreactive T cells from the donor are retained in the tissues of the recipient while cells unable to recognize the B alloantigens pass through the host tissues into the lymphatics from which they can be collected. Such 'negatively selected' populations can now be tested for their ability to recognize a foreign antigen X presented on cells of MHC type B in the absence of an alloreaction directed against the B alloantigens themselves. These experiments often, but not always, produce substantial responses restricted by B[9–12]. When they do, they demonstrate clearly that the MHC type of the thymus does not necessarily predict the MHC restriction repertoire of the T cells derived from it. In negative selection experiments the 'wrong' MHC type is not encountered by the responsive population at all during ontogeny, yet after appropriate antigen presentation a repertoire can be found for a response restricted by this MHC type.

What then, is the explanation for the thymic bias in chimaera experiments? For the time being this question must remain open. There is, however, some evidence to support the idea that the thymic bias may be maintained in chimaeras by suppression[13,14], probably acting on the repertoire at a peripheral rather than thymic level. It is as if responses to antigens presented by the non-thymic MHC type were actively inhibited. It is tempting to associate this kind of explanation for the thymic bias with the problems faced by $A \times B \to A$ chimaeras in the acquisition of self tolerance to their MHC alloantigens. One specialised function often proposed for the thymus is as a place in which autoreactive T cells generated by some process of repertoire diversification are eliminated. If this elimination is normally mediated by contact with antigens on the non-lymphoid cells of the thymus, $A \times B$ T cells differentiating in an A thymus cannot acquire tolerance of their own B MHC antigens in the normal way. It has been shown in both mice and rats that very profound tolerance to MHC antigens absent from the fixed cells of the thymus, (as in neonatal A strain animals injected with $A \times B$ marrow at birth) may be mediated by specific suppressor cells[15,16]. There is no demonstrated mechanism by which such suppressor cells work, but the effect is to prevent expansion of the anti-B reactive repertoire and the animal is effectively tolerant of B. The extension of these findings to $A \times B \to A$ chimaeras required for an explanation of the restriction bias towards A is to argue that the animals maintain a suppression of the alloreactive anti-B repertoire, and this suppression also includes exogenous antigens presented in association with the B allelic product. It would be of considerable interest to know whether supressor cells from an A type donor made neonatally tolerant of B at birth can influence the restriction repertoire of an $A \times B$ recipient to mimic the thymic MHC restriction bias of an $A \times B \to A$ chimaera.

An extension of this argument is that in a normal A type animal there is no biological need for suppression of reactions restricted by MHC-type B. After removal of alloreactivity against B by filtration, as described above, A type T cell populations may therefore retain a repertoire able to recognize an antigen restricted by B more easily than do T cells from $A \times B \to A$ chimaeras. In experiments involving Vaccinia virus in mice Doherty and Bennick have demonstrated this effect quite clearly[17]. MHC type A T cells negatively selected and unreactive against B alloantigens can produce a good primary anti-Vaccinia virus response restricted by MHC type B, while cells from an $A \times B \to A$ chimaera do not. One can argue that in this case the postulated suppression of reactivity to B and B-associated antigens in the chimaera is more 'inclusive' than the depletion of reactivity to B by negative selection.

It is obviously time to re-evaluate the thymus learning experiments. Clearly something special happens in the thymus: the question is, what? I can think of three clearly distinct functions for the organ, firstly, the functional differentiation of T cells from immunologically incompetent precursors; secondly, the distribution of a diverse repertoire among separate clones of cells by repeated cell division; and thirdly, the elimination of autoreactive cells from that repertoire to induce self tolerance. Only the third process involves specific interference with the response repertoire. Although there may not be a fully consistent argument available, it is tempting to attribute the normal MHC restriction behaviour of T cells to the specificity of normal self tolerance induction in the thymus, and abnormal MHC restriction behaviour in $A \times B \to A$ chimaeras to an abnormal mechanism of induction of self tolerance in a non-thymic site. □

Pb–Sr–Nd isotopic correlation and the chemistry of the North Atlantic mantle

Bernard Dupré & Claude J. Allègre

Laboratoire de Géochimie et Cosmochimie, Institut de Physique du Globe et Départment des Sciences de la Terre, Universités Paris VI et VII,
4 Place Jussieu, 75230 Paris Cedex 05, France

The Pb, Sr, Nd isotopic composition in North Atlantic mid-oceanic ridge basalts has been measured. A positive correlation is found between Sr and Pb and a negative one between Nd and Sr. There is also a negative correlation between Hf/Th or Ta/Th and isotopic ratios such as $^{87}Sr/^{86}Sr$ *or* $^{206}Pb/^{204}Pb$*. Using the data for oceanic island basalts with these coherent geochemical characteristics we discuss the origin of chemical variations in the North Atlantic mantle and the problem of the mantle geochemistry.*

SINCE the discovery of the variation of Nd isotopes in the terrestrial mantle[1], it has been argued that this variation seems to be anticorrelated with Sr isotopes but not with Pb isotopes. This problem is well expressed by the Sr–Pb isotope 'non-correlation' plot established by Sun and Hanson[2,3]. Thus Pb isotopes do not apparently follow the same logic as Nd and Sr isotopes in the mantle geochemistry and have been one of the problems in understanding mantle evolution. We have tried to clarify this problem by careful study of a restricted area and then by applying the results to other parts of the world. We also include a discussion of trace elements.

We have analysed tholeiites from 15 different sites of the Mid-Atlantic Ridge. Their locations are indicated on Fig. 1. The FAMOUS area has been studied in detail, and our results will be published elsewhere. We give here only mean or key samples from this area. We have measured Pb and Sr isotopic compositions on the same sample in each case with special treatment for Sr to minimize seawater exchanges. The positions, results and error limits are given in Table 1.

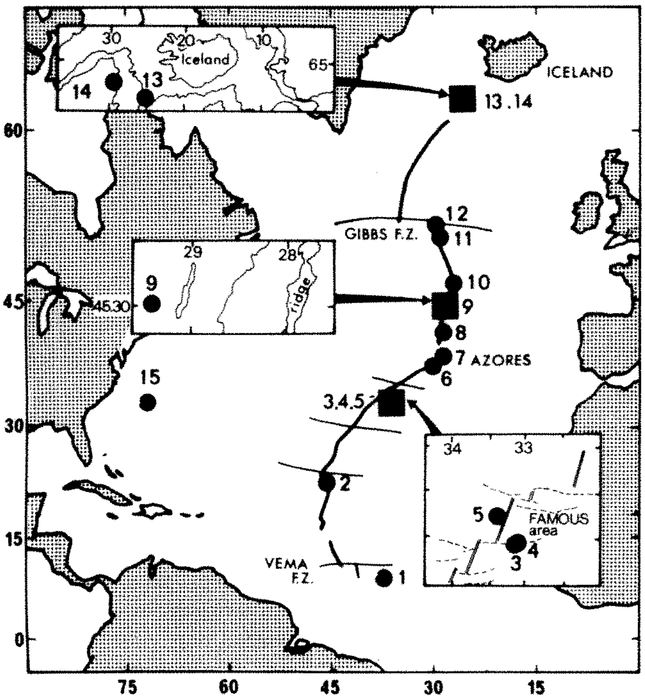

Fig. 1 Situation of the North Atlantic MORB samples.

Isotopic results

For the North Atlantic ocean, the expected inverse correlation between the Sr and Nd isotopic compositions is observed (see refs 1, 4, 5 and Fig. 2*c*). Comparison of the $^{206}Pb/^{204}Pb$ with $^{207}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ with $^{208}Pb/^{204}Pb$ diagrams give quite good correlations as was suggested by Tastumoto's work[6] on Pb isotopes in oceanic ridge basalts (Fig. 2*a*).

In contrast, the direct correlation between the Pb isotopes and the Sr isotopes is less expected (Fig. 2*b*). An inverse correlation between Nd and Pb isotopes is, of course, also obtained. Such an observation is true for $^{206}Pb/^{204}Pb$ as well as for the other Pb isotopic ratios. Note that one sample[10] is slightly out of correlation. When Sr isotopes were analysed for this sample by White and Schilling[7] without any treatment (leaching or diopside separation) a $^{87}Sr/^{86}Sr$ ratio of 0.70347 was obtained. Leaching lowers their value and as our leaching was incomplete our value may still be slightly too high, in which case the correlation could become perfect.

To appreciate this result one must remember that the Pb system on one hand and the Nd–Sr system on the other have been generally considered as being decoupled. This follows from Sun and Hanson's[2] plot in which a large cloud of points is observed rather than the line in the Nd–Sr diagram. We have then, for the first time, a coupling between Sr and Pb isotopes on mid-oceanic ridge basalts (MORB), which is exactly opposite to what has been claimed by Vidal and Dosso[8]. These remarkable regularities, also obtained by Cohen *et al.*[9] but on samples from more dispersed geographical areas in different oceans, are the basis of our following discussion.

Assuming that the present day Nd isotopic composition of the closed mantle is equal to that of achondrites and chondrites, the corresponding values of $^{87}Sr/^{86}Sr$ and Rb/Sr ratios can be deduced from the correlation diagram of Nd–Sr. These values are 0.70475 and 0.03 (ref. 10) with large errors. Using the same procedure for the Pb isotopes with our Sr–Pb isotope correlation, where we have more data. We obtain the following values:

$$^{206}Pb/^{204}Pb = 21.3\text{–}22$$

$$^{207}Pb/^{204}Pb = 15.78\text{–}15.90$$

$$^{208}Pb/^{204}Pb = 41.5\text{–}42.3$$

These values are called the 'planetary lead Atlantic' values (PLA) because they correspond to the planetary Sr in the correlation diagrams. Application of these values to the classical $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$ diagram reveals immediately that the

The values obtained by Tatsumoto[40] on AD 5.5. are reported; all the others are our results. Mattinson[41] measured Pb isotopes in some samples from the Leg 49 sites. We have obtained good agreement with his results. The Pb, Sr and Nd compositions have been measured using the techniques described respectively by Manhes *et al.*[25], Birck and C. J. A.[37] and Richard *et al.*[1] We have used the leaching technique on all samples for the Sr isotope compositions and also for some Pb measurements.

PLA values do not correspond to the closed system reference geochron (Fig. 2*a*), but are clearly in the so-called (*J*) field. This indicates that the U–Pb system has had an open system evolution through geological time. As, by definition, a planetary value should correspond to a closed system situation, the PLA values are certainly not planetary in the same way as Sr or Nd.

Relationship with trace elements

Trace elements are generally more difficult to handle than isotopic ratios because their concentrations are modified by magmatic processes (partial melting + fractional crystallization + other processes such as seawater interaction). Some elements are strongly enriched into the liquid during magmatic processes and are unmodified by interaction with seawater. Therefore their ratios can be considered representative of their mantle source. Such elements, called H elements by Treuil and Joron[11], are Hf, Ta, Th, La, Zr, Nb. We have a set of values for some of them in the North Atlantic published by Joron *et al.*[12] and Wood *et al.*[13,14]. Here we try to use only these elements, to avoid the secondary effects which would obscure the picture.

Sr and Pb isotopes have been compared with some H element ratios on Fig. 3*a*). Even if only five different sites can be used for

H elements, an inverse correlation is obtained between Sr or Pb isotopes and ratio like Hf/Th, La/Th, Ta/Th. The values obtained by Wood *et al.*[14] on samples from 63°N (site 13) seems anomalous as the ratios vary strongly within the site. If the Hf/Th, La/Th, Ta/Th ratios are considered which correspond to the $^{87}Sr/^{86}Sr$ planetary value a set of values is obtained which are very different from the chondritic values. For example Hf/Th corresponding to $^{87}Sr/^{86}Sr = 0.70475$ is about 1, while the chondritic value is about 10.

In a plot of Hf/Th versus Ta/Th where the ratios have the same denominator, mixing processes are represented by a straight line, as in the lead isotopes plot. The most remarkable observation (Fig. 3*b*) regarding the results for the North-Atlantic MORB is that they do not define simple straight lines. Therefore the variation for the North-Atlantic MORB source cannot be generated by a simple two-end member mixing process. Such a conclusion agrees with that of Langmuir *et al.*[16] which was obtained using different elements.

The 'regional' variations

A cross-section of regional variations along the ridge can be made from Iceland to the South. With our new Pb and Sr data which have been corrected for seawater contamination by a HCl leaching technique, we can draw two important conclusions from the regional variations which have been a source of confusion in the past.

(1) There is no clear correlation between bathymetry and isotopic ratios. Certainly some correlation occurs between the depth of the ridge and some trace element contents, especially for the incompatible ones, but this probably reflects a correlation between the bathymetry and the degree of partial melting rather than the composition of the mantle source. On the North-Atlantic scale, there is no clear correlation between bathymetry and isotopic ratios which would directly reflect the nature of the mantle source.

(2) The variation from Iceland to the South is not dominated by only two 'hot spots' (Iceland+Azores). Our Pb, Sr and Nd isotopic results reinforce those of White and Schilling[7] on Sr isotopic composition because Pb and Nd are not sensitive to alteration. The variations are such that if one wants to interpret the variations of isotopic ratios by a 'hot spot' model, a third hot spot must be added around 45°N and perhaps another around 9°N.

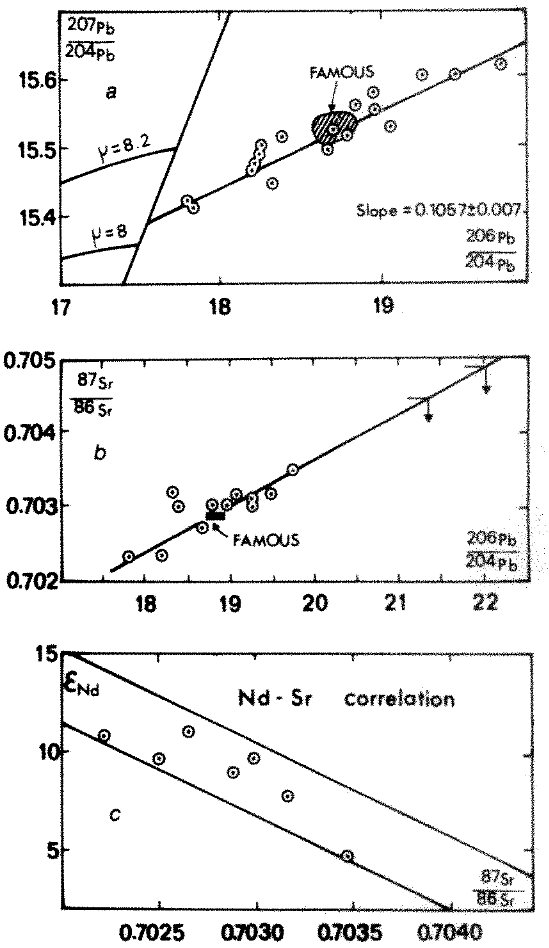

Fig. 2 Results for samples from North Atlantic tholeiites. *a*, $^{207}Pb/^{204}Pb$ versus $^{206}Pb/^{204}Pb$. The regression line has a slope of 0.1057±0.007. The model age is 1,720 Myr. *b*, Correlation $^{87}Sr/^{86}Sr$ versus $^{206}Pb/^{204}Pb$ for North Atlantic MORB. Lead isotopic Atlantic planetary values are determined from $^{87}Sr/^{86}Sr$ planetary value (0.70475). *c*, Nd–Sr isotopes correlation for the North Atlantic basalts. Data for MORB are from refs 1, 4, 5.

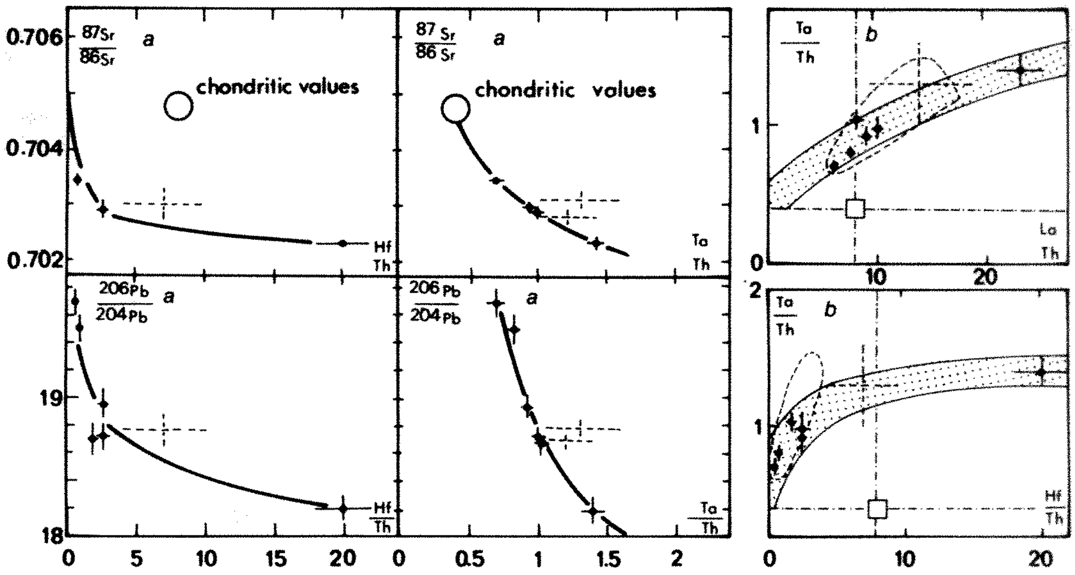

Fig. 3 *a*, $^{87}Sr/^{86}Sr$ versus $^{206}Pb/^{204}Pb$ versus HF/Th or La/Th trends for North Atlantic MORB. Data are from refs 12–14 and this paper (chondritic values are from refs 42, 43). The HF/Th and La/Th ratios are the mean value of these ratios for each site. The error of 0.1% for the isotopic ratios is taken as being equivalent to the dispersion observed on the FAMOUS site where many samples have been measured[38]. *b*, Ta/Th versus Hf/Th or La/Th trend for North Atlantic MORB. (Refs as in Fig. 4.) The dashed line area corresponds to oceanic islands domain (data from ref. 21).

Comparison of the North Atlantic MORB with other oceanic basalts

Only a few results have been obtained on the same samples for Pb-Sr-Nd isotopes (Fig. 4) using modern techniques and leaching or diopside separation to eliminate Sr seawater contamination. The only available results are those of Cohen *et al.*[9] on volcanic glasses and some of our unpublished results on Pacific and Indian oceans. Pb-Pb or Sr-Pb diagrams show a very good positive correlation which is identical with our Atlantic lines. Thus the values for Pb isotopes corresponding to the planetary strontium isotopic ratio are about the same as PLA. This being so the above anomaly should be considered a worldwide characteristic and not a local one.

We do not have measurements for some other oceans but preliminary data for the Pacific MORB seem to plot on the general trend in the Hf/Th Ta/Th) diagrams (H. Bougault, personal communication).

As Pb, Sr and Nd isotopes have been analysed in Icelandic samples[17-20]and in the Azores islands (see ref. 15 for Pb; refs 1, 22 for Sr and Nd) we can then try to place these samples with respect to MORB in the (Sr, Pb) isotope correlation diagram.

Iceland, Terceira, Corvo and Santa Maria are roughly in the correlation band. Other islands, like Faial or Sao Miguel are out of the trend. Sao Miguel is also outside the (Nd-Sr) main trend[22]. However, a more careful analysis shows that two populations of oceanic island basalts which do not follow the trend are older than the others. For instance, only the old part of the Sao Miguel island does not really follow the trend. All other islands, including the Canary Islands[24], plot around the main trend. Of course, this argument is rather statistical but the positive correlation including the North Atlantic islands is clear.

Although different isotopic ratios were often found in separate samples we will use the compilation of Sun[3] (Fig. 4). Such a compilation shows that the basalts from oceanic islands define a large band completely outside the MORB (Pb-Sr) or (Pb-Pb) correlations. In the (Pb-Sr) correlation diagram such a band can be even considered 'orthogonal' to the MORB's trend. In the (Pb-Pb) diagram, there is also a clear distinction between these two populations. Such a behaviour is in great contrast with the (Sr-Nd) diagram, which exhibits the correlation for both MORB and OIB.

We also want to emphasize another major difference. In the Sr-Nd diagram, the values observed for OIB can be interpreted as the result of a material derived from a planetary reservoir and contaminated by the MORB reservoir during its ascent. In contrast, for Pb isotopes, the OIB reservoir is clearly in the (*J*) type field, and thus corresponds to a largely open system (independent of any contamination by the MORB reservoir). Thus the OIB reservoir is certainly not the protected closed system proposed by Wasserburg and De Paolo[26].

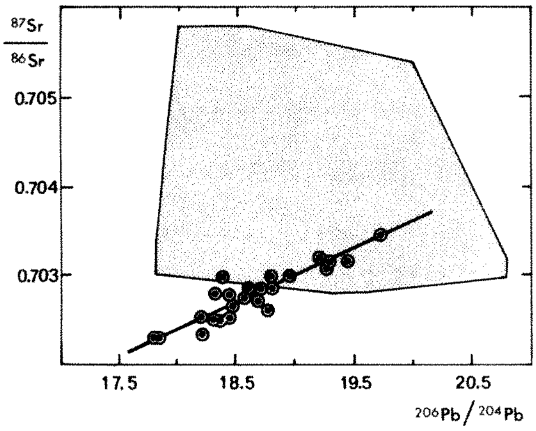

Fig. 4 $^{87}Sr/^{86}Sr$ versus $^{206}Pb/^{204}Pb$ for oceanic basalts. Oceanic island basalts do not seem to be correlated (dotted area from ref. 3) whereas MORB data define a positive correlation from our data and those of Cohen *et al.*[9].

We have plotted a large number of data concerning oceanic islands in (Hf/Th, Ta/Th) and (La/Th, Ta/Th) diagrams (Fig. 3*b*) which show that Ta/Th ratios from MORB and OIB, although distinct are very similar, and not too far from chondritic values. In contrast Hf/Th and Hf/Ta ratios are much lower in OIB than in MORB, and are very different from chondritic ratios. Unfortunately as Hf is less hygromagmatophile than Ta, Th and La (ref. 11) and because alkali basalts are created by small degrees of partial melting (with perhaps more or less fluid transfer and metasomatism), one does not know whether the Hf/Th and Hf/Ta ratios for OIB reflect that of their source or result from their formation processes. Thus we shall not include these ratios in the discussion of OIB sources.

Theoretical interpretations

The main result of the previous investigations is that we clearly have a coherent behaviour of the Rb-Sr, Sm-Nd, U-Th-Pb and Hf, Ta, Th, La systems for the North Atlantic province. This is the first demonstration of such a coherence with such detail. We will now try to explain the significance of these trends.

Models can be built in which the mantle heterogeneity is created by liquid-solid fractionation processes operating through geological time[27]. In this context, the inverse correlation between Nd and Sr isotopes, and the $^{87}Sr/^{86}Sr$ depletion compared with planetary values can be easily interpreted[27]. These observations can be understood if one remembers that Rb is enriched in liquid compared with Sr, and that Nd is enriched in liquid compared with Sr.

If the U-Th-Pb system is taken into account in this model, the positive correlation between Pb and Sr isotopes indicates that U and Th are more enriched in magmatic liquids than Pb. This conclusion agrees with the observations made in magmatic suites[28] and apparently solves the Pb paradox previously pointed out by C. J. A.[29]. However, as we have mentioned above, the problem with Pb is that the 'planetary values' determined from the correlations are not on the Pb-Pb closed system curve.

In the same way, the negative correlation between Hf/Th, Ta/Th, or La/Th and $^{87}Sr/^{86}Sr$ correspond to the fact that Hf, Ta or La are less enriched in magmatic liquids than Th. The slopes of the correlation lines in Hf/Th-Ta/Th and Hf/Th-La/Th diagrams indicate the degree of relative enrichment of Hf, Ta and La in the liquid. Then we can deduce the following increasing order of enrichment in the liquid: Hf < La < Ta < Th, which corresponds more or less to what can be established from the observation of the trace element fractionation in magmatic suites[11].

The preceding observations lead us to distinguish, on a worldwide scale, the existence of two reservoirs, one for MORB, one for OIB. Such a distinction was in fact made in the first isotopic measurements on MORB by Tatsumoto[6] and was subsequently adopted by others[2,30]. However, we feel that evidence presented here reinforces such an interpretation. Our description of these two reservoirs differs from the usual one. We do not consider here the subcontinental lithosphere which constitutes another reservoir, and this is discussed elsewhere[31].

The MORB reservoir is called the upper mantle, the OIB reservoir is considered to be the lower mantle. The OIB is probably partly contaminated by the MORB reservoir during ascent.

The upper mantle is isotopically extremely coherent but not homogeneous. The data for the Atlantic as well as the Pacific or Indian basalts (ref. 9 and our unpublished data) clearly indicate that variations may occur on regional scales. For trace elements, such variations are even more pronouned compared with the lower mantle. The variations observed in MORB are not the result of contamination by OIB as is usually claimed, but are created by the geodynamical system linked with the seafloor spreading which implies chemical fractionation. Imperfect homogenization results from convection. The basis of such processes which can be called 'chemical geodynamics' are discussed elsewhere[27,36].

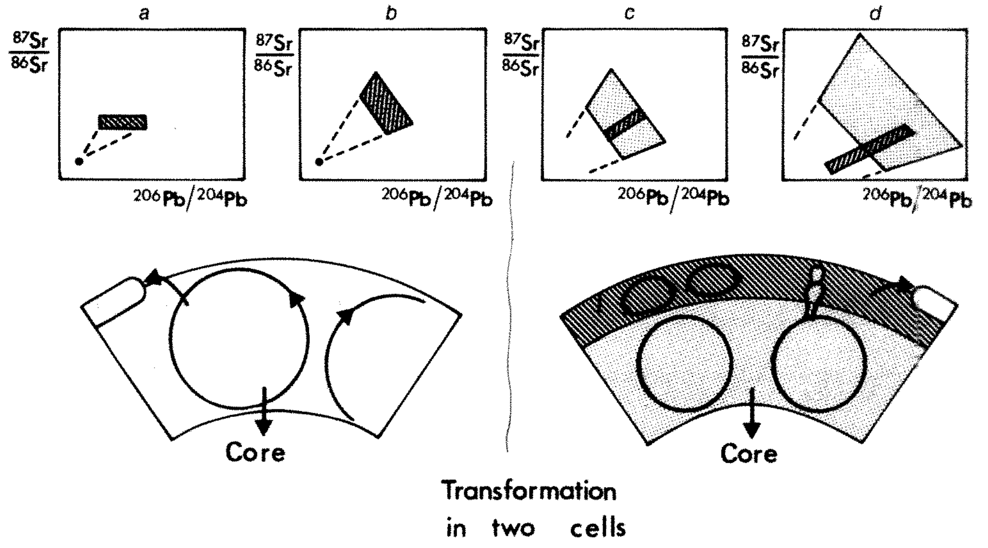

Fig. 5 *a*, Fractionation of U/Pb ratios in the early history of the Earth by core formation creates variations of Pb isotopic ratio only. *b*, The formation of the continental crust fractionates both Rb/Sr and U/Pb ratios, creating variation of Sr and Pb isotopic ratios. *c*, *d*, The transformation of the whole mantle into two independent cells leads to the creation of two types of reservoirs with distinct isotopic characters: relatively homogeneous and less radiogenic MORB reservoir compared with a heterogeneous and more radiogenic OIB reservoir.

The lower mantle is the source for OIB but is not an homogenized, uniform reservoir. It may be more uniform for Sr, Nd and H elements than the upper mantle, but strongly heterogeneous for Pb isotopes and then U/Pb ratios. This reservoir is not planetary for Pb isotopes, for some H elements, and probably also for Sr or Nd as has been shown for Sao Miguel[22]. This means that the reservoir has been fractionated in some way.

The different behaviour of Pb isotopes compared with Sr isotopes is illustrated by the lack of Pb–Sr correlation for OIB and by the planetary Atlantic values being in the *J*-field in the Pb–Pb diagram. There have been two interpretations for these features:

(1) An interaction between the core and the lower mantle has been admitted through geological times; Pb is buried in the core because it is chalcophilic and the core contains suphide. The rate of burying is assumed to decrease exponentially with time, with a time constant of 5,000 myr. This mechanism had been previously considered for a short period just after the differentiation of the Earth[32,33]. Vidal and Dosso[8] have also discussed this hypothesis but in their model, Rb was also buried; in such a case the Nd–Sr correlation would be destroyed, which does not occur. Although this long-term interaction has not been proposed by geochemists it agrees with the suggestion by Runcorn[34] of a continuous, but decaying with time, growth curve for the core.

(2) The alternative interpretation proposed by O'Nions *et al.*[35] allows a reinjection of sediments into the lower mantle. These sediments are H elements enriched by upwards migration within the continental crust. Reinjection rate decreases with time. However, the similarity of hygromagmatophile element ratios such as Ta/Th and La/Th for MORB and OIB does not favour such a model. Furthermore, this model would decouple Sr and Nd isotopes but not Pb and Sr as it is U and Rb simultaneous enrichment of the upper continental crust which is observed.

Note that a fundamental consequence of our observations is that the two reservoirs were connected at some time in the past.

The Pb isotopes systematic of MORB clearly show that the PLA values are anomalous. One way of explaining such anomalies is by assuming that the upper mantle exchanged with the core in the past. Some convection between upper mantle and core is needed. In the same way, H elements in the lower mantle should have been fractionated through time as their values are not chondritic. These elements have no chalcophile or siderophile character and the interaction with the core has no effect on them. The method of fractionating such elements is related to liquid–solid fractionation (or CO_2–magma fractionation?) or in other words to processes associated with the surface activity. This also leads to the conclusion that the two reservoirs were once linked.

Hence we conclude that convection cells affected the whole mantle during the Archaean and maybe even later. During that time seafloor spreading and continental crust differentiation occured at the same time as the core–mantle interaction. Later, the convection cells broke up and split in two cells, or continuously differentiated an upper mantle. The exact process for this mechanism remains unclear. In the lower cells, only the U–Pb system fractionated further, as probably did all other siderophile and chalcophile elements. The upper cells, probably of smaller dimension, are fractionated further through continental crust formation and vigorously stirred by advection. This creates the presently observed patterns of isotopic variations in MORB. And indeed, ~2,000 Myr are necessary to create the observed variation for Pb, Sr and Nd isotopes by such a process (Fig. 5). In which case a separated upper mantle would be an old phenomenon.

This study was supported by CNEXO. Some samples were given by Schilling, all the others were given by the COB. We thank D. Rousseau, M. Polvé, G. Manhes, O. Brévard and J. F. Minster for their help, and H. Bougault for discussions.

Palaeomagnetic polarity in a 930-m core from Searles Valley, California

Joseph C. Liddicoat & Neil D. Opdyke
Lamont-Doherty Geological Observatory, Columbia University, Palisades, New York 10964
George I. Smith
US Geological Survey, 345 Middlefield Road, Menlo Park, California 94025

Palaeomagnetic polarity to the base of the Mammoth subchron (3.15 Myr) has been determined in a core of lacustrine sediments from ancient Searles Lake. The magnetostratigraphy provides a chronological framework for palynological, tephrochronological and palaeoecological studies of the core. Five zones of inclination are found that are not in the polarity time scale of Mankinen and Dalrymple. Three of the zones may correlate with K–Ar-dated lava flows of that polarity elsewhere, and the other two may be new discoveries.

A 930-m, surface-to-bedrock core from Searles Valley, California (35°43'N, 242°40'E), has been used to study palaeoclimate in the western US[1]. The upper 695 m is sediment from Searles Lake, now dry; the remaining 235 m is arkose deposited by intermittent streams on an alluvial fan. The history of climate is in the Searles Lake deposits, the mineralogy and chemistry of which varied with the growth and recession of the lake[2]. The presence or absence of the lake closely mirrored changes in climate, for Searles Lake was near the terminus of a chain of lakes fed by runoff from the Sierra Nevada[3]. As such, Searles Lake was perennial and deep during wet (pluvial) periods; during dry (interpluvial) periods like the present, the lake shrunk to a playa or a salt flat.

A useful interpretation of palaeoclimate must be keyed to an accurate time base, which is also a requirement of corollary investigations (palynology, tephrochronology, palaeoecology), in progress, on the core. Radiocarbon dating of the upper ~50 m of valley fill is extensive [4–7], but radiometric dating of sediment beyond the range of ^{14}C has not been successful. The palaeomagnetic data reported here provide the necessary geochronology for the older portion of the core.

Searles Valley core

The core, called KM-3, was drilled in 1968 by the Kerr–McGee Chemical Corporation, which mines subsurface brines in Searles Valley, and in 1976, KM-3 was released to the US Geological Survey for scientific study. The core has a 9-cm diameter, and because of cracking during drying, is in pieces no longer than 50 cm each. However, some edges may be matched so that longer pieces can be reconstructed, some approaching 2 m in length.

Relatively thin, alternating layers of mud and salines make up the intervals between depths of 0–38, 69–228 and 291–403 m. Thick sections of deep-lake muds lie between depths of 38–69, 228–291 and 542–693 m. The interval between 403 and 542 m is brown sediment formed mostly in a playa lake[1]. (Conforming to accepted terminology[1,2], we use 'salines' for the evaporite minerals, and 'mud' as a general term for clay, silt, and marl that was moist and plastic when extruded as core; now dry, the clay and silt are claystone and siltstone, respectively.)

There are numerous tephra layers in the core, and a sequence of them in the interval 169.3–178.6 m may represent the Bishop Tuff (R. Hay, personal communication), a pyroclastic erupted in Long Valley (California) ~0.7 Myr ago[8,9]. A more positive identification of the tuff would provide an important time-line in the core, and this is in progress. Two other tephra layers lie near the bottom of the lacustrine section (684.0 and 690.9 m); if they too can be traced to their source and dated, another cross-check on the magnetostratigraphy will be available.

Sampling and laboratory procedures

Palaeomagnetic samples were taken at intervals of ~3 m or less in non-saline portions of the core below 100 m depth. Above 100 m, the core is not sufficiently intact to be reliable for palaeomagnetism. The large diameter of the core allowed us to take three specimens at each measured horizon. Each specimen was encased in a polythyrene box of 6.6 cm³, and the specimens from a horizon had the same relative azimuth.

For each subset of specimens, we partially demagnetized one specimen in stepwise increments to 300 Oe peak alternating fields or higher, and demagnetized the other two at the median destructive field. This was 200–300 Oe (Fig. 1) for about 80% of the specimens; for the remaining specimens (from saline-rich horizons), the median destructive field was 50–150 Oe. Within most subsets, and almost always below 400 m where the remanence is nearly 100-fold stronger than that of saline-rich zones, the grouping of magnetic vectors is good—the spread of values of inclination being commonly <5°. Samples taken at 581.0 and 619.8 m (brown mud deposited in a playa) were thermally demagnetized, and the directions were compared with those of the a.f. demagnetized specimens from those depths; in each case, there was no appreciable change in the magnetic vector (Fig. 1).

Magnetostratigraphy in Searles Valley

Interpretation of polarity change in KM-3 is most convincing if linked to one or more reliable markers in the Pleistocene. Although only tentatively identified in the core, the Bishop Tuff would serve as one such calibration point because it lies near the

0028–0836/80/270022–04$01.00

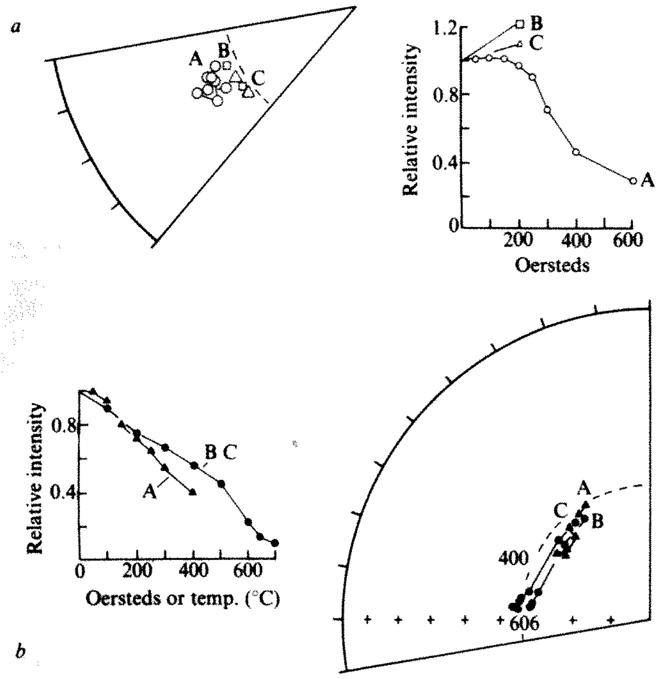

Fig. 1 Normalized a.f. and/or thermal demagnetization curves and equal-area plot of palaeomagnetic directions for: *a*, three specimens from 480.5 m (reversed polarity); and *b*, from 581.0 m (normal polarity). The azimuth of specimens within each horizon is the same, but different between horizons. In *b*, specimen A was a.f. demagnetized; specimens B and C were thermally demagnetized. The dashed line in the equal-area plot represents inclination of an axial dipole field (55°) for the site latitude; solid symbols are plotted on the lower hemisphere, open symbols on the upper.

Brunhes/Matuyama boundary[10]. Indeed, the youngest horizon of negative inclination is at 195.0 m, or $\sim$15 m below the zone of tephra layers that is thought to represent the Bishop Tuff. The nearest overlying horizon of positive inclination is at 174.9 m, so we interpret the Brunhes/Mayuyama boundary at 185.0 ± 10.0 m (Table 1). The underlying $\sim$320 m is predominantly of negative inclination (Fig. 2), which we assume to represent the Matuyama chron. Below that, the predominantly positive inclination is most probably the upper part of the Gauss chron.

Assuming that we have correctly identified the Brunhes/Matuyama and Matuyama/Gauss boundaries, it is then possible to plot age against depth to identify the zones of positive inclination within the Matuyama chron. From Fig. 3 it can be readily ascertained that the zones centred at $\sim$210 m, 390 m, 410 m, and 450 m correspond to the Jaramillo, Olduvai, and two-part Réunion subchrons, respectively. Further, the zones of negative inclination in the Gauss chron that are centred at about 630 m and 660 m would correlate to the Kaena and Mammoth subchrons, respectively (Table 1).

Note in Fig. 3 that there is a nearly linear relationship between the position of the polarity boundaries and the age assigned to them using the time scale of Mankinen and Dalrymple[11]. This is especially true for sediment below 400 m, where the lack of saline layers allows an approximation of uniform sedimentation rate. For those 295 m, spanning nearly 1.2 Myr, the average rate of sedimentation is $\sim$40 yr cm^{-1} (0.25 mm yr^{-1}). It is difficult to calculate sedimentation rates for other parts of the core because the time represented by saline layers can be either very long or short; salines initially accumulate more rapidly than mud, but this is countered by periods of almost no deposition when the lake becomes a seasonally flooded salt flat[2]. Nonetheless, the overall sedimentation rate to 695 m is $\sim$45 yr cm^{-1}, or only 10% slower than that of mud of the perennial lake.

Five zones of inclination in KM-3 are not in the standard polarity time scale proposed by Mankinen and Dalrymple[11]. Three of the zones may correspond to subchrons that have been proposed[12–14] but not universally accepted, while the other two could be new. These previously undetected short subchrons are not entirely surprising as their existence was predicted on the assumption that durations of polarity changes conform to a Poisson distribution[15]. The advantage of using lacustrine deposits such as in Searles Valley to search for short subchrons is that the sedimentation rate is at least 50-fold greater than in most deep-sea sediments, and is much less discontinuous than the eruption of lava flows. An obvious disadvantage is that part of the core might be inverted, accidentally either during initial recovery or some time during the intervening 8 yr of storage. As we were not present at the time of drilling, there is no guarantee that the top of the core was properly labelled on the drill rig or after splitting and storage; a realistic approach would be to assume that part of so long a core was inverted by human error. However, this probably did not occur during storage because we have compared the present core to Kerr-McGee's colour photographs of it taken at the time of recovery. When we removed samples, we photographed the potentially useful boxes of core, and those photographs have enabled us to check the orientation of back-up samples.

The question of inverted samples becomes critical when comparing measured zones of constant inclination to the generally accepted polarity time scale, or when detection of a new subchron is claimed. We examined notes made at the time of sampling to see if any of the unnamed short zones of inclination are restricted to a single core box or coring run, as these portions could be those most likely to be inverted. Three new zones of inclination were found restricted to single coring runs, and resampling of cores from adjacent runs showed that inversion of the core was probably not responsible for the zones. Additional checks included matching saw marks on the split side of the core to see if they were similar from piece to piece in a storage box, and determining whether the switch in inclination occurred between segments of core where the lithology suggested a discontinuity.

Matuyama chron

The zone of positive inclination that we interpret to be the Jaramillo subchron (0.90–0.97 Myr) lies between $\sim$205 and 220 m (Table 1). It includes four measured horizons and spans two boxes of core. The two horizons of negative inclination between the top of the zone and where we place the Brunhes/Matuyama boundary (Fig. 2) are also from two boxes of

Table 1 Location of polarity boundaries and unnamed zones of inclination in KM-3

Boundary	Depth (m)	Lithology
Brunhes–Matuyama	185.0 ± 10.0	Interbedded mud and salines

Mammoth–Gauss	683.9 ± 4.2	

* We assume the Réunion to be a multiple subchron[29,30].

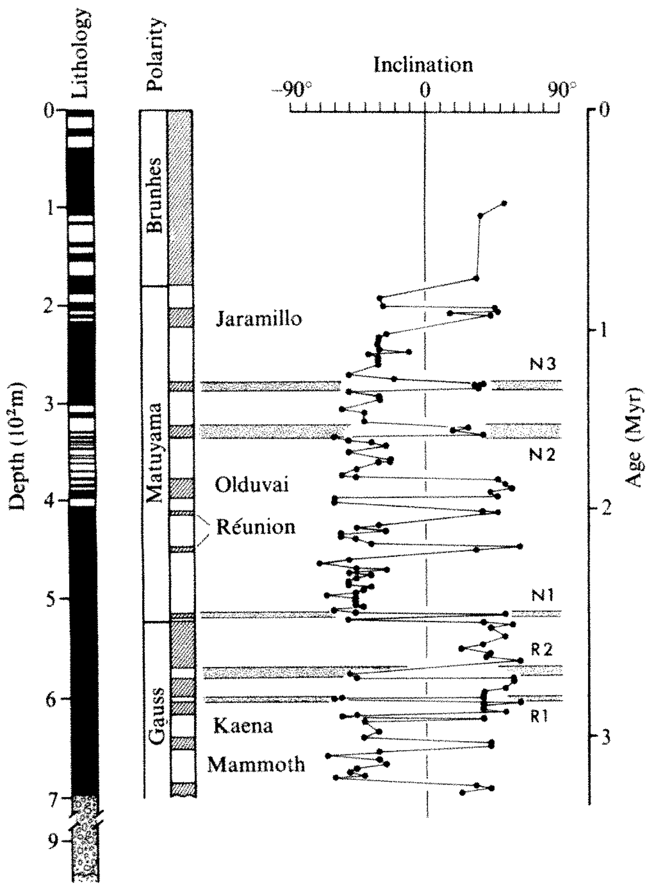

Fig. 2 Palaeomagnetic polarity in Searles Valley core KM-3. Shaded region highlights the unnamed zones of inclination, three in the Matuyama chron and two in the Gauss chron. In the lithological column: unshaded area, salines; black area, mud; spotted area, arkose. In the polarity column; hatched area, normal polarity; unshaded area, reversed polarity. Age is extrapolated from polarity boundaries in the time scale of Mankinen and Dalrymple[11], and by assuming a uniform sedimentation rate. Note that the time scale is not linear.

core, and the horizon of negative inclination below the zone is from another box. The switch from positive to negative inclination at the top of the zone occurs within one section of core pipe (each section is 10 m long), eliminating the possibility that the coring run was inverted or mislabelled at the time of recovery.

The other universally recognized subchron in the Matuyama chron is the Olduvai subchron (1.67–1.87 Myr); we place it between 379 and 399 m (Table 1). This portion of the core involves four measured horizons, one each from two different boxes of core and two from a third box. The third box also contains the horizon of negative inclination at the base of the subchron, and the two samples in that box are separated by ~0.3 m. Again, the change from positive to negative inclination occurs within one section of core pipe.

The two short zones of positive inclination below the Olduvai subchron we consider to be the multiple Réunion subchron (2.12–2.14 and 2.01–2.04 Myr)[16–18]. The older half occurs between 447 and 456 m (Table 1) and includes two measured horizons, one each from separate boxes of core that is little disturbed. The samples of negative inclination that bracket the zone are from two other boxes of core, and the switch in inclination is within a section of core. The younger half is between 408 and 424 m, and the two samples came from the same box of core. As is the case for the older part of the subchron, the horizons of negative inclination on either side came from different boxes of core. However, unlike the older part, the positive inclinations are all in one section of drill pipe that was obtained separately from the sections containing the horizons above and below; this raises the possibility of an inverted section of core.

Unnamed zones of inclination in the Matuyama chron

The palaeomagnetic record in KM-3 contains three other short segments of positive inclination that are not included in the Mankinen and Dalrymple time scale[11]. The youngest (N3; Fig. 2) is in deep-lake mud between 281 and 288 m (Table 1). The zone is found in two boxes of very good core from the same core run (the measured horizons above and below the zone are from different runs) and terminates 60 m below the start of the Jaramillo subchron; 54 of these 60 m are deep-lake mud. Using the 40 yr cm^{-1} accumulation rate cited above for the mud, this part of the core spans ~20,000 yr between 1.24 and 1.26 Myr ago. If no time is assigned to the 6 m of salines between the disappearance of the deep-water lake and onset of the Jaramillo subchron, this unnamed zone is dated 1.20–1.22 Myr.

Mankinen *et al.*[12] recently reviewed the evidence for a short subchron close to and preceding the Jaramillo subchron, and have identified one (Cobb Mountain subchron) in the volcanic units near Clear Lake, California. The K–Ar age given the Cobb Mountain subchron is 1.12 ± 0.02 Myr, so we cannot closely match the unnamed zone of inclination in KM-3 with that one, but given the uncertainty in sedimentation rate, the correlation is possible. It might also equate with the K–Ar-dated basalt of normal polarity in Madiera[19] and in the Lesser Antilles (Guadeloupe and St Vincent)[20] if the dates are accurate, and to a normally magnetized ash layer in the Osaka Group, Japan, having a fission-track age 1.1 ± 0.1 Myr (refs 21–23).

The zone of positive inclination near the middle of the Matuyama chron (N2; Fig. 2) may correlate with the controversial Gilsa subchron, whose existence has been affirmed and denied several times during the past decade[24]. The three measured horizons are in different boxes of core, and the samples used to bracket the zone are from two other boxes. Although the quality of that portion of the core is good, the horizons in question are from a single core run, and the opposite inclination on either side is from two other runs. Thus, we are concerned about whether the entire core run was mislabeled or inverted.

The oldest zone of positive inclination in the Matuyama chron (N1; Fig. 2) is near its beginning and might correspond to the 'X' subchron[14] that has been seen in some magnetic anomaly data; however, it may correlate to the short subchron observed in Icelandic lavas very close to the Matuyama/Gauss boundary[25]. The measured horizon is in part of the good core, and the switch in inclination occurs within one core run.

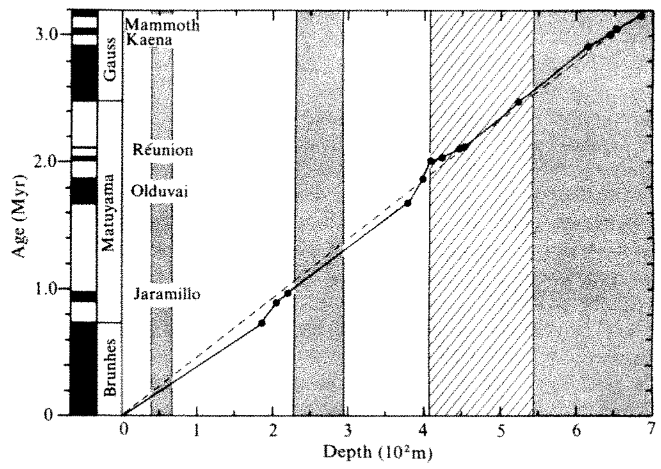

Fig. 3 Depth of interpreted polarity boundaries in KM-3 versus age in the polarity time scale[11]. Shaded area, mud deposited by a deep, perennial lake; hatched area, mud deposited by a playa lake[2]. Overall rate of sedimentation is ~45 cm yr^{-1} (dashed line); for the perennial lake, it is 40 cm yr^{-1}.

Gauss chron

We equate the two zones of negative inclination near the bottom of the lacustrine section with the Kaena subchron (2.92–3.01 Myr) and Mammoth subchron (3.05–3.15 Myr). Each represents at least five measured horizons, and they are in different boxes of core. The two horizons of positive inclination that separate the subchrons are also from separate boxes of core, and the switch of inclination occurs in one core run.

Unnamed zones of inclination in the Gauss chron

Reversed magnetozones occur in upper Gauss time in mud from a perennial, deep lake, the sediment type we believe to be the most reliable magnetic recorder in the core. Using estimated sedimentation rates again, the younger zone (R2; Fig. 2) spans ~40,000 yr, and the older one (R1; Fig. 2) perhaps 20,000 yr. Extrapolating from the Matuyama–Gauss boundary (2.48 Myr) (ref. 11) the ages for these zones are then 2.67–2.71 and 2.79–2.81 Myr, respectively. Some reversely magnetized K–Ar-dated basalt flows in this age range have been reported: two from Oahu in Hawaii[26], one in west Iceland[27] and one in St Vincent[20]. Thus, these may be real subchrons, but because of their brevity, they can only be clearly defined in a high sedimentation-rate environment such as Searles Lake. We must re-emphasize that the measured horizons defining both zones were found in single boxes of core (although the opposite polarity occurs in single core runs). For the younger of the two zones, there are two horizons of positive inclination and two of negative inclination, and the separation between the portion of the core where the inclination switches is 0.46 m, or slightly less than 1,000 yr using the assumed sedimentation rate for that part of the core. Three closely spaced horizons of good core define the older zone, and the horizon above and below are in different boxes of core and at least 2.2 m apart.

Conclusions

Based on the record of palaeomagnetic polarity in KM-3, the oldest lake deposits in Searles Valley formed ~3.2 Myr ago (Fig. 2). The timing of a changing climate that might have produced a permanent lake in that part of the Great Basin coincides with a general cooling in the Northern Hemisphere as seen in the $\delta^{18}O$ record in deep-sea core V28-179 (ref. 28). The sedimentary record is probably a result of the interplay of tectonics and climatic events[1].

Five unnamed zones of inclination are present in the core, and four involve two or more measured horizons. The three unnamed zones in the Matuyama chron may correspond to subchrons that have been proposed by others but are not universally accepted. The two unnamed zones in the Gauss chron occur in good-quality core, and the change from positive to negative inclination for both zones occurs in single, 10-m sections of core.

We thank D. A. McGee, chairman of Kerr-McGee Corporation, for permission to study this core, G. Moulton and C. Cowie for logistical support while obtaining samples, S. Liddicoat for field assistance, D. Lafferty for laboratory assistance, and R. Coe, R. Hay, C. Denham, E. Mankinen, S. Grommé, D. Champian, D. Kent, and G. Kukla for helpful comments. Funding was provided by the Climate Program of the US Geological Survey (contract 14-08-0001-18282). Lamont-Doherty Geological Observatory Contribution no. 2990.

Nerve growth factors in the rat iris

Ted Ebendal*, Lars Olson†, Åke Seiger† & Kjell-Olof Hedlund*

* Department of Zoology, Uppsala University, Box 561, S-751 22 Uppsala, Sweden

Nerve growth factor (NGF) activity was not detected by bioassay in irides killed immediately after excision but NGF appeared within 24 h in living irides placed in culture or grafted to a host eye. Furthermore, sensory and, although less effective, sympathetic denervation of irides in situ *led within 10 days to the appearance of NGF activity. In addition, freezing and thawing released a parasympathetic neuronotrophic factor activity from irides.*

THE protein nerve growth factor (NGF)[1] has been suggested to mediate trophic influences to sympathetic and sensory neurones from innervated target organs[2]. However, little is known about the distribution of NGF in peripheral tissues to support this concept[3]. Except for some very rich sources of NGF (the male mouse submandibular gland[1], the guinea pig prostate[4]), mammalian tissues are normally inactive when tested as homogenates in the sensitive bioassay based on NGF-susceptible embryonic ganglia[3,5]. We now show that explants of the adult rat iris immediately killed by freezing do not contain NGF at levels detectable by bioassay but that NGF is readily detectable in irides killed by freezing within a day after transfer to a recon-

0028-0836/80/270025-04$01.00

stituted collagen gel[6] (compare refs 7, 8) or to the anterior eye chamber of another rat[9]. After re-innervation of the iris transplants, NGF was no longer detectable. Most compelling is the fact that the levels of NGF were also raised in irides *in situ* 10 days after sensory denervation and, although less prominent, 10 days after sympathetic denervation. Furthermore, evidence was obtained for the actions of a parasympathetic, non-NGF, trophic factor released from the rat iris after freezing and thawing. The results support a role for NGF as a signal initiating and directing regenerating sensory and sympathetic fibres in adult mammals and suggest that other trophic factors may fulfill a similar role in other fibre systems.

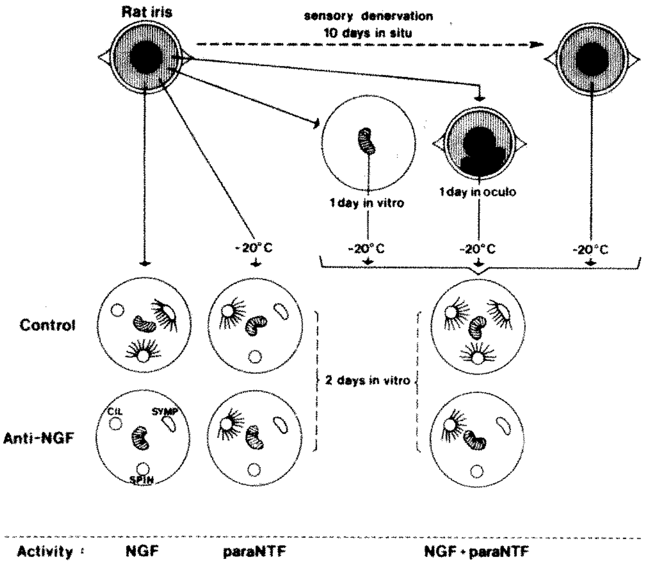

Fig. 1 Schematic representation of the experiments with rat irides and the resulting patterns of neurite growth responses in chick sympathetic (symp), spinal (spin) and ciliary (cil) ganglia. The results are interpreted as evoked by the actions of nerve growth factor (NGF), of a parasympathetic neuronotrophic factor (paraNTF) and of the simultaneous action of these two. Circles represent culture dishes. Irides were from normal rats (left) or from rats in which the trigeminal nerve had been lesioned (sensory denervation, right). For bioassay sympathetic, spinal and ciliary ganglia from 8- to 10-day-old chick embryos were placed surrounding a living or killed (by freezing to −20 °C) half-iris in an 0.3–0.5-mm thick collagen gel in a 35-mm plastic culture dish. The medium of the gel was Eagle's basal medium supplemented with 1% fetal calf serum, penicillin (100 units ml^{-1}) and streptomycin (100 $\mu\mathrm{g\,ml}^{-1}$). Parallel dishes received in addition 2–5 μl per ml of specific rabbit anti-mouse-βNGF antiserum[22], levels that readily blocked the activity of 1 biological unit (BU) of NGF. Cultures were incubated at 37 °C with 5% $\mathrm{CO_2}$ in water-saturated air for 2 days and then examined by phase-contrast microscopy.

Effects of culturing on NGF synthesis in the iris

To study the content of NGF, irides of adult Sprague–Dawley rats were excised aseptically and tested in a ganglionic bioassay (Fig. 1). The criterion for NGF activity is an induction of neurite outgrowth in the chick sympathetic and spinal ganglia, which in parallel dishes can be blocked by antiserum to NGF, combined with a lack of fibre response in the ciliary ganglion[6]. Three distinct patterns of neurite outgrowth responses were observed (Fig. 1). Living iris explants taken directly into co-culture with ganglia evoked neurite outgrowth in the sympathetic and spinal ganglia within 20–24 h. Outgrowths developed fully within 2 days (Table 1), were directed mainly towards the living iris explants and had fibre densities resembling those evoked by 0.8 to 1 biological units of NGF (BU)[1]. Anti-NGF nearly completely inhibited these outgrowths (Table 1, $P<0.01$). Thus it is evident that the living irides in culture release NGF. The ciliary ganglia showed nearly no nerve fibre outgrowth when combined with living iris tissue. In control cultures without irides all three types of ganglia failed to extend neurites[6] (Table 1).

To test whether NGF is present in freshly excised irides or whether it is synthesized *in vitro*, irides were killed by immediate freezing to −20 °C for 1 to 30 days and then thawed. No NGF activity was detected in such iris tissue in the bioassay (Figs 1, 2*a*): in sympathetic ganglia slightly more fibres extended than in controls ($P<0.05$) but anti-NGF did not significantly (by the *U*-test) reduce this outgrowth (Table 1). On the other hand, killed iris tissue significantly increased formation of neurite bundles in the ciliary ganglia (Fig. 2*b*; Table 1, $P<0.01$). This stimulation was not abolished by adding anti-NGF, although the antiserum sometimes slightly impaired the response in the ciliary ganglion in this and in the following culture combinations. These results suggest the existence in the iris of a parasympathetic neuronotrophic factor[2] (paraNTF), stimulating the cholinergic neurones of the ciliary ganglion, and being released only after disrupting cells by freezing and thawing. Furthermore, the results show that NGF is not present at detectable levels in the iris *in situ*, but that the iris begins to synthesize NGF when placed in culture.

Effects of freezing and transplantation

To rule out the possibility that the freezing–thawing itself destroys NGF activity in the iris, explanted irides were cultured for 1 day in order to accumulate NGF before being killed. Bioassay demonstrated the same level of NGF activity in these explants as in the living ones (Figs 1, 2*c*; Table 1). Moreover, the ciliary ganglia exhibited dense outgrowths of neurites not significantly different from those evoked by immediately killed irides (Table 1). Thus these cultures showed a pattern of neurite stimulation that evidently represents the combined activities of NGF and paraNTF (Fig. 1). Anti-NGF inhibited outgrowth of neurites in the sympathetic (Table 1; $P<0.01$) and spinal ganglia but did not affect outgrowth in ciliary ganglia.

Table 1 Relative density of neurite outgrowths in chick ganglia

			With irides killed after:				
	Without iris explants	With living iris explants	No special treatment	Culture *in vitro* (1 day)	Grafting *in oculo* (1 day)	Sympathetic denervation *in situ* (10 days)	Sensory denervation *in situ* (10 days)
Sympathetic ganglia							
without anti-NGF	0.0±0.0 (8)	1.0±0.0 (9)	0.3±0.1 (9)	1.0±0.0 (9)	1.0±0.0 (5)	0.6±0.1 (10)	0.9±0.0 (15)
with anti-NGF	0.0±0.0 (8)	0.1±0.0 (8)	0.2±0.1 (8)	0.4±0.1 (5)	0.4±0.1 (5)	0.3±0.1 (7)	0.3±0.1 (11)
Ciliary ganglia	0.0±0.0 (8)	0.1±0.1 (5)	0.7±0.0 (5)	0.8±0.1 (5)	0.8±0.1 (5)	0.8±0.0 (5)	0.7±0.1 (13)

Mean values ± s.e.m. are given. For each group 5 to 15 ganglia (number given in parentheses) were scored for density of outgrowing neurites after 2 days on a blind basis. The scores ranged from 0 (no neurites at all) to 1 (maximum density, fibre halo with circular outline). The scores for the two types of ganglia are not strictly comparable due to differences in neurite morphology. *P* values given in the text refer to rankings of the individual scores evaluated by the Mann–Whitney *U*-test.

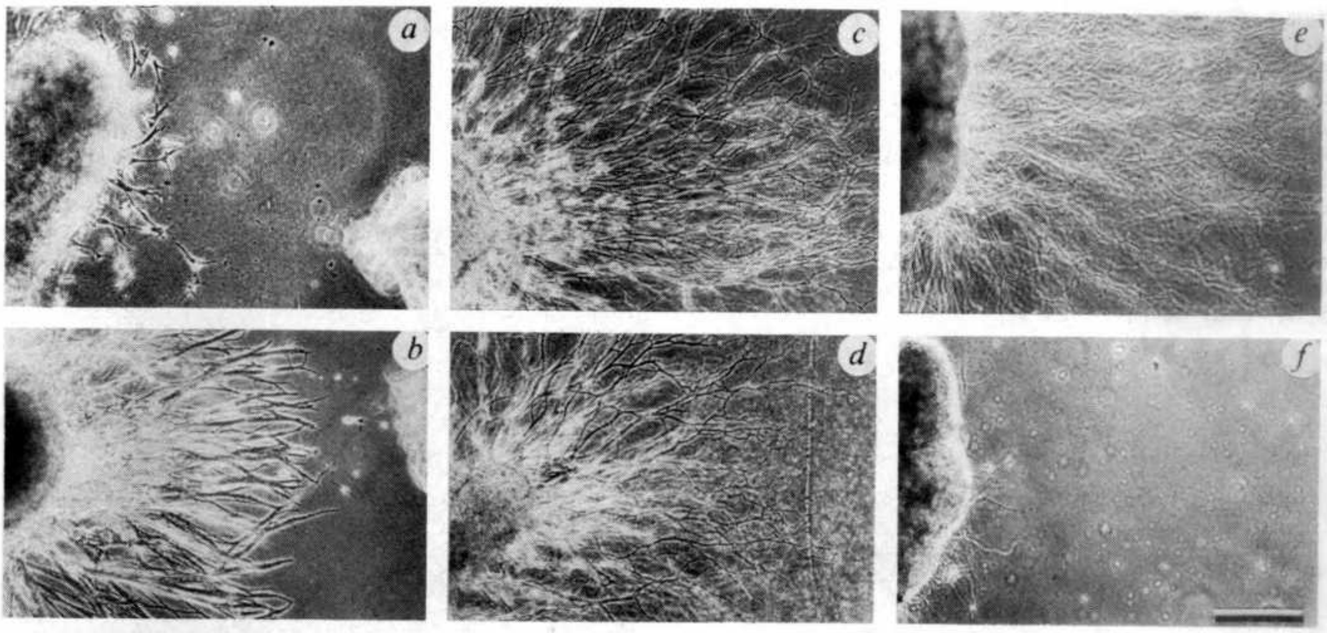

Fig. 2 *a*, Sympathetic ganglion (left) combined for 2 days in culture with rat iris (right) immediately killed after extirpation. No neurites emerge from the ganglion. *b*, Ciliary ganglion in the same conditions. In this parasympathetic ganglion extensive formation of thick neurite fascicles (identity controlled by the transmission electron microscope) is elicited by the killed iris explant. *c*, Sympathetic ganglion with dense fibre outgrowth elicited by an iris that had been cultured for 1 day and then frozen–thawed before being tested in the bioassay. *d*, Sympathetic ganglion combined with an iris transplanted to the anterior eye chamber of another rat for 1 day before being killed and tested. *e*, Extensive neurite formation in a sympathetic ganglion evoked by an iris killed 10 days after sensory denervation *in situ*. *f*, Inhibition by anti-βNGF of the neurite outgrowth in the foregoing combination. Phase contrast micrographs. Scale bar, 0.2 mm. See also ref. 13 for low-power darkfield micrographs of total outgrowths elicited by living irides.

To test whether NGF is produced in the iris only in *in vitro* conditions, the iris was either transplanted to the anterior eye chamber of another rat, rather than to a culture dish, or was left *in situ* but subjected either to sympathetic denervation by extirpation of the superior cervical ganglion or to sensory denervation by lesioning the trigeminal nerve[9] (Fig. 1). To prevent appearance of NGF during the subsequent bioassay the irides were killed by freezing before being combined with ganglia (Fig. 1).

After 1 day in the anterior eye chamber the transplanted iris contained the same amount of NGF as iris explants cultured *in vitro* for 1 day (Fig. 2*d*; Table 1). After 4, 7 and 11 days *in oculo* the same levels of NGF activity persisted but after 1 month, at which time the iris transplant had become at least sympathetically reinnervated by the host iris[10], NGF activity was no longer detectable. The responses evoked in the ciliary ganglia were the same as those elicited by the other frozen–thawed irides (Table 1).

Role of innervation in NGF synthesis

Experiments with irides denervated *in situ* show more clearly that the level of NGF is in some way related to the state of innervation. Irides taken for bioassay 10 days after sensory denervation consistently gave dense fibre outgrowths in sympathetic (Figs 1, 2*e*, Table 1; the increase over normal killed irides is significant, $P<0.01$) and spinal ganglia. The resulting outgrowth could be significantly reduced by anti-NGF (Figs 1, 2*f*, Table 1; $P<0.01$). Sympathetic denervation for 10 days resulted in a much less although significant ($P<0.05$) increase in fibre density in sympathetic ganglia (Table 1). That NGF is involved here also is indicated by the significant ($P<0.05$) reduction in fibre outgrowth by anti-NGF (Table 1). No NGF was detected 2 or 4 days after denervating the iris *in situ* nor was NGF found 1 month after denervation (at which time some reinnervation is likely to have taken place). Combined sensory and sympathetic denervations gave as high levels of NGF after 10 days as did sensory denervation. For the ciliary ganglia the denervations caused no further increase in fibre density above that evoked by normal killed irides (Table 1).

Sections of the ganglia cut for light microscopy at the end of bioassay add some information on the survival of neurones in response to the irides. In full agreement with the neurite outgrowth response the ciliary ganglion showed excellent neuronal survival after exposure to any iris that had been frozen–thawed (Fig. 3*a*; 19 ± 1 neurone profiles were found within an area of 0.01 mm^2; mean ± s.e.m. from sections of 5 ganglia) whereas living irides to a less ($P<0.01$) extent did promote survival of ciliary neurones (Fig. 3*b*; 5 ± 1 neurone profiles with living irides compared with 1 ± 0 neurone profiles in cultured control ganglia, $P<0.05$). The outcome for sympathetic ganglia was less expected: here the presence of iris tissue enhanced neuronal survival whether or not outgrowth of neurites occurred (Fig. 3*c*). The number of neurone profiles was thus 63 ± 4 with normal killed irides, which is not significantly different from the 71 ± 4 neurone profiles found with killed irides plus anti-NGF, whereas neuronal survival was significantly lower ($P<0.01$) in cultured control ganglia (Fig. 3*d*; 30 ± 3 neurone profiles). The enhancement may be due to an nonspecific, non-NGF, trophic influence on the neurones exerted by the presence of serum in the explanted irides: thus adding rat serum at 10% by volume resulted in 56 ± 5 neurone profiles. Rat serum, however, totally failed to induce neurite outgrowth in the sympathetic as well as the ciliary ganglia.

The present experiments show that the level of NGF may be raised in a mammalian tissue *in situ* by sensory or sympathetic denervation. The results thus favour the concept that a tissue after denervation during adulthood, and probably also during development, signals with NGF to initiate and attract growing or regrowing sympathetic and sensory nerve fibres[1,2]. This view is also supported by the finding that NGF content falls to undetectable levels concomitant with reinnervation of the iris grafts.

The appearance of NGF in the iris as a result of explantation, transplantation or denervation may be the result of an active

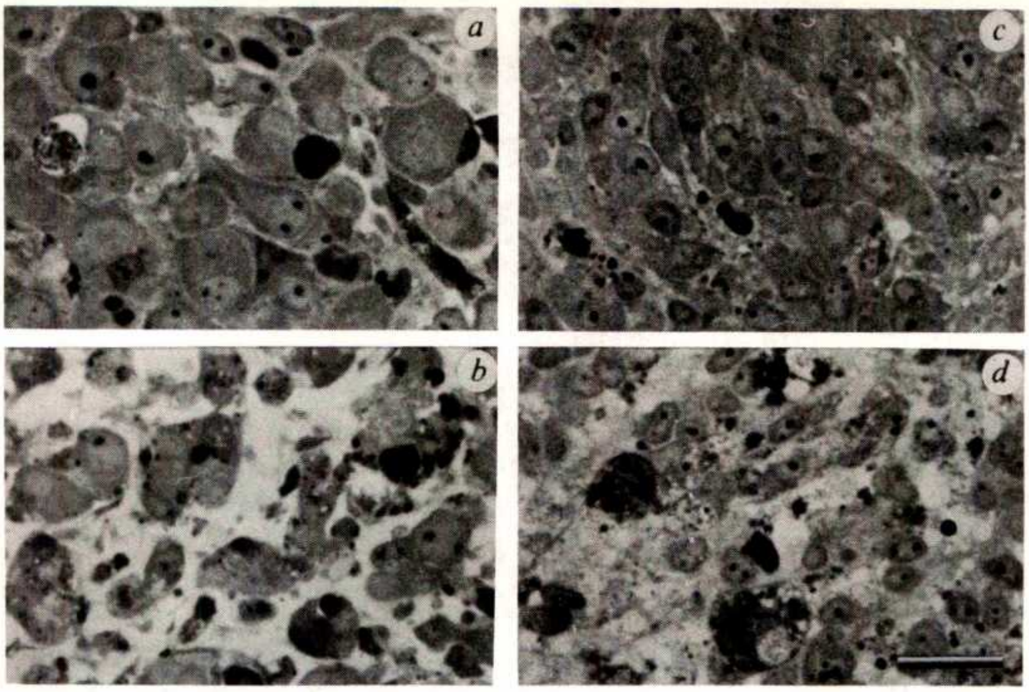

Fig. 3 *a*, Ciliary ganglion combined with a killed rat iris for 2 days in culture. A high neuronal survival is evident. *b*, Same but with a living iris explant. A massive death of neurones, also seen in control cultures, is not prevented by the living iris. *c*, Sympathetic ganglion cultured with an iris killed immediately after extirpation. Despite the addition of anti-βNGF and the fact that no or only few neurites extend from the ganglion (see Fig. 2*a*), a markedly good neuronal survival is induced by the iris tissue. *d*, Sympathetic control ganglion cultured without the presence of iris tissue. Only a few neurones survive in these conditions. For data on neurone survival, see text. Micrographs of toluidine blue-stained 2-μm sections of ganglia fixed in 1.5% glutaraldehyde plus 1.5% paraformaldehyde and embedded in Epon. Scale bar, 20 μm.

response of the iris to increase the production of the factor. Although less plausible, it may also be that the iris is normally drained of the NGF produced in it by retrograde axonal transport[11] to such an extent that the appearance of NGF after, for example, denervation represents an accumulation of the factor rather than an increased production.

The amounts of NGF released from the iris explants that induce a 0.8 to 1 BU response in chick ganglia (Fig. 2*c*, *d*, *e*) can be roughly calculated. The response was evoked only within a zone of about 2 mm around the approximately 5×1 mm half iris in the 0.3–0.5-mm thick gel. Thus the half iris spreads NGF to about 10–20 μl of the gel. If it is assumed[1] that 1 BU corresponds to 5 ng of NGF per ml and that the NGF is evenly distributed, this volume should contain about 40–80 pg. The wet weight of the half iris is about 0.5 mg and thus a reasonable amount of NGF released is of the order of 80–160 ng per g wet weight of cultured or denervated iris tissue. This value is slightly higher than that stated by Johnson *et al.*[8] measuring the release of NGF from irides to a culture medium by radioimmunoassay (RIA). Given the limits of detection of NGF activity for the present bioassay (0.03–0.06 BU)[6], and as we did not detect any NGF activity in initially killed irides, this tissue should release less than about 5–10 ng of NGF per g wet weight. Johnson *et al.*[8] stated that the iris initially contains 15–20 ng NGF per g as measured by RIA but this may be an overestimation due to their technique[12]. The present results thus show that the level of NGF is increased by at least one order of magnitude in the positive iris explants.

It is noteworthy that sensory denervation was a much more potent stimulus for the NGF increase *in situ* than sympathetic denervation (Table 1). One possible explanation for this difference may be that the lesioning technique used to obtain sensory denervation also damages a considerable proportion of the sympathetic axons to the iris. This may also explain why a combined sensory and sympathetic denervation was not found more effective in stimulating the production of NGF than was the trigeminal lesion alone. It is also of note that sensory denervation has been shown to cause massive ingrowth of central noradrenergic fibres into the iris from transplants of nucleus locus coeruleus (see ref. 9). Since this nucleus does not respond to NGF[13] the mechanism for this fibre stimulation is, however, unlikely to be a response to the increase in NGF demonstrated here.

A parasympathetic stimulation was evident by irides treated by freezing and thawing, indicating the presence in the iris of trophic factors besides NGF. Similar trophic factors have been found in rat cardiac and skeletal muscle[5,14]. Factors stimulating the ciliary ganglion have also recently been reported in the embryonic chick heart[6,15,16] and chick iris[17,18] as well as in culture medium conditioned by chick heart[19] and muscle cells[20].

Conclusions

Thus two nerve growth stimulating factors, one affecting sympathetic and sensory neurones and the other affecting parasympathetic neurones, were found in rat iris tissue. The present results provide the first demonstration that the level of NGF is raised in a tissue *in situ* as a result of denervation. Our data are in line with the demonstration that immunosympathectomy[1] is brought about by neutralizing endogenous NGF[21] and support the concept of NGF as a messenger between target organs and peripheral neurones in mammals.

Comparison of white pock (h) mutants of monkeypox virus with parental monkeypox and with variola-like viruses isolated from animals

K. R. Dumbell & L. C. Archard

Department of Virology, St Mary's Hospital Medical School, London W2 1PG, UK

Monkeypox mutants arising spontaneously or after serial, high multiplicity passage were characterized phenotypically and by restriction endonuclease mapping. Some resemble 'whitepox' and variola viruses in several of the markers tested but all are distinguishable phenotypically from these. None resembles 'whitepox' viruses in genome structure although near-terminal deletions or symmetrical, terminal rearrangements, relative to parental monkeypox, occurred. 'Whitepox' viruses isolated from animals closely resemble variola in both phenotype and genome structure.

THE last naturally occurring case of smallpox was in Somalia in 1977 and the WHO is satisfied that a human reservoir of this disease no longer exists. Attention is now focused on whether there exists any non-human reservoir of variola virus that might threaten the permanence of the eradication of smallpox. A few cases clinically resembling smallpox have occurred sporadically in villages or small towns in the rain forest belt of West Africa. These were caused, not by variola virus, but by another pox virus called monkeypox[1]. Monkeypox virus has shown no evidence of sustained transmission in man and seems not to be a serious public health problem[2].

Attempts to find the natural reservoir of monkeypox virus in West Africa have so far failed to provide any isolates of this virus from wild animals. Four pox viruses, however, which have been recovered from specimens of animals caught in Zaire, have proved indistinguishable from variola virus by biological tests in the laboratory. These four and two similar viruses isolated from monkeys imported into Holland from Malaysia have collectively been called the whitepox viruses. Their natural history is unknown, but there are two reports[3,4] that viruses with the laboratory phenotype of whitepox virus have been obtained from stocks of monkeypox virus, either from hamsters inoculated with monkeypox or by cloning on the chick chorioallantois (CAM).

The implication is that monkeypox virus, which does on rare occasions infect humans, can also produce, as a genetic variant, a virus which may have the same propensities as variola. It is clearly important to examine this question as closely as possible.

Restriction endonuclease cleavage sites were first mapped on a pox virus genome by Wittek *et al.*[5] and this technique has been used by Mackett and L.C.A.[6] to study the structure and relatedness of the genomes of several orthopoxviruses. Here we report the early results of an investigation of monkeypox variants, both by phenotype and by DNA analysis, to assess whether any such variants can be considered identical with whitepox viruses in all ascertainable respects.

Cloning technique

Stage 1: Material sampled from a single pock on the CAM was homogenized by manual shaking with sterile glass beads and 1 ml of 4 mM McIlvaine buffer, *p*H 7.4. The extract was then treated in an ultrasonic bath (Megasonic, 80 kc) for 1 min and centrifuged at 1,000g for 5 min. The supernatant was filtered through a Millipore filter, average pore size 650 μm, to remove most of the aggregates of virions. Filtration reduced the titre by about 90% and was assumed to leave a predominantly monodisperse suspension; suspensions were too dilute to check this by electron microscopy.

Stage 2: Dilutions were made immediately of the filtrate from stage 1 and were inoculated on the CAM and incubated for 64 h at 35 °C. A piece of membrane bearing a single pock was excised from a membrane having no other visible pock lesion, extracted as described above, and the extract inoculated on the CAM to produce stock virus. It was considered that two sequential 'clonings' resulted in a population which could be reasonably considered as the progeny of a single virion. Note that a 'clone' need not have invariant properties but might itself become genetically heterogeneous during multiple cycles of replication. Stability of biological properties was not taken as a criterion for the purity of a clone, although such constancy was found in practice for most of the clones studied.

Phenotypic characterization

Four markers were used in these experiments, each of which differentiated variola or whitepox from monkeypox. (1) Pock type. Monkeypox virus produces small, pink, haemorrhagic (h^+) pocks on the CAM at 35 °C. Variola or 'whitepox' viruses give small, non-ulcerated white (h) lesions. The 'white pock' character was used for the primary selection of the variants, so that the class of monkeypox variants described here all produce white pocks on the CAM, but are not necessarily whitepox viruses as defined above. (2) Ceiling temperature. Monkeypox virus, but not variola virus, will produce pocks on the CAM of eggs incubated at 39 °C (ref. 7). In the experiments described here ceiling temperature was tested in the CV-1 line of monkey kidney cells which supported the growth of all relevant viruses at 35 °C, but at 40 °C monkeypox virus (t^+) would grow and variola virus (t) would not. Note that embryonated eggs, being exothermic, maintain a temperature above the recorded temperature of the incubator[8] and that ceiling temperatures determined in cell cultures may therefore seem to be up to 1 °C higher than those measured on the CAM. (3) Haemagglutinin. Most strains of variola do not produce detectable haemagglutinin (HA) for

0028-0836/80/270029-04$01.00

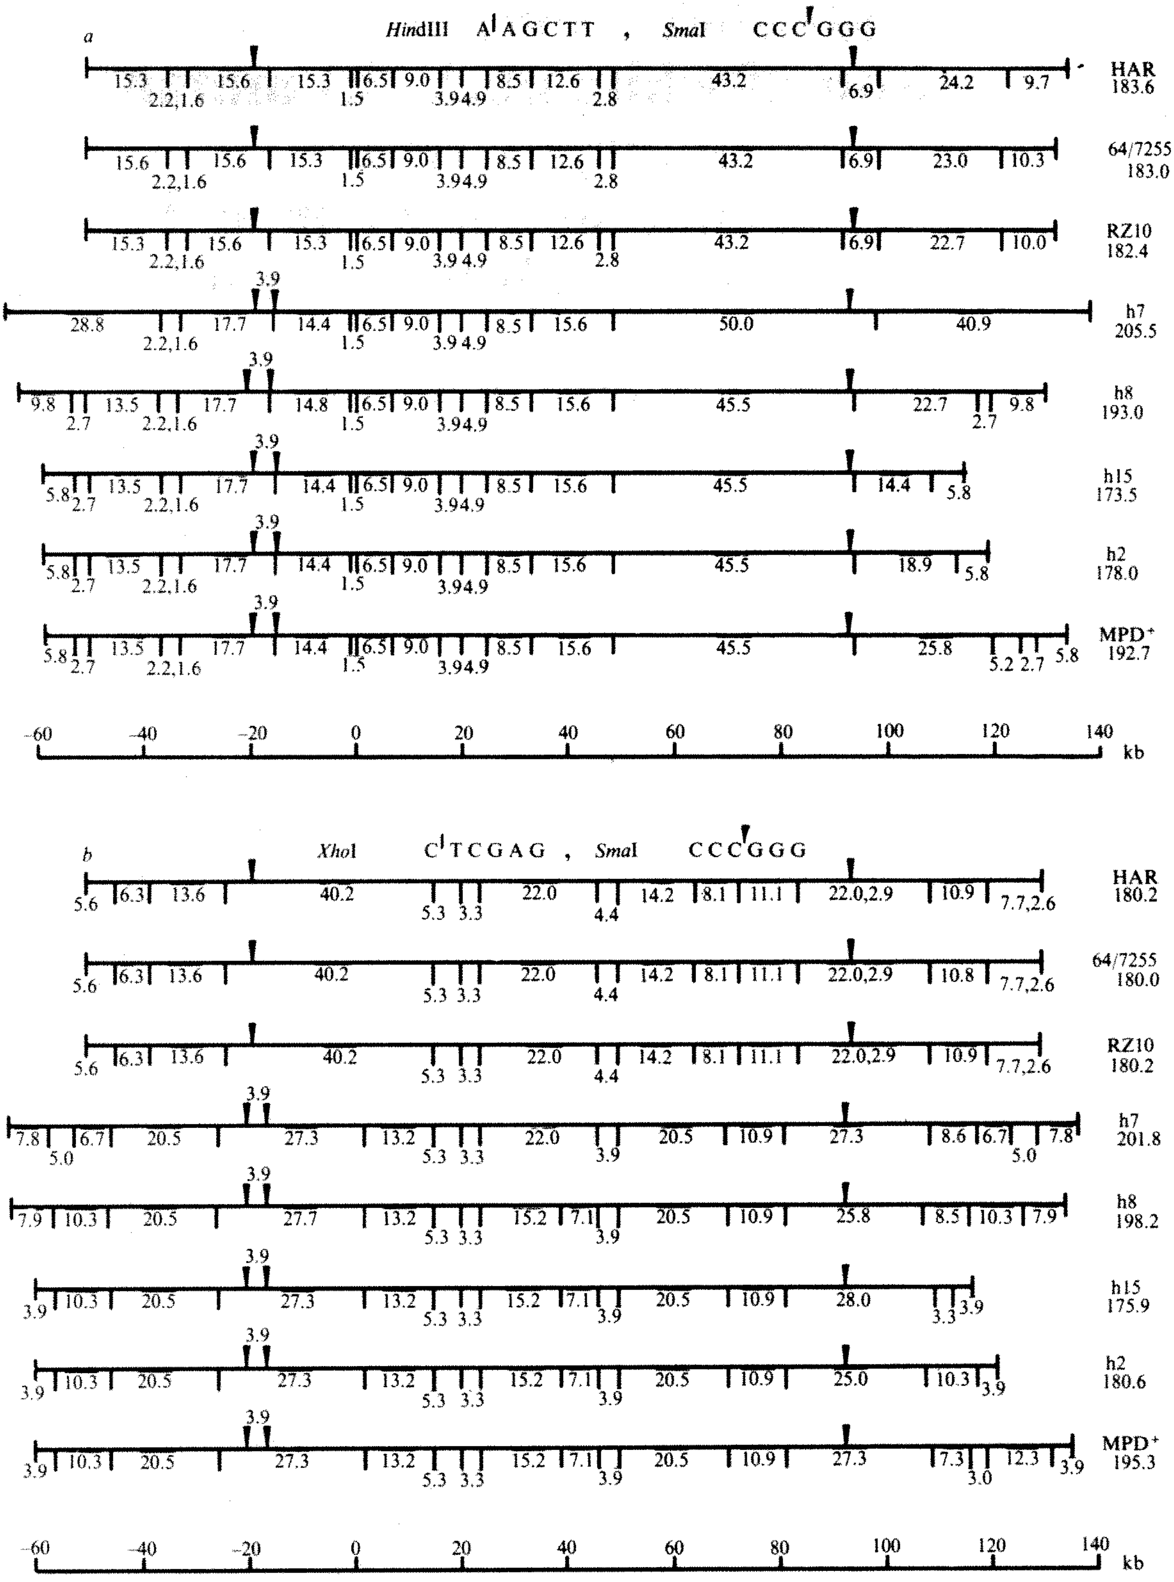

Fig. 1 Physical map locations of *Hin*dIII or *Sma*I restriction fragments (*a*) and *Xho*I or *Sma*I restriction fragments (*b*) of DNA from: variola Harvey (HAR), whitepox viruses 64/7255 and RZ10, monkeypox Copenhagen (MPD) and white pock mutants of MPD (h2, h7, h8, h15). Numbers indicate estimated sizes of individual fragments in kilobases (kb).

vaccinia-sensitive fowl erythrocytes when inoculated into RK13 cell cultures; monkeypox, on the other hand, makes large amounts of HA in RK13 cells[9] and some is produced by two of the whitepox viruses[10]. In our study, viruses were classed as HA producers in RK cells (rh$^+$) if 8 or more units were produced in standard HA titration[10]. (4) Growth in PEK cells. Marennikova *et al.*[11] reported that variola and whitepox viruses could be passed readily in a pig embryo kidney (PEK) cell line, but that monkeypox viruses were lost on passage. Ueda and K.R.D. (unpublished) confirmed that variola and vaccinia replicated to high titre in a line of pig kidney cells. Strains of monkeypox virus either did not replicate or reached only low titres in these cells and were classed as 'p'. Whitepox viruses all replicated in these cells to significant titre (p$^+$).

Isolation and phenotype of the h mutants

When the cloned wild-type monkeypox strain Copenhagen was inoculated on the CAM at approximately 50 pock forming units (PkFU) per membrane, less than 0.1% of the pocks were white. Two clones (h2, h15) were isolated.

The frequency of white pocks was significantly increased after passage of the wild stock on the CAM in high concentration. After four passes with an inoculum of $10^{6.0}$ PkFU, white pocks were present as 2–3% of the total and after six such passes, 50–60% of pocks were white. In a control series of eggs inoculated with 10^3 PkFU the frequency of white pocks remained at 0.2% after four and six passes. One clone (h3) was isolated after four passes at high concentration and seven (h4–h10) after the sixth such passage.

In subsequent experiments, two clones (h5 and h7) were re-passaged four times in high concentration and then recloned to give h5/1, h5/2, h7/1 and h7/3. Clone h7 was also recloned several times successively and stocks were made from the fifth and seventh reclonings (h7/c5, h7/c7). Another mutant (h16) was derived from a culture inoculated with parental monkeypox virus and incubated for 48 h in arginine-free medium, followed by a further 24 h in complete medium.

The phenotypes of all the h mutants are shown in Table 1. It will be seen that three clones (h2, h15, h6) are like the wild type except for the white pock character used in their selection. Five clones (h3, h4, h8, h9, h10) have one phenotypic change other than the white pock and two clones (h5, h7) resemble whitepox in three of the four markers used. Clones h5 and h7 did not change phenotype following passage in high concentration and recloning (clones h5/1, h5/2, h7/1, h7/3). None of the clones in this series had a lowered ceiling temperature, and this distinguishes them all from whitepox virus. However, a white pock mutant with a low ceiling temperature has been isolated from another strain of monkeypox and by using a different selection procedure. It is probable, therefore, that in an extended series, mutants would be found which were phenotypically like whitepox in all four characters used.

DNA analysis

Methods for virus growth and purification, extraction and cleavage of DNA and characterization of DNA restriction fragments were essentially as described previously[6,12].

Physical maps of cleavage sites were constructed mainly by hybridizations between restriction fragments generated from genomes of closely related viruses on the basis that, with the exception of terminal repetitions, fragments having sequence homology represent geographically equivalent regions of the genomes. Maps were also constructed by hybridizations between fragments cleaved from the same virus DNA by different restriction endonucleases. In some cases, physical maps of DNA from virus variants may be constructed from unequivocal interpretation of changes in the size of fragments generated by endonucleases *Hin*dIII, *Xho*I or *Sma*I and various double digests compared with those from wild-type DNA.

Comparative descriptions of the genomes of different orthopoxviruses and of changes between wild type and mutants are confusing when DNA fragments are labelled separately in order of size for each virus and for each restriction endonuclease. Additionally, it is impractical to measure from one end of the genome as most variation between and within orthopoxvirus types is found near the termini[6] and, even within a single strain of virus, variations are found in the length of the terminal fragments between one cloned line and another[13]. It was decided to select one arbitrary reference point in an internal region of the genome; we chose the site separating the contiguous *Hin*dIII fragments O and I in the original map of rabbitpox[5]. Fragments of similar size map in equivalent locations in all orthopoxvirus genomes for which *Hin*dIII maps have been constructed[6], and this region of the genomes is highly conserved. The reference point separates wild-type monkeypox *Hin*dIII fragments Q and I[6]. Locations of cleavage sites for particular endonucleases are defined as distances from the reference point measured in kilobases, with a positive sign if to the right and a negative sign if to the left. Sizes of genomes were derived by summation of restriction fragments sized by co-electrophoresis with digests of wild-type DNA. Physical maps were drawn to scale and the sizes of individual fragments indicated in kilobases (Fig. 1).

Physical maps of the cleavage sites for endonucleases *Hin*dIII, *Xho*I and *Sma*I in the genomes of two strains of variola and of three strains of wild-type monkeypox including Copenhagen (MPD) have been presented previously[6]. Physical maps for the same three endonucleases have been constructed from hybridization data and confirmed by double digestion for two of the whitepox viruses (64/7255 and RZ10) and are shown in Fig. 1. These are the first maps of whitepox viruses to be constructed, although electropherograms of endonuclease digests of whitepox DNA have been presented previously[14]. Viruses 64/7255 and RZ10 map very similarly to variola strain Harvey (HAR), preserving all characteristic internal cleavage sites but showing small variations in the size of the *Hin*dIII termini and of near-terminal *Hin*dIII or *Xho*I fragments mapping between 100 and 120 kilobases. The sizes of *Hin*dIII, *Xho*I or *Sma*I restriction fragments from the genomes of the other four whitepox viruses and of two whitepox-like viruses (Ham 8, Ham 9) isolated from hamsters[3] are similar to those presented here.

A general feature of orthopoxvirus genome structure is the presence of species-specific, terminal repetitions containing subsets of common sequences[6,15]. Because of this, the opposing terminal fragments from any particular genome cross-hybridize and either terminus will hybridize to both termini of the genome of another orthopoxvirus. A structural feature peculiar to variola and whitepox viruses is that the opposing termini fail to cross-hybridize. Additionally, the MPD/*Hin*dIII 2 molar terminal 5.8-kilobase fragment hybridizes specifically with only right-hand terminal fragments and the 2 molar MPD/*Hin*dIII 2.7-kilobase fragment with only left-hand terminal fragments of variola-like genomes. Such genome organization in relation to that of other orthopoxviruses may have resulted from non-symmetrical deletion of sequences within hypothetical repetitions or, from exchange of specific repetitive sequences between termini suggesting conjunction of the termini at some stage of replication.

Three sorts of genome have been obtained from the different white pock mutants of monkeypox (MPD). One (h16) has no change detectable by analysis with *Hin*dIII, *Xho*I or *Sma*I. White pock mutants of other monkeypox strains having a similar relationship to the respective parents have also been isolated. Second, the two spontaneous MPD white mutants (h2, h15) map with large deletions close to the right-hand terminus and another, not fully characterized, seems to be of the same class. The deleted sequences overlap partially and represent about 15 and 19 kilobases respectively. Variation at this locus is common in orthopoxvirus genome structure[6]. Third, white pock mutants isolated following high multiplicity passage (h3–h8, h10) show

Table 1 Phenotype of monkeypox virus and its 'h' mutants

Phenotype		Viruses
$h^+ t^+ rh^+ p$		Monkeypox, wild type
$t^+ rh^+ p$	h	h2, h6, h15
$t^+ rh^+$	$h \quad p^+$	h3, h4, h8, h9
$t^+ \quad p$	h rh	h10, h16
t^+	$h\ rh\ p^+$	h5, h7
t^+	$h\ rh\ p^+$	h5/1, h5/2, h7/1, h7/3, h7/c5, h7/c7
rh^+	$h\ t\ p^+$	64/7255, 64/7275 (whitepox viruses)
	$h\ t\ rh\ p^+$	Chimp 9, Mk7, RZ10, RZ38, (whitepox viruses)

Pocks: haemorrhagic, h^+; white, h. Growth in CV1 at 40 °C, t^+; no growth, t. Haemagglutinin in RK13 cells: titre ≥16, rh^+; <8, rh. Growth in PEK cells; good, p^+; none, p.

major and complex changes involving both termini of the genome symmetrically and smaller changes at some internal sites. Mutants h3–h7 and h10 are essentially similar and have genomes about 7–9 kilobases larger than that of the wild type. Assuming that symmetrical, near-terminal fragments generated by endonuclease *Xho*I result solely from cleavages within the terminal repetitive sequences, the repetition is then both larger than and divergent in sequence from that of the wild-type genome. A minimum estimate of the size of the parental repetition by summation of the symmetrical near-terminal fragments is 8.5 kilobases, whereas that for white mutants of this type is 19.5 kilobases and contains no sites for endonuclease *Hin*dIII. With the exception of h3, the genomes of these mutants have also lost a *Xho*I site in an internal, normally highly conserved region at the 38-kilobase position. A *Xho*I site at this locus, present in the genome of mutant h6 when isolated, was lost on subsequent recloning. Mutant h8 also shows extensive, symmetrical, near-terminal sequence rearrangements; the minimum size of the terminal repetition is 18 kilobases and the *Hin*dIII sites defining the MPD 2.7 kilobase fragment are retained. Mutant h8 is similar to h2 in some respects, showing a near-terminal deletion (3–4 kilobases) mapping to the right of the *Sma*I site located at 92 kilobases, and symmetrical, near-terminal sites for *Xho*I. Additionally, h8 has an apparent insertion, relative to the parental genome, of 0.4 kilobases mapping between −1.5 kilobases and the *Sma*I site at −15.5 kilobases. A similar small insertion is seen in the same region of the genome of mutant h5. Mutant h8 retains the internal *Xho*I site at the 38-kilobase position. The locations of *Sma*I sites, relative to those in wild-type DNA, are preserved in all the monkeypox mutants described.

The rearranged genome exemplified by mutant h7 is apparently a stable configuration as neither four further high multiplicity passages followed by recloning nor nine successive reclonings generated further changes detectable by restriction analysis with *Hin*dIII, *Xho*I or *Sma*I.

Although the genotypes of the spontaneous mutants h2 and h15 are readily recognizable as variants of wild-type monkeypox, the changes exhibited by, for example, mutants h7 and h8, seem to be as extensive as those distinguishing some orthopoxvirus species[6]. However, the genomes of these mutants remain readily distinguishable from those of variola and whitepox viruses.

Discussion

Monkeypox mutants. The objective of the present study was to characterize mutants of monkeypox virus, both phenotypically and by DNA analysis, and to assess how closely they might mimic whitepox or variola. The mutants were derived in different experimental conditions but each was selected initially from a white pock produced on the CAM.

Spontaneous white-pock mutants are relatively rare in monkeypox. The two which were obtained each had a genome substantially shorter than that of MPD due to deletion of DNA sequences near the right-hand terminus, together with some rearrangement of terminal sequences. The mutants obtained after high-multiplicity passage had more complex, symmetrical rearrangements of terminal sequences and the genomes were as big as or bigger than that of MPD. Smaller deletions of sequences were detected in some of them in approximately the same locus as the large deletions in the genomes of the spontaneous mutants. Although the numbers are small, it seems that particular experimental conditions affect the kind of mutant most likely to be selected. It is suggested that the spontaneous mutants may represent an early, and the high-multiplicity mutants a late stage in a process which can engender complex changes in genome structure during replication. This hypothesis is now being tested. Several phenotypically different mutants had genomes with maps similar to those shown for mutant h7. The genome of h7 seems to represent a stable configuration. The maps of h7 showed no detectable changes after further passages at high multiplicity and several reclonings. The symmetrical nature of the changes which occur at the two ends of the genome strongly suggest that the near-terminal configurations had been determined in the same process or that sequences from one end had been copied to the other. On either basis, the evidence supports the previously proposed[16,17] idea of transient circularization at some stage in the replication of orthopoxvirus DNA.

The mutants exhibited a variety of phenotypic changes but it was not expected that these could be correlated with the changes in the relatively crude restriction maps; indeed, one mutant (h16), with no changes detectable in the maps, had two changes in the phenotypic markers.

Whitepox and monkeypox. No phenotypic character has yet been described which distinguishes the group of whitepox viruses from variola. Consistent with this, the maps of the genomes of the whitepox viruses are closely similar to those of variola HAR, and they share with variola the failure of one terminus to cross-hybridize with the opposing terminal fragment. Although the present maps are too crude to prove identity, they add to the steadily growing evidence of the close relationship of whitepox to variola.

On the other hand, there are significant differences between the genomes of whitepox and monkeypox. Apart from the differences in near-terminal sequences, there are four cleavage-site differences within the conserved region of the genome. The *Sma*I site at −15 kilobases and the *Xho*I sites at 3 and 38 kilobases are present in monkeypox but not in variola or whitepox, whereas a *Hin*dIII site at 45 kilobases is present in variola and whitepox but not in monkeypox. Of these four sites, the only one found to be changed in some of the h mutants is the *Xho*I site at 38 kilobases. Even the two mutants (h5 and h7) which resemble whitepox in three of the four phenotypic markers have genomes which differ significantly from that of variola. On the other hand, there is evidence that different experimental conditions select for different kinds of complex mutations and some caution is necessary in forecasting what limits could be set to the possible variations in the monkeypox genome.

Our experiments have failed to generate any monkeypox mutants with genomes similar to those of the whitepox-like viruses described by Marennikova and Sheluchina[3]; however, the methods used in the generation of our mutants differ from those described by these authors.

A crucial question is whether variola virus possesses any DNA sequences unique to itself and which are missing from monkeypox (and even perhaps from whitepox), as rearrangements, however complex, could not be expected to create significant new information. This question cannot yet be answered, but several ways of approaching it are theoretically possible and one main reason for any continuing work with variola would be to obtain the answer.

We thank Drs R. Gispen, S. S. Marennikova and P. von Magnus for providing strains of whitepox viruses and monkeypox Copenhagen, and Mrs Ruth Reith for assistance. The work was supported by grants from the MRC and the WHO.

Structure of southern bean mosaic virus at 2.8 Å resolution

Celerino Abad-Zapatero, Sherin S. Abdel-Meguid, John E. Johnson, Andrew G. W. Leslie*, Ivan Rayment†, Michael G. Rossmann, Dietrich Suck‡ & Tomitake Tsukihara§

Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907

X-ray diffraction studies reveal that the polypeptide chain of the southern bean mosaic virus protein subunit has a fold closely similar to the shell domain of tomato bushy stunt virus. The protruding domain of tomato bushy stunt virus is absent in southern bean mosaic virus. The tertiary structure observed in these viruses may be particularly suitable for the formation of the protein coat in small, spherical, RNA-containing, plant viruses.

SIMPLE plant viruses are composed of nucleic acid and a protein coat consisting of multiple copies of covalently identical subunits arranged in a symmetrical manner[1,2]. These viruses can be broadly categorized as rod-shaped, bacillus-shaped and spherical. The morphological classes can be subdivided into groups based on physical and biological properties such as stability, symmetry and strategy of replication[3,4]. High resolution X-ray structure determinations have been accomplished for the rod-shaped tobacco mosaic virus[5] (TMV) and its disk protein[6] as well as the spherical tomato bushy stunt virus[7] (TBSV). The contrasting structures of the proteins in these two viruses reveal differing requirements for assembly into a helical rod and icosahedral shell. Although TMV protein subunits consist primarily of four, roughly radial, α-helices, the two domains of TBSV are composed almost entirely of anti-parallel β-pleated sheet. A possible common feature in the two virus classes is the flexibility of the protein which interacts with the RNA. Although TMV is the only rod-shaped virus being studied at high resolution, several spherical plant viruses, representing different groups, are being investigated (ref. 8, and P. Argos and P. Colman, personal communications). We report here the structure determination of southern bean mosaic virus (SBMV) seen at 2.8 Å resolution. Although SBMV represents a group of viruses[9] with properties significantly different from those of the TBSV group, its viral envelope was found to possess a tertiary and quaternary structure closely similar to that of the TBSV shell (S) domains. It is proposed here and also by Argos[10] that other groups of small, spherical, RNA-containing, plant viruses may also be based on the same folding and assembly principles.

Structure determination

The high resolution structure of SBMV was determined using the rhombohedral type II SBMV crystals[11] with hexagonal axes of $a = 334.3$, $c = 757.5$ Å and a single particle in the unit cell. The R32 space group requires the particle to be situated on a site with 32 crystallographic symmetry, thus placing 10 icosahedral units within the crystallographic asymmetric unit (Fig. 1*a*).

Data for the native crystals and four heavy atom derivatives were collected using oscillation photography[12-15]. The X-ray source was an Elliott rotating anode generator, equipped with a 0.1-mm focal cup and a copper target. The Ni-filtered radiation was focused with two perpendicular mirrors[16]. Some details of the data collection are shown in Table 1*a*. In total, 2,022,187 useful intensities were measured which permitted the determination of phases for 275,966 independent reflections with the multiple isomorphous replacement method. This represented 71% of all possible reflections within the limiting 2.8-Å resolution sphere.

The analysis of the first heavy atom derivative was given previously[17] as were the results of a 5-Å resolution electron density map[18]. The heavy atom positions of four derivatives were found with difference electron density maps and refined by a least-squares procedure[19]. The final atomic parameters will be given elsewhere[20], but some statistics for the multiple isomorphous replacement phase determination are shown in Table 1*b*.

The final 'best' multiple isomorphous replacement (MIR) electron density map was averaged over the 10 different icosahedral units within one crystallographic asymmetric unit[21]. This map was originally used to solve the SBMV coat protein structure. One cycle of phase refinement using the molecular replacement method[22-24] has been completed which provided some improvement in the apparent resolution. For convenience and in accordance with general practice these maps will be referred to as having 2.8 Å resolution, even though the phasing and quality of data are less at high resolution than at low resolution. A more full account of the crystallographic work is reported elsewhere[20].

The averaged MIR electron density map was displayed in sections perpendicular to an icosahedral 2-fold axis. The quasi-3-fold axis relating the three subunits within the icosahedral unit was immediately obvious (Fig. 1*b*). The effect was particularly striking because this axis was nearly parallel to its neighbouring icosahedral 2-fold axis and, hence, perpendicular to the map sections. A similar situation pertains to TBSV[25]. The dominant feature in the SBMV map was a 'β-barrel' type structure (see ref. 26) in which the extended strands were well resolved from each other. A substantial portion of the polypeptide chain could be traced but some ambiguities remained in the connectivity of the strands at the end of the β-sheets. Five helices could be recognized and these determined the direction of the polypeptide. Certain features, in particular the amino-terminal arm, present in only the C subunit (Fig. 1*c*), were then seen to be similar to the TBSV structure. Superposition of the TBSV C_α co-ordinates onto the SBMV electron density map revealed a remarkable resemblance of the TBSV shell domain and the SBMV subunit. The TBSV co-ordinates had been referred to an icosahedral axial system and were used without change in radius on the SBMV map. This permitted an interpretation of all turns and bends on the original MIR map which was subsequently readily verified on the molecular replacement map. These results demonstrated the similarity not only of fold but also of the

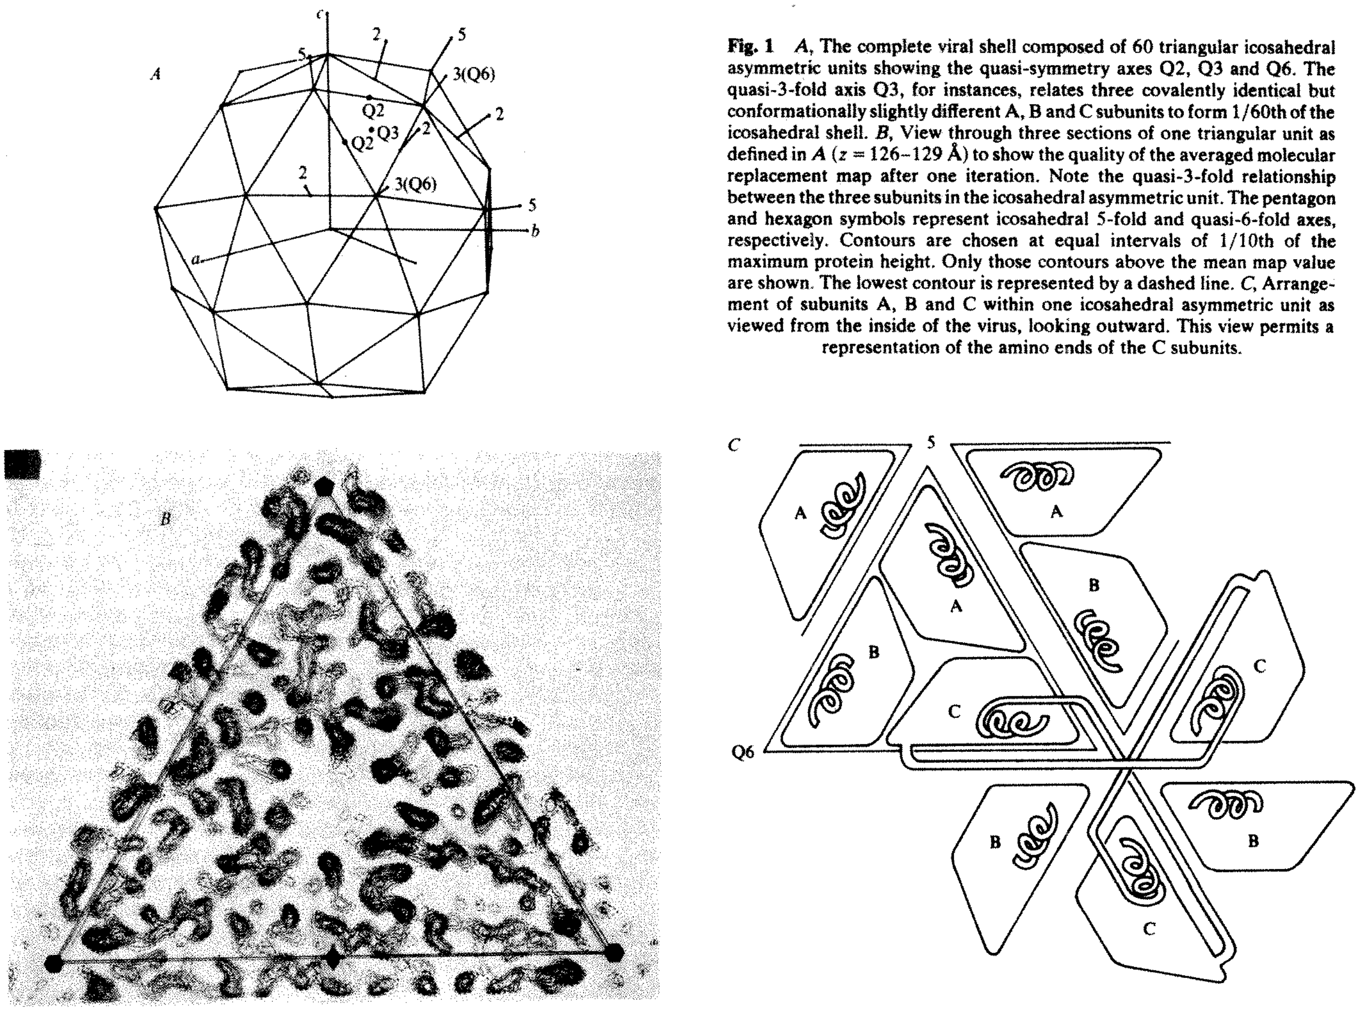

Fig. 1 *A*, The complete viral shell composed of 60 triangular icosahedral asymmetric units showing the quasi-symmetry axes Q2, Q3 and Q6. The quasi-3-fold axis Q3, for instances, relates three covalently identical but conformationally slightly different A, B and C subunits to form 1/60th of the icosahedral shell. *B*, View through three sections of one triangular unit as defined in *A* ($z = 126$–129 Å) to show the quality of the averaged molecular replacement map after one iteration. Note the quasi-3-fold relationship between the three subunits in the icosahedral asymmetric unit. The pentagon and hexagon symbols represent icosahedral 5-fold and quasi-6-fold axes, respectively. Contours are chosen at equal intervals of 1/10th of the maximum protein height. Only those contours above the mean map value are shown. The lowest contour is represented by a dashed line. *C*, Arrangement of subunits A, B and C within one icosahedral asymmetric unit as viewed from the inside of the virus, looking outward. This view permits a representation of the amino ends of the C subunits.

PHMBS, *p*-hydroxymercuribenzoate sulphonate. $<m>$ is the mean figure of merit. n is the number of phased reflections in shell.

$$*R = \frac{\sum_h \sum_i |(F_{hi}^2 - \bar{F}_h^2)|}{\sum_h \sum_i \bar{F}_h^2} \times 100$$

where $\bar{F}_h^2$ is the mean of the i observations F_{hi}^2 on the reflection h.

$$\dagger R = \frac{\sum |[|F_{HV}| - |(F_V + f_H)|]|}{\sum |f_H|} \times 100$$

where F_{HV}, F_V, and f_H are the structure factors for the heavy atom derivative, the native virus crystals and the heavy atoms alone, respectively.

packing of protein subunits in the viral shells. Backbone models of the C subunits (see Fig. 1*b*) were built into a Richards optical comparator[27] with Kendrew-Watson model parts on a scale of 2 cm ≡ 1 Å. The co-ordinates of the SBMV backbone atoms were measured with a plumb line and checked for gross error. These have been deposited with the Protein Data Bank at Brookhaven National Laboratory[28].

The chain tracings of the C subunit, together with the corresponding structures of the quasi-3-fold-related A and B subunits, accounted for all the major features in the map. The internal boundary of the protein shell was well defined. Features of the electron density in the interior of the virus were lower and disconnected in the averaged maps, permitting no explicit recognition of nucleotides.

The 2.8-Å resolution map did not differ in substance from the earlier 5.0-Å map[18]; indeed, the electron density distributions were remarkably similar. The selection of the subunit boundaries had been essentially correct in the low resolution map. The feature referred to as a 'small lobe of the subunit' was now seen to be the extra protruding helix near the quasi-3-fold axis in SBMV (*vide infra*). The 'large helix-containing lobe' did not, in fact, contain helix but was related to the very obvious protrusions near the 5- and quasi-6-fold axes. The sheet near the 2-fold axes corresponded to one side of the β-barrel. The '26 distinct phosphate sites' seen at 5 Å resolution must now be regarded with some scepticism. Although these features within the RNA region remain in position, they are lower in density relative to the protein in the averaged isomorphous replacement map.

The protein shell and viral exterior

The SBMV subunit is primarily an eight-stranded anti-parallel β-barrel (Fig. 2). However, at least 66 residues at the amino end are not a part of the barrel, but form a partially ordered 'arm' in the interior of the virus. The protein shell of SBMV is about 35 Å thick, extending from around 110 Å to 145 Å radius. Each quasi-3-fold axis is 27 Å distant and parallel to its nearest icosahedral 2-fold axis. A careful analysis of the conformational differences between the three quasi-symmetrically related subunits A, B and C has not been completed. An initial examination of the electron density and position of equivalent heavy atoms[20] shows that the A subunits differ significantly from the B and C subunits at turns close to the 5-fold axes, where SBMV has insertions relative to TBSV. Other regions show less deviation, as was also the case in TBSV[7], where differences were less than 1 Å.

Figure 3 shows a superposition of the C_α coordinates for the S domain of TBSV and the SBMV subunits. Both structures are referred to the same icosahedral axial system. The r.m.s. difference in C_α coordinates is 2.7 Å over 182 residues, excluding those residues which are insertions or deletions in one or the other subunits. The extent of topological equivalence is almost as good as that between the α and β chains of horse haemoglobin and is certainly much better than that between the NAD-binding domains of lactate dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase (Table 2).

Harrison (personal communication) has assigned a tentative amino acid numbering system to the TBSV C subunit which is shown in Figs 2 and 3, and shall also be used in SBMV. Some residues may have to be inserted or deleted pending the full amino acid sequence determination of TBSV and SBMV. The ordered amino-terminal arm of the TBSV C subunit runs from 1 to 32 followed by the S domain from 33 to 200. The TBSV P domain consists of the final 111 residues within the polypeptide chain. Major differences between the SBMV subunit and the TBSV S domain are (1) an extra α-helix (see following section), a feature which is ordered in all three quasi-equivalent subunits, (2) the organization of the β-annulus structure about the icosahedral 3-fold axes, (3) insertions of residues 49A and 177A, 177B, 177C, 177D near the quasi-6-fold and icosahedral 5-fold axes, (4) insertion of 17 residues between 155 and 160, replacing residues 156–159 near the quasi-3-fold axis, (5) deletion of residues 55–61 opposite the TBSV P domain on the viral exterior and replacement by residue 55A, (6) deletion of residue 104 at a subunit interface, (7) deletion of residue 114 and insertion of residue 118A at a different subunit interface near the viral surface, and (8) deletion of residue 130 and insertion of some residues at the protein–RNA interface.

The most dramatic alterations between TBSV and SBMV occur on the viral surface. The larger protruding P domains about the 2-fold axes in TBSV are replaced by the abbreviated protrusions around the quasi-3-fold axes in SBMV (Fig. 4*a*). The SBMV protrusions are formed by the insertion of a three-turn helix (155A to 155M) running tangential to the viral surface and a one-turn addition (155N–155Q) to the radial helix 160–164. The latter makes a 60° left-handed turn over a distance of 12 Å about the quasi-3-fold axis, thus forming a keratin-like structure[29] when taken in conjunction with its two neighbouring subunits. There is also a protrusion around the icosahedral 5-fold (Fig. 4*b*) and quasi-6-fold (Fig. 4*c*) axes in SBMV which is absent in TBSV. Both the trimer (Fig. 4*a*) and the pentamer (Fig. 4*b*) -hexamer (Fig. 4*c*) clustering in SBMV had been observed previously in a 22.5-Å resolution map[30]. The third major difference is the deletion of TBSV residues 55–61. These residues make an excursion, towards the TBSV P domain, out of the β-strand that runs between residues 52–62. They stabilize the orientation of the P domain in the C subunit, where the hinge between the domains is bent more acutely than in the A and B subunits. This function is not required in SBMV. The evolution of surface differences between TBSV and SBMV might be a recognition mechanism for altering host specificity by adapting to the properties of host or vector.

Both TBSV and SBMV require metal ions for assembly and stabilization of their protein shell. The function of calcium and magnesium ions has been extensively studied with respect to the properties of SBMV[31–34]. In the absence of metal ions and at alkaline *p*H these viruses swell by about 7% in radius. Wells and Sisler[35] have shown that swollen SBMV has only 2% of the infectivity of native SBMV. This could be due to the loss of integrity of the viral surface features or it might be the consequence of the ease with which the swollen virus can be degraded by nucleases and proteases. The positions of the metal ions in TBSV have been determined by Harrison *et al.* (ref. 7 and personal communication). There are significant conformational differences (Fig. 3) between TBSV and SBMV in the region (residues 113–120) of this site.

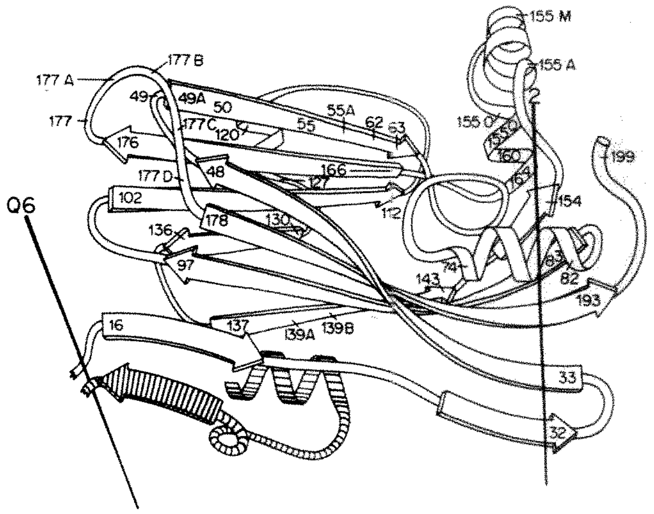

Fig. 2 Diagrammatic representation of the SBMV C subunit with its amino-terminal arm and α-helix. The latter is bound to the base of a subunit, possibly related by a 3-fold rotation. The very tentative amino acid numbering scheme is shown. Numbers such as 177A, 177B are insertions in SBMV relative to TBSV. Drawing by Jane Richardson.

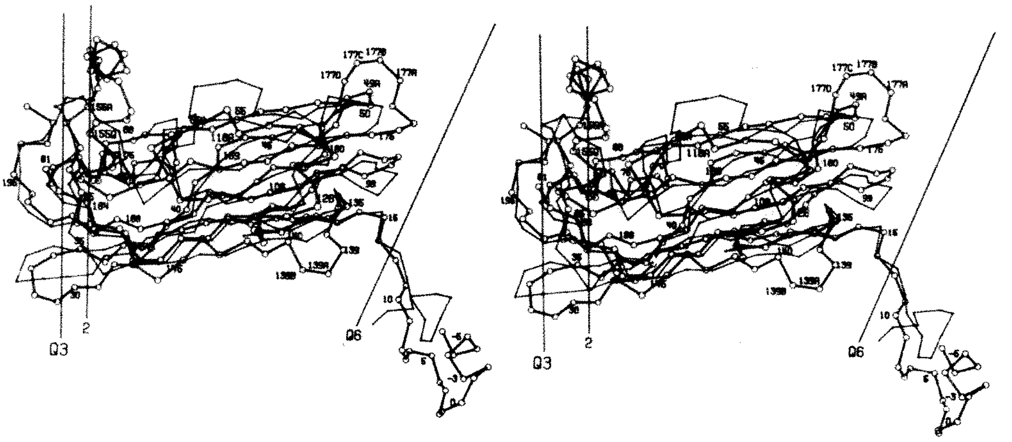

Fig. 3 Stereo diagram showing the C_α atoms in SBMV (large circles connected with thick bonds) superimposed on the TBSV shell domain (thin bonds). Both viruses are referred to the same icosahedral axial system. The amino acid numbering of SBMV is shown. It relates to a tentative system for TBSV.

The amino acid composition of SBMV has been determined by Tremaine[36], Ghabrial *et al.*[37] and Dietrich[38]. Dietrich has also partially determined the amino acid sequence of 15 tryptic and 2 cyanogen bromide fragments. Attempts to find the position of these peptides (the largest being 16 residues long) in the electron density map were only partially and tentatively successful.

The RNA–protein interface

The structure of SBMV as well as TBSV has the interesting feature of an 'amino-terminal arm' which is ordered only in the C subunits. It is positioned between quasi-6-fold-related C and B subunits and runs from a quasi-6-fold to an icosahedral 2-fold axis. Harrison *et al.*[7] point out that the space for this arm can only exist in the vicinity of an icosahedral 2-fold axis (the quasi-3-fold axes are parallel to the icosahedral 2-fold axes but make an acute angle with the quasi-2-fold axes). The differences of the arm structure are required to accommodate the quasi-symmetry of the $T = 3$ surface arrangement. The disordered arm in the A and B subunits must thus be closely associated with the RNA but in variable positions relative to the icosahedral coat. Chauvin *et al.*[39] have shown with neutron scattering of suitably matched solutions of TBSV with D_2O that the significant portion of this protein–RNA interaction is at a radius of less than 80 Å.

In the SBMV protein there is a structural feature situated between the base of the β-barrel and the RNA interior, consisting of an α-helix and extended polypeptide chain, that was not visible in the TBSV structure. This helix, interacting with the C subunit barrel, represents either the amino end of a neighbouring, 3-fold-related, C subunit (Fig. 2) or an insertion within the C subunit at position 139. The β-annulus structure around the quasi-6-fold axis in SBMV is a '2-way overlap', not a '3-way overlap' as in TBSV (Fig. 5*a*). The extra 'amino-terminal' helix and extended strand are clearly visible in the A, B and C subunits, but the β-annulus and amino-terminal arm (residues 8–32) are visible only in the C subunit (Fig. 5*b*). It is therefore possible that the extra 'amino-terminal' helix in subunits A (forming the pentamer cluster) or in the B subunits (forming the hexamer cluster with the C subunits) are associated with their own β-barrel rather than a neighbouring subunit.

Table 2 Quality of structural similarity between various proteins or protein domains

Comparison Molecule 1	Molecule 2	Equivalenced residues No.	r.m.s. distance (Å)	% of equivalenced residues Mol. 1	Mol. 2
TBSV(S)	SBMV	182	2.7	91.0	82.7
Hb(α)	Hb(β)	139	1.6	98.5	95.3
NAD domain LDH	NAD domain GAPDH	83	2.9	57.5	56.1
TBSV(S)	TBSV(P)	69	3.8	41.3	62.8

Abbreviations: LDH, lactate dehydrogenase; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; Hb, haemoglobin. Equivalencing of residues is restricted to those in the same topological sequence[52].

There are a total of 220 ordered residues in the SBMV C subunit. An error of only a few residues might be expected in view of the close similarity in the placement of amino acids in homologous regions of SBMV and TBSV. The total number of residues in SBMV has been estimated to be between 260 and 270 (refs 36–38). Thus, the ordered SBMV C subunit lacks between 40 and 50 residues. A similar estimate by Harrison *et al.*[7] showed that there were probably around 50 disordered residues in the C subunit of TBSV, even without observing the extra 'amino-terminal' α-helix. The amino terminus of the extra α-helix in SBMV is buried by the β-annulus, leaving no room for any extension. It is therefore more likely that the missing polypeptide is inserted around residue 8, which has weak density and is accessible to the viral interior (Fig. 5*b*). Support for the occurrence and position of ordered and disordered protein segments comes from an analysis of heavy atom positions[20].

Sehgal has shown that swollen SBMV virions, produced by removal of calcium and magnesium, are susceptible to trypsin digestion[40], and Tremaine[41] has shown that the cleaved portion is strongly basic and consists of about 63 residues. The treated virus reassembles into particles of diameter 150–180 Å. Similar observations have been made for brome mosaic virus (BMV; ref. 42 and B. Verduin, personal communication), TBSV and turnip crinkle virus[43,44] and alfalfa mosaic virus[45] (AMV), with the cleaved fragment always being at the amino terminus. A β-annulus structure, near the amino terminus, and the insertion of the amino-terminal arm between subunits may thus be essential requirements for the formation of a hexamer cluster and hence in the construction of spherical viral coats with $T > 1$. If the amino-terminal segment is cleaved (including the β-annulus), only pentamer clusters can form, producing capsids similar to the satellite tobacco necrosis virus (STNV) with a diameter of around 190 Å.

The amino-terminal region of many spherical and bacillus-shaped plant virus coat proteins is often strongly basic (for example, SBMV, cowpea chlorotic mottle virus, BMV, AMV and STNV) and predicts as an α-helix where the amino acid sequence is known (see Argos[10]). In SBMV there are residues which form an α-helix binding to the base of the β-barrel at the protein–RNA interface. Thus, the side of the helix exposed to the RNA is likely to be basic and the other side hydrophobic. Indeed, the SBMV electron density shows that residue −3 (Fig. 3) is almost certainly arginine. These properties will make the amino-terminal region particularly susceptible to trypsin digestion once it has been sufficiently exposed[40].

There are on the average around 8 basic residues per subunit, where the amino-terminal arm sequence is known, providing a total of 1,440 positive charges within the RNA of the complete virus. As there are about 5,000 bases in the nucleic acid of SBMV, it follows that the amino termini together must contribute significantly towards the cancellation of charge within the virus and hence presumably are largely responsible for the RNA

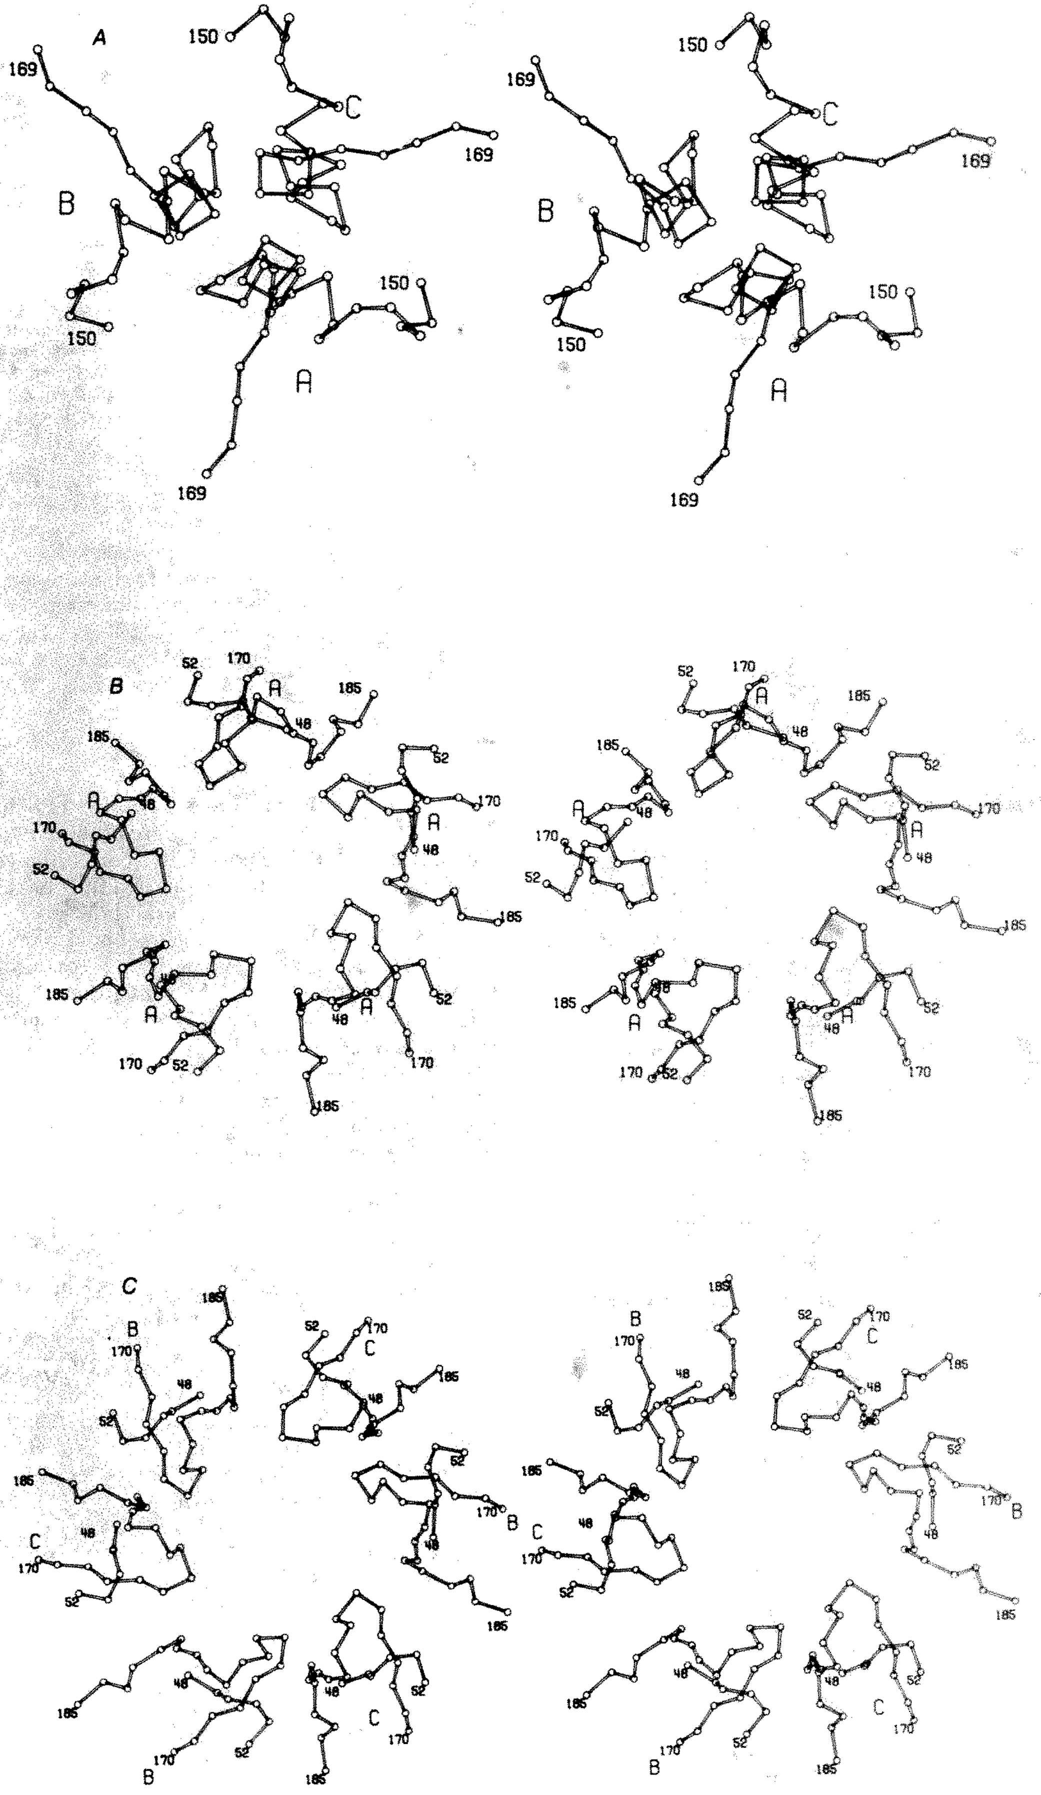

Fig. 4 Views of the viral exterior surface. *A*, Stereo diagram showing the protrusion around a quasi-3-fold axis produced by subunits A, B and C. The tangential α-helix occurs only in SBMV. The radial helix forms a keratin-like structure about the quasi-3-fold axis. *B*, Stereo diagram showing protrusion around an icosahedral 5-fold axis produced by adjacent A subunits. *C*, Stereo diagram showing protrusion around a quasi-6-fold axis produced by three C subunits separated by three B subunits.

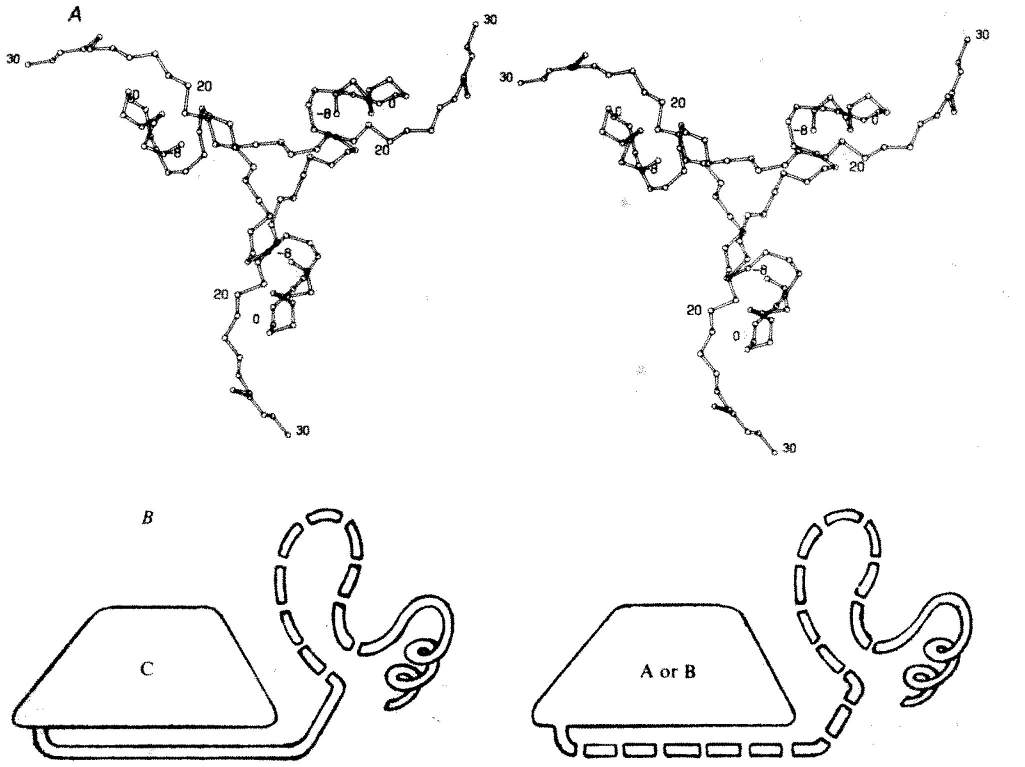

Fig. 5 *A*, Possible arrangement between C subunits in the vicinity of an icosahedral 3-fold axis which together form a 'β-annulus' structure. An alternative interpretation of the electron density places the amino-terminal helix as an insertion at position 139. *B*, Ordered and disordered (dashed) polypeptide in the A, B and C subunits of SBMV.

folding during viral assembly. The apparent tendency of α-helical formation with hydrophobic sides[10] suggests that the RNA backbones will have closely associated α-helical protein which form hydrophobic 'bundles'. These in turn can pack more easily within the virus by exclusion of water. A similar situation is encountered in the formation of α-helices when protamines associate with tRNA and also probably with DNA[46].

Histones H2A, H2B, H3 and H4, like viral coat proteins, also have basic amino-terminal ends which are not part of the ordered nucleosome structure. The H3 and H4 histones apparently undergo an ordering phenomenon by binding to the linker DNA[47–49]. The ordering of protein incurred by the binding of RNA to TMV, or the requirement of the random amino-terminal segments to assemble spherical viral RNA, is analogous.

The structure of other small, spherical, RNA-containing plant viruses

The most surprising aspect in the present report is the observation that, in spite of the obvious differences in physical characteristics, the structure of SBMV is closely related to that of TBSV. Argos[10] has shown that the amino acid sequence of some other viruses is consistent with a similar coat protein structure. Complementary arguments based on packing the SBMV shell protein are given here for the small $T=1$ STNV particle. Indeed, it has already been observed that trypsin-treated SBMV[40,41], turnip crinkle virus[43,44], AMV[45] and BMV[42] can form particles similar in diameter to STNV[50].

The overall dimensions of the SBMV subunit are given by a 35-Å thickness, a 27-Å separation between the quasi-3-fold and icosahedral 2-fold axes and a separation varying from 42 to 55 Å between the icosahedral 2-fold and quasi-6-fold axes. Similar measurements pertain to the thickness of the protein coat, the separation of the icosahedral 2-fold and 3-fold axes and the separation of the icosahedral 2-fold and 5-fold axes of the $T=1$ STNV particle, respectively[50]. Computer experiments in which pentamer clusters of SBMV A subunits are placed into a $T=1$ icosahedral lattice confirmed that the subunits pack without overlap when the external radius is 88 Å along the 3-fold axes. Furthermore, the general direction of the strands within the β-sheet of STNV runs between the 5-fold and 3-fold axes[50], consistent with the respective strand direction in SBMV.

The close similarity between SBMV and the S domain of TBSV strongly supports divergence of these two viruses from a common ancestor. The possibility of an earlier gene duplication from which the P and S domains of TBSV have evolved is also possible in light of their structural similarity[51]. The possibility that not only the coat protein genes but also much of the rest of the SBMV and TBSV genome have a common ancestry must therefore be considered. The similarities shown here and by Argos[10] between various groups of small spherical RNA viruses suggest that the β-barrel found in the SBMV subunit and TBSV S domain has been selected to comply with the functional needs of such viruses. The results of the structural studies of STNV[50], cowpea mosaic virus[8] and belladonna mottle virus (P. Argos, personal communication) will, therefore, be awaited with much interest.

This work has been possible only through the dedication of many people over a period of nine years. In particular we thank Mrs Mary Ann Wagner, Dr Ira Smiley, Dr Toshio Akimoto, Mr Joel White, Miss Karen Babos and Mrs Kumiko Tsukihara, also Dr Patrick Argos for stimulating discussions, Jane Richardson for producing the diagrammatic representation of SBMV, Dr Steve Harrison for supplying the TBSV C_α co-ordinates, Dr Saul Rosen, Mr John Steele and Dr Victor Abell for support in computations, Drs Richard Lister and Andrew Jackson for advice on the growth of SBMV, Mr Eric Henss, the late Mr Philip Hamilton and Sharon Wilder for technical assistance. The work was supported by NIH grant AI 11219, NSF grant PCM78-16584 and a grant from the Lilly Company. D.S. was supported by a Deutsche Forschungsgemeinschaft Postdoctoral Fellowship and S.S.A., J.E.J. and I.R. by NIH postdoctoral fellowships 1 F32 GM 07103, 6 F22 CA 00557 and 1 F32 AI 05600, respectively, during part of this work.

Cosmic X-ray background and intergalactic gas accretion onto intergalactic collapsed objects

E. P. T. Liang

Institute of Theoretical Physics and Department of Applied Physics, Stanford University, Stanford, California 94305

The origin of the diffuse cosmic X-ray background (CXB) has become the subject of much speculation recently, with most theorists divided between the intergalactic hot gas bremstralung hypothesis and the QSO contribution theory. Stimulated by Sargent's recent argument about the existence of a cool, low density intergalactic gas, we investigate here the third possibility of its accretion onto intergalactic collapsed objects as the sources of the X-ray background. We conclude that if the CXB is hot thermal bremstralung (TB) from the accretion of Sargent type intergalactic gas onto intergalactic collapsed objects, a new class of faint ($L_x \lesssim 10^{41}$ erg s^{-1}) low mass ($M \sim 10^7$–$10^{10} M_\odot$) discrete X-ray sources must exist with no optical or IR images, some of which could be detected by the Einstein observatory.

HEAO 1 observations have established that the cosmic X-ray background spectrum (3–50 keV) is most naturally fit by TB with $kT = 45 \pm 5$ keV (ref. 1). Yet the hypothesis that it may be emission from a hot intergalactic gas (IGG) of Ω_0 (present mean density/closure density) $\sim 0.5(\langle\rho\rangle/\langle\rho^2\rangle^{1/2})$ faces severe difficulties, including the huge energy requirement, the destruction of H I clouds believed to be causing the quasar absorption lines, the Compton distortion of the microwave spectrum, and so on[2]. On the other hand, source counts by the Einstein observatory indicate that faint sources down to ~0.002 UFU (Uhuru flux unit) already make up 30–40% (at least in the 1–3 keV band) of the CXB. If the present number-flux relation $N(>S) = KS^{n(=1.5-1.8)}$ holds to much fainter S, then known discrete sources may easily account for all (or even exceed) the CXB intensity[3], consistent with the conjecture that contribution from known optical QSOs brighter than $B \simeq 20.3$ mag could account for essentially all of the CXB if L_x/L_{optical} remains large down to such magnitudes[4,5]. Reasonable as such estimates seem, they remain unverified extrapolations at present, not to mention the highly uncertain nature of QSO X-ray spectra. Hence it is still interesting to investigate alternative sources for at least a significant fraction of the CXB.

Recently, Sargent *et al.*[6] have proposed that the survival of the intergalactic H I absorption clouds favours the existence of an IGG with $\Omega \sim 0.1$ and $T \sim 10^5$ K at $Z \sim 2.5$, too cool to produce the CXB. However, its existence raises the question of whether the CXB might be produced by accretion onto an intergalactic population of collapsed objects whose existence could not be detected otherwise. Such a hypothesis has some merits as (1) accretion onto compact objects is the most efficient mechanism known in X-ray production; (2) the low IGG density makes high temperature TB favourable and leads to low X-ray luminosity objects difficult to resolve. Here we investigate the constraints on such a model. The dominant contribution comes from the present epoch ($Z < 3$). Our work, therefore, complements that of Carr[7] on pregalactic black holes ($Z > 10$).

A collapsed compact object of mass M moving with Mach number $\mathcal{M}$ in a fully ionized IGG of density ρ and temperature $T_4 10^4$ K (sound speed $c_s \sim 10^6\, T_4^{1/2}$) will accrete at the Bondi rate[8]

$$\dot{M} \simeq 10^{35}\,\mathrm{g\,s^{-1}} \left(\frac{M}{M_\odot}\right)^2 \rho T_4^{-3/2} \mu^{-3}; \quad \mu \equiv (1+\mathcal{M}^2)^{1/2} \qquad (1)$$

when the IGG turbulent velocity at distances $\gtrsim GM/c_s^2$ is small compared with keplerian orbital velocity, which we assume. The X-ray luminosity from accretion is

$$L_X = \varepsilon_X \dot{M} c^2 \simeq 10^{56}\,\mathrm{erg\,s^{-1}} \left(\frac{M}{M_\odot}\right)^2 \varepsilon_X \rho T_4^{-3/2} \mu^{-3} \qquad (2)$$

where ε_X, the X-ray energy conversion efficiency is assumed M-independent. For $T_4 > 1$ the dominant cooling of IGG is adiabatic[2]. Hence $T \propto (1+Z)^2$, $\rho \propto (1+Z)^3$ and L_X is epoch-independent provided ε_X is. For such non-evolving sources 80% of their contribution to the CXB comes from $Z \leqslant 1$ (ref. 9) and the volume emissivity needed to account for the observed CXB intensity is

$$\eta_X \simeq 6 \times 10^{-35}\,\mathrm{erg\,cm^{-3}\,s^{-1}}\,(1+Z)^3 \qquad (3)$$

If most of the CXB comes from sources of mass M and number density N then equating $\eta_X = NL_X$ we have

$$N_0 \left(\frac{M}{M_\odot}\right)^2 \varepsilon_X \rho_0 T_{04}^{-3/2} \mu_0^{-3} = 6 \times 10^{-91} \qquad (4)$$

where all quantities with subscript '0' refers to $Z = 0$. In the model by Sargent *et al.*[6], T drops faster than adiabatic after $Z \leqslant 2$ due to He-recombination cooling, leading to $T_0 \sim 10^3$ K (incomplete ionization) and contribution from $Z \leqslant 1$ greater than 80%. However, the uncertainties in other parameters are such that we can use equation (4) even in this case, lumping any correction into say, μ_0. Rewriting $N_0 M = \Omega_B 4.7 \times 10^{-30}$ g cm^{-3} and $\rho_0 = \Omega_0 4.7 \times 10^{-30}$ g cm^{-3}($H_0 = 50$ km s^{-1} Mpc^{-1}) gives

0028-0836/80/270039-02$01.00

$$\frac{M}{M_\odot} = 54\,q^{-1}; \qquad L_X = 1.2\times10^{30}\,\mathrm{erg\,s^{-1}}q^{-1}\Omega_B^{-1}$$

$$N_0 = 1.3\times10^{9}\,\mathrm{Mpc^{-3}}q\Omega_B \tag{5}$$

where $q \equiv \varepsilon_X\Omega_0\Omega_B T_{04}^{-3/2}\mu_0^{-3}$ is expected to be $\ll 1$. Hence such objects must be supermassive black holes. These constraints can be generalized to a power law mass spectrum of compact objects, say $\mathrm{d}N/\mathrm{d}M \propto M^{-\gamma}$ for $M_1 \leqslant M \leqslant M_2$. Then the mass constraint in equation (5) applies approximately to M_2 for $\gamma < 2$ or M_1 for $\gamma > 3$.

The strongest constraint on the parameters in equation (5) comes from the sources count and fluctuation limit. From Uhuru and Ariel 5 small scale fluctuations ($\delta I/I \leqslant 2.5\%$ at 0.004 sr beam width), Schwartz[9] already puts an upper limit on possible contribution of unknown classes of discrete sources to K (number of sources with $S > 1$ UFU per sr) < 10. The Einstein survey gives $K \simeq 7\pm3$ for all sources[3], most of which have optical images. In the preliminary Draco and Eridanus surveys, only three out of 43 sources have empty optical fields[3]. Hence it seems reasonable to put a conservative upper limit for the contribution of accreting intergalactic black holes to the source count

$$K_B \leqslant 2 \tag{6}$$

Future observations may further lower this limit. As most such contributions would come from $Z \leqslant 1$ we have (see ref. 9):

$$K_B \simeq 3.7\times10^{6} L_{X44}^{3/2} N_0;\ L_{X44} = L_X/10^{44}\,\mathrm{erg\,s^{-1}} \tag{7}$$

Combining equations (5), (6) and (7) we have:

$$\varepsilon_X^{1/2}\Omega_B \geqslant 3.2\times10^{-6}\Omega_0^{-1/2}T_{04}^{3/4}\mu_0^{3/2} \tag{8}$$

$$L_X \leqslant 1.2\times10^{41}\,\mathrm{erg\,s^{-1}} \tag{9}$$

$$M/M_\odot \leqslant 1.7\times10^{7}\,\varepsilon_X^{-1/2}\Omega_0^{-1/2}T_{04}^{3/4}\mu_0^{3/2} \tag{10}$$

$$N_0 \geqslant 1.3\times10^{-2}\,(\mathrm{Mpc})^{-3} \tag{11}$$

For the IGG proposed by Sargent *et al.*[6] with $\Omega_0 \sim 0.1$, $T_{04} \sim 1$ and $\mu_0 \sim 10$ we find $\Omega_B \geqslant 3\times10^{-4}\,\varepsilon_X^{-1/2}$ and $M \leqslant 2\times10^{9}\,M_\odot\varepsilon_X^{-1/2}$.

If the IGG contains even a minute amount of organized angular momentum, the accretion flow will turn into a disk near the black hole[10] where most of the X-ray is emitted, in which case ε_X could be high. The familiar disk model with optically thin TB emission has maximum temperature $T_e \sim 10(\dot{M}M_\odot/M)^{1/2}$ provided $10^7\,K \ll T_e \leqslant 10^9\,\mathrm{K}$ (ref. 11). If we set this to the observed CXB TB temperature we find (see equation (5))

$$\varepsilon_X\Omega_B \sim 10^{-7} \tag{12}$$

When equation (12) is combined with equations (8) and (5) we get the constraints

$$\varepsilon_X \leqslant 10^{-3}\,\Omega_0 T_{04}^{-3/2}\mu_0^{-3};\ \Omega_B \geqslant 10^{-4}\,\Omega_0^{-1}T_{04}^{3/2}\mu_0^{3}$$

$$\frac{M}{M_\odot} \sim 5\times10^{8}\,\Omega_0^{-1}T_{04}^{3/2}\mu_0^{3} \tag{13}$$

These numbers are uncertain to the extent the TB disk models are. Also, the requirement that the IGG is not depleted by accretion in a Hubble time demands $\varepsilon_X\Omega_B \geqslant 10^{-8}$. The above results are summarized in Fig. 1.

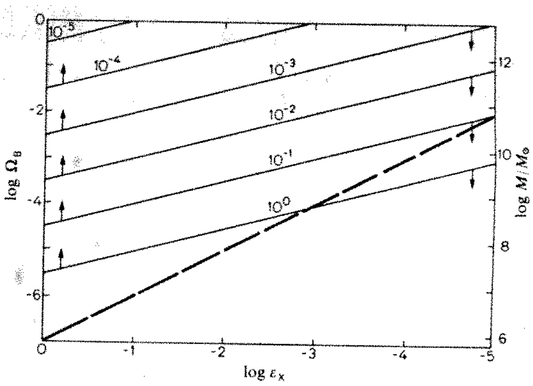

Fig. 1 Solid curves give the lower limit on Ω_B and upper limit on M as provided by the source count limit $K_B \leqslant 2$. The number on each curve labels the value of $\omega \equiv \Omega_0^{1/2}T_{04}^{-3/4}\mu_0^{-3/2}$ of the IGG (see equation (5)). The dashed curve represents the constraint on Ω_B for the TB disk model to give the observed CXB temperature. In this case M is independent of Ω_B or ε_X (see equation (13)).

We conclude that it is possible that much of the CXB is produced by the hot TB emission of Sargent type IGG accreting onto intergalactic black holes in the present epoch ($Z \leqslant 3$). This picture then predicts the existence of a new class of faint ($L_X \leqslant 10^{41}\,\mathrm{erg\,s^{-1}}$), numerous ($N_0 \geqslant 10^{-2}\,\mathrm{Mpc^{-3}}$) and low mass ($M \sim 10^{7}$–$10^{10}M_\odot$) discrete sources without optical or IR images. Gorenstein has pointed out that such objects may be separated from (optically) faint QSOs in the Einstein survey by studying the distribution of the lower limits to their L_X/L_{optical} ratio (P. Gorenstein, personal communication). Note that the bulk of such sources are fainter than the limit of the HR I of Einstein so their predicted $N \propto S^{-1.5}$ does not conflict with the observed steeper distribution. Note that these masses overlap with the mass corresponding to nonlinear density clumps ($\delta\rho/\rho \sim 1$) at decoupling as extrapolated from the present power law density correlation function[12,13]. Some of such clumps could (but need not) directly collapse into black holes without fragmenting into stellar systems at $Z \geqslant 10$ and their X-rays could have Compton-heated the denser IGG[7]. In such case the IGG would not evolve adiabatically and Carr finds that the direct contribution of accretion to the CXB at $Z = 10$ may also be significant[7].

I thank B. J. Carr for his pregalactic black hole results before publication, also D. Sciama, V. Petrosian and P. Gorenstein for helpful discussions.

Discontinuities in the jovian plasma disk of sulphur and oxygen ions

W.-H. Ip

Max-Planck-Institut für Aeronomie, D-3411 Katlenburg-Lindau 3, FRG

The process of local acceleration of the plasma cloud freshly ejected from Io into the jovian magnetosphere is considered here. A physical model previously employed to investigate the motion of artificial barium cloud, is used to estimate the time scale for such transient acceleration. In normal conditions, the new ions could be accelerated to full corotation within ~3 × 10^2s of injection. But the corresponding time scale might be increased 10-fold or so at the peaks of mass injection. In this way the observations of non-rigid corotation of the S^+ ions of sporadic nature may be understood. The temperature and ionization discontinuities in the Io torus as observed by the Voyager experiments is also considered. Here we propose that such a sharp transition is related to the coupling of the radial diffusion and heating plus cooling of the thermal plasma.

0028-0836/80/270040-04$01.00

Ground-based observations[1–6] indicate that the S^+ optical emissions of the jovian sulphur nebula at 6,717 and 6,730 Å usually have a very sharp cutoff at, or inside of, the orbit of Io at 6 R_J, whereas the inner boundary between 3 and 4 R_J has a diffuse appearance. At the same time, it has been established that the motion of the sulphur ions in this nebula is in corotation with the jovian magnetosphere[1]. Although these descriptions may be considered to represent the norm of the S^+ plasma disk, Mekler *et al.*[7] have recently presented evidence of occasional weak S^+ emission outside the orbit of Io. Particularly interesting are the velocities of the S^+ ions in this anomalous emission. Although the motion of the S^+ plasma inside of the sharp boundary was in rigid corotation, the corresponding motion in the outer emission was slower than would be expected for corotation. Such unusual phenomena may be caused by some disturbances in the jovian magnetosphere (for example, substorms), or simply related to the injection process of the sulphur ions from Io. [Note that evidence of non-rigid corotation (up to a few per cent) of the jovian magnetospheric plasma in the vicinity of the orbit of Io have been recently reported[8,9] on the basis of plasma wave and planetary radio astronomy experiments. These observations are presumably more representative of the quiescent state of the Io torus.]

A model formulated by Scholer[10] to study the motion of ionized barium cloud artificially released in the Earth's magnetosphere[11,12] will now be applied to the case of the Io torus of sulphur and oxygen ions. Although highly simplified, this treatment gives a reasonable approximation to the MHD transfer of angular momentum from Jupiter to the Io torus and the resultant heating of the ion cloud. This model together with considerations on the radial diffusion and cooling of the ion cloud, and the new information from the Voyager 1 and 2 observations of the jovian system[13–18], would allow us to interpret systematically the non-corotation events and several other related observations.

The geometry of the MHD coupling between the Io torus and the jovian ionosphere will first be represented by a two-dimensional system with both the ionosphere and the ion cloud idealized as flat slabs of finite vertical thickness and width in the y-direction, and the extension in the x-direction is supposed to be infinite, see Fig. 1. The planetary magnetic fields of uniform strength B are pointing in the z-direction. Furthermore, the magnetosphere between the ionosphere and the Io torus is assumed to have a plasma density of ρ, while the surface density of the torus is m_0 (in g cm^{-2}). The motion of the torus is then coupled to that of the ionosphere through the continuous transmissions and reflections of the Alfvén waves propagating between these two regions[19] with acceleration of the ion cloud as the end result.

More specifically, as the waves travel through the magnetosphere with the Alfvén speed $V_A = B/(4\pi\rho)^{1/2}$ there will be a polarization current j_p carried at the wave fronts[10,20–23]. As shown in Fig. 1*a*, the current will be closed in such a way that the $\mathbf{j} \times \mathbf{B}$ forces would decelerate the magnetospheric, or the ionospheric, plasma but accelerate the ion cloud. The total polarization current can be expressed as $I_p = \sum_A \mathbf{E}\uparrow$, where $\mathbf{E}\uparrow$ is the electric field applied at the (upward going) wave front and $\sum_A = c^2/4\pi V_A$ is the so-called wave conductivity of the magnetosphere. As the wave reaches the ionosphere with a height-integrated Pedersen conductivity $\sum$, an electric field $\mathbf{E}\downarrow$ will be reflected, whereas a conduction current $I_\perp = \sum(\mathbf{E}\uparrow - \mathbf{E}\downarrow)$ will be set up flowing across the magnetic field.

As the ionospheric conduction current must be equal to the total current in the magnetosphere, that is:

$$\textstyle\sum(\mathbf{E}\uparrow - \mathbf{E}\downarrow) = \sum_A(\mathbf{E}\uparrow + \mathbf{E}\downarrow) \qquad (1)$$

we have the following relationship between the incoming and reflected waves:

$$\mathbf{E}\downarrow = \left[\frac{1-X}{1+X}\right]E\uparrow \qquad (2)$$

with $X = \sum/\sum_A$. Thus, the reflection coefficient of the Alfvén waves at the ionospheric boundary is given by $\alpha = (1-X)/(1+X)$. From the same reasoning we can see that after a time $T_A = 2L/V_A$, which is the characteristic time for an Alfvén wave to travel back and forth between the ion cloud and the ionosphere, there will be another reflection, and so on. The acceleration of the ion cloud is, therefore, not just a function of the ratio between $\sum$ and $\sum_A$ but also time t. Another important factor in this dynamical problem is the distributed mass of the ion cloud. Assuming that the central slab is initially at rest (which is pertinent to the case when an ion cloud is just ejected from Io) and taking the inertia of the ion cloud into account, a general solution for the velocity of the cloud can be derived as was done by Scholer[10] for the barium cloud release experiments. In the present context we have

$$V(t) = V_0\{1 - \sum_{n=0} (-1)^n\alpha^n[\exp(-t_n/T_0)L_n(2t_n/T_0) + \alpha\exp(-t_{n+1}/T_0)L_n(2t_{n+1}/T_0)]\} \qquad (3)$$

Here $t_n = t - nT_A$, $T_0 = 2m_0V_A/B^2$, V_0 is the corotation speed, and the summation is carried out only for the Laguerre polynomials $L_n(t_n)$ with $t_n \geq 0$. The normalized velocity profiles for various combinations of T_0, T_A, and α are shown in Fig. 2.

Briefly, for $\sum \gg \sum_A$ and hence $\alpha \approx -1$, the MHD coupling between the ionosphere and the ion cloud is very strong, and in the case of small T_A/T_0 ratio the ion cloud will be accelerated to full corotation speed in just a few times of T_A. On the other hand, if $\sum \ll \sum_A$ and hence $\alpha \approx 1$, the motion of the ion cloud is only weakly coupled to the ionosphere by Alfvén waves. Acceleration of the ion cloud would be very slow. The inertia effect of the ion cloud can also be observed by examining the velocity profiles with different T_A/T_0 ratios but the same value of α.

To explore this result further we assume, for example, the magnetospheric plasma density to be ≈ 1 proton cm^{-2}, the surface number density n_s of the ion cloud just ejected from Io to be $\approx 2 \times 10^{12}$ ions cm^{-2}, and the length scale L to be $\approx 10R_J$; the

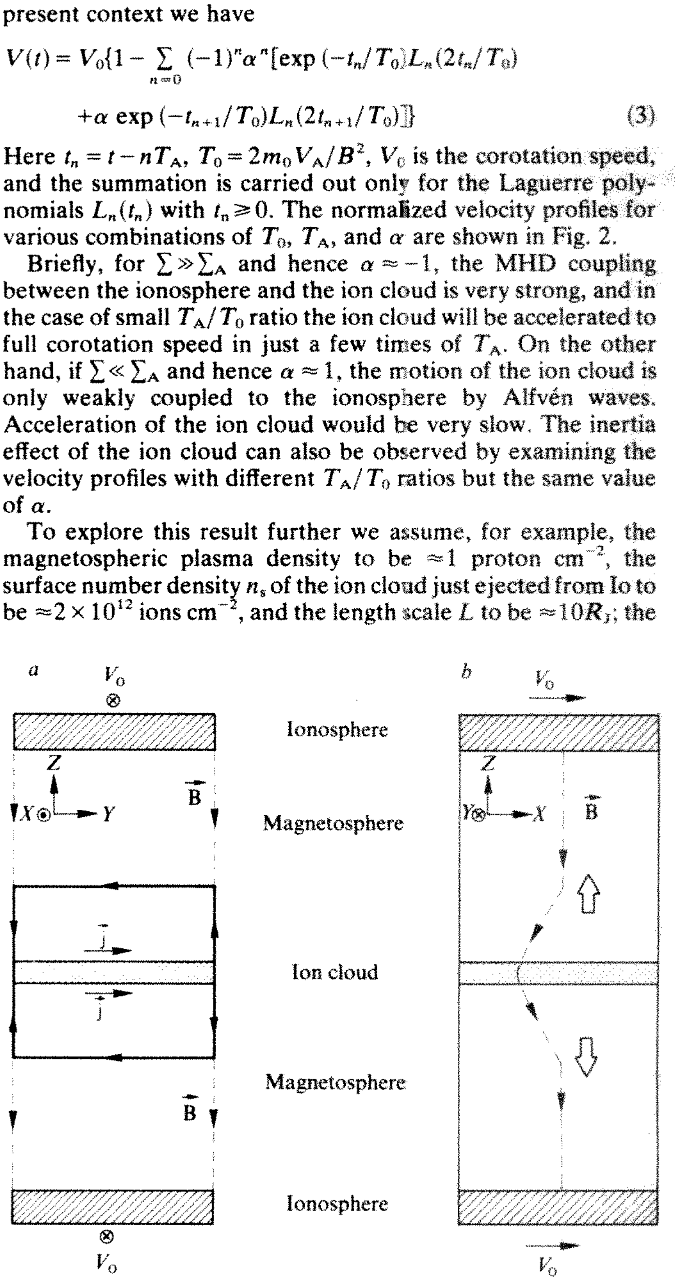

Fig. 1 *a*, A cross-section of the model in the Y–Z plane. The wave current system decelerating the magnetosphere and accelerating the ion cloud is sketched. As a result of the successive transmissions and reflections of these guided waves, a field-aligned current system will be established between the ionosphere and the Io cloud, similar to the current system detected in the vicinity of Io[21,40–43]. The auroral hiss observed on the inner edge of the torus at $L \approx 5.6$ R_J (ref. 43) is probably caused by the beaming of low energy electrons (10 eV–1 keV) associated with such current flows. *b*, A finite section of the model in the X–Z plane. The upward and downward propagations of the Alfvén waves are indicated.

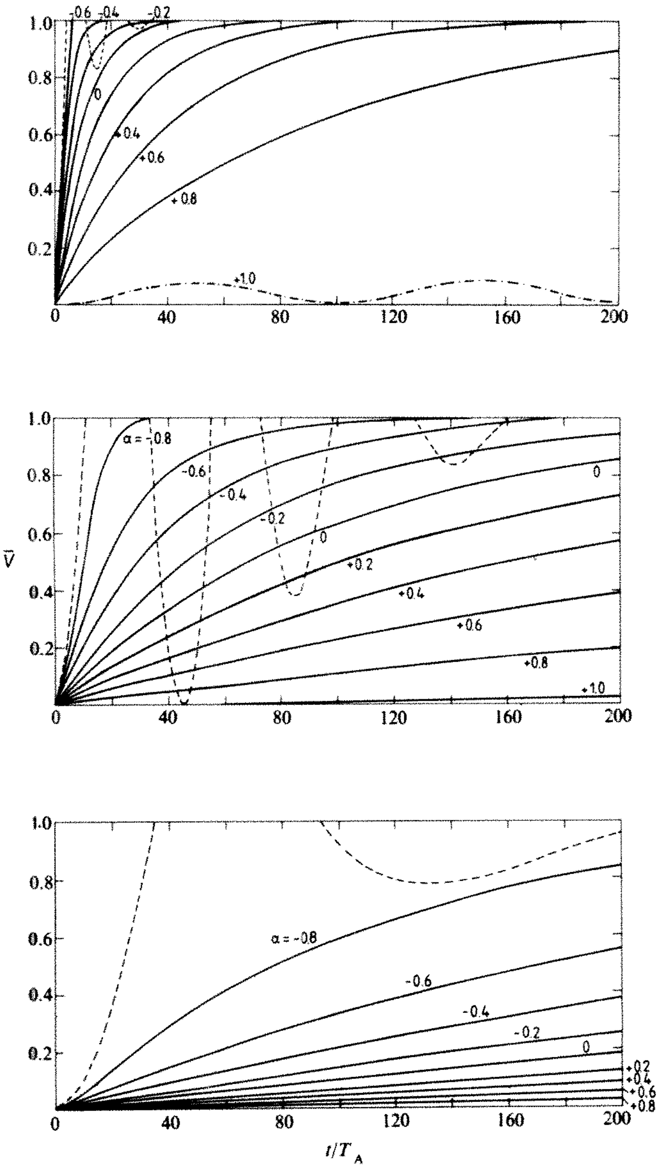

Fig. 2 Velocity profiles of the ion cloud (initially at rest) normalized to the corotation velocity V_0 for various values of the T_A/T_0 ratio and the reflection coefficients α. For $\alpha \leq -0.6, \Sigma \geq 4\Sigma_A$. If the plasma density in the magnetosphere is 1 proton cm^{-3}, and $B = 2\times10^3$ nT we have $\Sigma_A \geq 0.02$ S, consequently $\Sigma \geq 0.1$ S. In this MHD approximation, the ion cloud velocity oscillates before reaching the corotation velocity for $\alpha \to -1$ (see dashed lines). A more realistic description is for the ion cloud to be accelerated to the full speed without such overshoots. *a*, $T_A/T_0 = 10^{-1}$; *b*, $T_A/T_0 = 10^{-2}$; *c*, $T_A/T_0 = 10^{-3}$.

value of the ratio T_A/T_0 can then be approximated to be ≈ 0.1. (As the total ejection rate can be written as $\dot{N} \approx 2n_0R_sV_0$, $\dot{N} \approx 5\times10^{27}$ ions s^{-1} if $n_s \approx 2\times10^{12}$ and R_s is the radius of Io. This value is compatible with the production rate of the sulphur and oxygen ions as estimated by Broadfoot *et al.*[15].) As the S$^+$ nebula was generally observed to be in rigid corotation with the jovian magnetosphere, the characteristic time scale for the corresponding acceleration of the ion cloud probably is no more than a few times of T_A. Thus the α value may be taken to be ≤ -0.6, or $\Sigma/\Sigma_A \geq 4$, say. With $T_A \approx 30$ s and $V_0 = 57$ km s^{-1}, Fig. 2 shows that the ions picked up directly from the ionosphere/exosphere of Io will be accelerated to full corotation within 10 Io radii. This trail of slow moving ions may be interpreted as the wake of the satellite ionosphere[24–26]. (This picture would still hold qualitatively for the interaction of Io with the torus of dense hot plasma.)

Now, if the ejection rate $\dot{N}$ were occasionally increased by a factor of 10 or so (for example, at the maximum of volcanic activities if ionospheric loss is the dominant injection process), $T_A/T_0 \leq 0.01$ and the resulting acceleration time scale will be lengthened by a similar factor. Thus, after its first ejection from Io, the ion cloud would probably stay behind corotation for at least an hour, leaving an ion wake ~150° long. This non-corotation effect could persist even longer if the volcanic activity lasts more than a few hours. The large mass of the fresh S$^+$ and O$^+$ ions injected in these events, of course, would enable the non-rigid corotation behaviour to be discerned more easily, especially outside the nominal edge of the S II nebula.

If the non-corotation of the weak emission of S$^+$ ions observed outside the nominal outer edge[7] could be explained by the inertia effect of the MHD acceleration process plus the sporadic outbursts of the volcanic activities, how do we explain the simultaneous corotation of the S$^+$ ions observed in the inner region of stronger emission? And above all, why should there be a sharp discontinuity confining the S$^+$ emission within 6 R_J in the first place. These questions may be answered by referring to the Voyager observations of the Io torus. First, the EUV experiment[15] and the plasma experiments[16] have found that the bulk of the heavy ions is apparently in the form of S^{2+}, S^{3+}, and O^{2+} with thermal temperature $kT \approx 5$–50 eV. This hot ion torus—with its point of maximum number density approximately located at 5.8 R_J—has 5R_J as its inner boundary and 7–8 R_J the outer boundary. Second, a sharp drop in temperature from $kT \approx 10$ eV to 1 eV was found at 5.7 R_J by the plasma experiments[16]. Together with the temperature change, there is also an apparent change in the ionization state of the heavy ions from S^{2+}, O^{2+} to S$^+$ and O$^+$. Such stratification of the plasma temperature and ionization might be related to the balance between ionization equilibrium and thermal equilibrium as was found in the structures of planetary nebulae[27–29]. Note that the ions freshly created in the vicinity of Io can have kT as high as 260 eV for O$^+$ and 520 eV for S$^+$ (ref. 30) the maximum time scale for cooling of these new ions[31] can be calculated to be $t_c \leq 1.5\times10^5$s. In comparison, adopting a radial diffusion coefficient of 10^{-6} R_J^2 s^{-1} (ref. 32), the time scale for diffusion across a distance of 0.5 R_J at this region is $t_d \approx 7\times10^4$s. As $t_d \geq t_c$, the heating of the Io torus is then limited to a distance of less than 0.5 R_J around the orbit of Io. Although this may partly explain the sharp division between the hot and cold plasma at 5.7 R_J, issue could be raised about the absence of such discontinuity at 6.3 R_J or so. An explanation of such asymmetric behaviour may come from the additional heating effect beyond 6 R_J as a result of Landau damping of the ion cyclotron waves, for example (ref. 33 and C. K. Goertz, personal communication). We may argue that the energetic (S$^+$ and O$^+$) ions, which are responsible for generation of the ion cyclotron turbulence, would not be able to diffuse across Io due to its absorption effect; and this in turn would limit the plasma wave activities and hence plasma heating to radial distance >5.9 R_J.

The ionization state and thermal condition of the Io plasma disk is therefore determined by four inter-related time-dependent processes, namely: (1) the ejection rate; (2) the MHD acceleration; (3) the radial diffusion; and (4) the cooling and heating of the ion cloud. Not just the structure of the 'quiescent' S$^+$ nebula and the non-corotation of the anomalous emission during the 'disturbed' periods, but also the temperature and density discontinuities together with the apparent ionization stratification in the Io torus can be explained in this way.

While we have concentrated on the local and transient effect acceleration of the plasma just ejected from Io, clearly the time-averaged acceleration and transfer of angular momentum of the Io torus in a more global scale must be of the same vein. For a description of the non-rigid corotation of the jovian magnetospheric plasma at radial distances beyond 6R_J see refs 34–36. Alternative views on the asymmetric radial distribution of the thermal plasma[37,38] addressing the possibility of two different diffusion mechanisms at both sides of Io had also been proposed. The effect of such process on our hypothesis of the temperature and ionization discontinuity remains to be investigated. The recent report by Shemanski that an upper limit of 10^{27} ions s^{-1} may be derived for the ion source in the vicinity of Io is also problematic as it sets a stringent condition on the model of local mass pick up[25,26]. In any event, our primary result for the transient acceleration of the Io plasma cloud is by no means affected because, in principle, it is valid for both local (ionospheric scavenging) and more extended (ionization of the sputtered atoms) ion sources.

I thank Dr C. K. Goertz for useful discussions on the problem of magnetospheric propagation of the Alfvén waves.

S-wave anisotropy in the upper mantle under a volcanic area in Japan

Masataka Ando & Yuzo Ishikawa*

Most ultra-basic nodules that probably originated in the upper mantle have anisotropic petrofabric and elastic properties[1,2]. Within seismology, however, the Earth is generally assumed to be isotropic and this assumption is appropriate for most seismological studies. Thus, rocks can be considered isotropic on large scales although anisotropic on a scale of hand specimen[3]. This interpretation is questionable, however, in light of the increasing resolution of seismic observations. Many reliable reports on seismic anisotropies have been accumulating: for example, azimuthal anisotropy in P_n velocities in oceanic basins[4], and in the continent[5] and the back-arc basin[6], and an S-wave splitting of the SH and SV waves revealing an anisotropic structure as deep as 190 km (ref. 7). These suggest that some unsuccessful detections of the Earth's anisotropies may be due to lack of appropriate observations. We describe here the recent discovery of shear wave anisotropy in a volcanic area in Japan, which was revealed by an improvement in the seismographic observation systems.

Telemetery systems of the seismographic stations have recently been established by Kyoto and Nagoya Universities[8] (Fig. 1) in the Chubu area, Japan, beneath which the Pacific plate is subducting. This instrumental development improves the spatial coverage, timing accuracy and recording conditions of seismic observations. The Kamitakara Observatory of Kyoto University is located in the northern part of this area[9] (Fig. 1). Immediately beneath the observatory (Takayama area), at a depth of ~260 km (ref. 10) there are often deep earthquakes. These are very useful events for studies of structures within the wedge between the subducting plate and the Earth's surface in the island arc. As seismic ray paths from these events to the seismographic stations are almost vertical, the wave forms are quite simple because of little contamination of converted waves generated at conspicuous layer boundaries. The stations AMJ and KTJ of this observatory are equipped with the three-component seismographs and the station NRJ with a vertical component one only. The natural pendulum period T_0 is 1 s for both vertical and horizontal seismographs.

Figure 2*a* shows seismograms of one of those deep earthquakes (the earthquake 1 in Fig. 1 and Table 1) recorded at the Kamitakara Observatory. Because the P-wave arrives at the three stations within 0.2 s, the incidence angle is less than 5°. Remarkably, the horizontal seismograms show two distinct arrivals of the shear wave, a fast arrival for the NS component and a slower arrival for the EW one. The horizontal seismograms of three more earthquakes from the same area (earthquakes 2, 3 and 6 in Fig. 1 and Table 1) were examined. These seismograms showed the two different arrivals of the S-wave similar to that in Fig. 2*a*. Such differences in the arrival time of the S-wave between the two horizontal components would be caused by interference of converted waves, but for the present case this interpretation should be dismissed. No significant signal is in fact observed on the vertical component in Fig. 2*a*. A probable interpretation is that S-wave splitting is caused by anisotropy of the medium at intermediate locations between earthquake source and seismographic stations. The incident S-wave is generally resolved into two shear waves that travel along the same path with different velocities—a phenomenon known as acoustic 'double refraction'[11].

As the directions of horizontal seismographs, NS and EW, are not necessarily those of the principal axes of anisotropy, the two split shear waves are generally not resolved on the two horizontal seismograms. Figure 2*a* implies, however, that the directions of the principal axes of the anisotropy are rather close to NS and EW. To determine precise directions of the velocity axes, we synthesized the S-wave forms, by rotating the two orthogonal axes in a clockwise direction at an interval 15°, and projecting the observed S-wave particle motion onto the rotated axes. When a rotation angle θ from the north or east coincided with a principal axis, the two orthogonal S-waves became most widely separated. As shown in Fig. 2*b*, $\theta = 15°$ seems to provide the clearest separation for both records of AMJ and KTJ. The azimuth of maximum velocity, thus, is N15°E and the azimuth of minimum velocity is E15°S.

D, The arrival time difference between the two shear waves in s. A_z, The azimuth of the vibration with the maximum velocity in deg. *Q*, the quality of the data.

To constrain the size and location of the anisotropy, we collected more data which were recorded at neighbouring seismographic networks, the Hokuriku Observatory of Kyoto University (7 stations), and Nagoya University (10 stations) (Fig. 1). The seismographs of the Hokuriku Observatory are the same type as in the Kamitakara Observatory and the two-horizontal-component-observation was carried out at either KAJ or IMJ. In the large seismographic network of Nagoya University, two horizontal-component seismographs are installed at all the stations ($T_0 = 10$ s for both vertical and horizontal components). In each network, vertical seismograms were recorded continuously on paper, but horizontal seismograms were stored on only magnetic tapes when signal amplitudes exceeded a threshold value.

A clear split of the S-wave of earthquake 1 was also recorded on horizontal seismograms at TAK of Nagoya University, 20 km away from KTJ (Fig. 2*c*). The long-period nature of the seismographs of Nagoya University well suppresses short-period noises. The same procedure as described above was used to determine the anisotropic parameters for the Nagoya seismograms. The arrival time difference was 0.7 s, and the directions of the maximum and minimum velocity axes were N15°E and E15°S, respectively (Fig. 2*c*). The polarization angle of the S-wave's first motion corrected for the differential arrival is consistent with the P-wave's nodal plane solution. The consistency of the anisotropic parameters between the two independent networks is further evidence for the existence of the anisotropy under Takayama.

Twelve earthquakes were selected between September 1977 and October 1978; 28 ray paths were used (Table 1). Most of the earthquakes originated from the source 260 km beneath Takayama. To each S-wave signal, the same procedures represented in Fig. 2*b*, *c*, *d* were carried out. The azimuth of the principal axis of the maximum velocity from the north, the arrival time difference between the two S-wave components, and the quality of the data (A, B and C from high to low) are listed in Table 1. Data with quality C were not used for the estimation of the arrival time difference. To avoid corruption of S-wave form by converted waves, we restricted our study to emergence angles <20° at the hypocentre. Because each network has its own amplitude threshold for the start of magnetic tape recording and individual transmission-recording characteristics, the number of earthquakes available for this study differs among the networks. As the coverage of ray paths so far has been concentrated primarily under Takayama and its vicinity, we limit our discussion of anisotropy to that area.

The results are given in Table 1 and can be summarized as follows: (1) the S-wave splitting is observed at AMJ, KTJ and TAK for the earthquakes immediately beneath these stations, but not observed at ITD, TKC, IMJ and KAJ away from these stations; (2) the S-wave splitting is, on the other hand, not

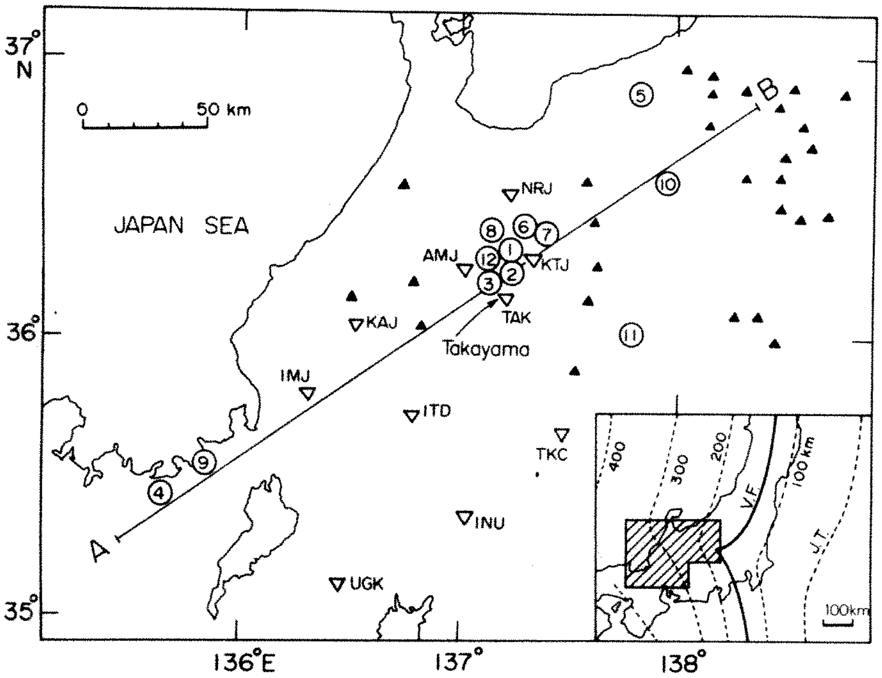

Fig. 1 Epicentres (○), seismographic stations (▽) and Quaternary volcanoes (▲) in the Chubu area, Japan. Numerals denote epicentres of the earthquakes corresponding to Table 1. Quaternary volcanoes are taken from Isshiki *et al.*[17]. The insert shows depths of earthquakes on the deep-focused seismic plane from Utsu[18], and the volcanic front which forms the trenchward bound active volcanism[16]. Line A–B refers to Fig. 3.

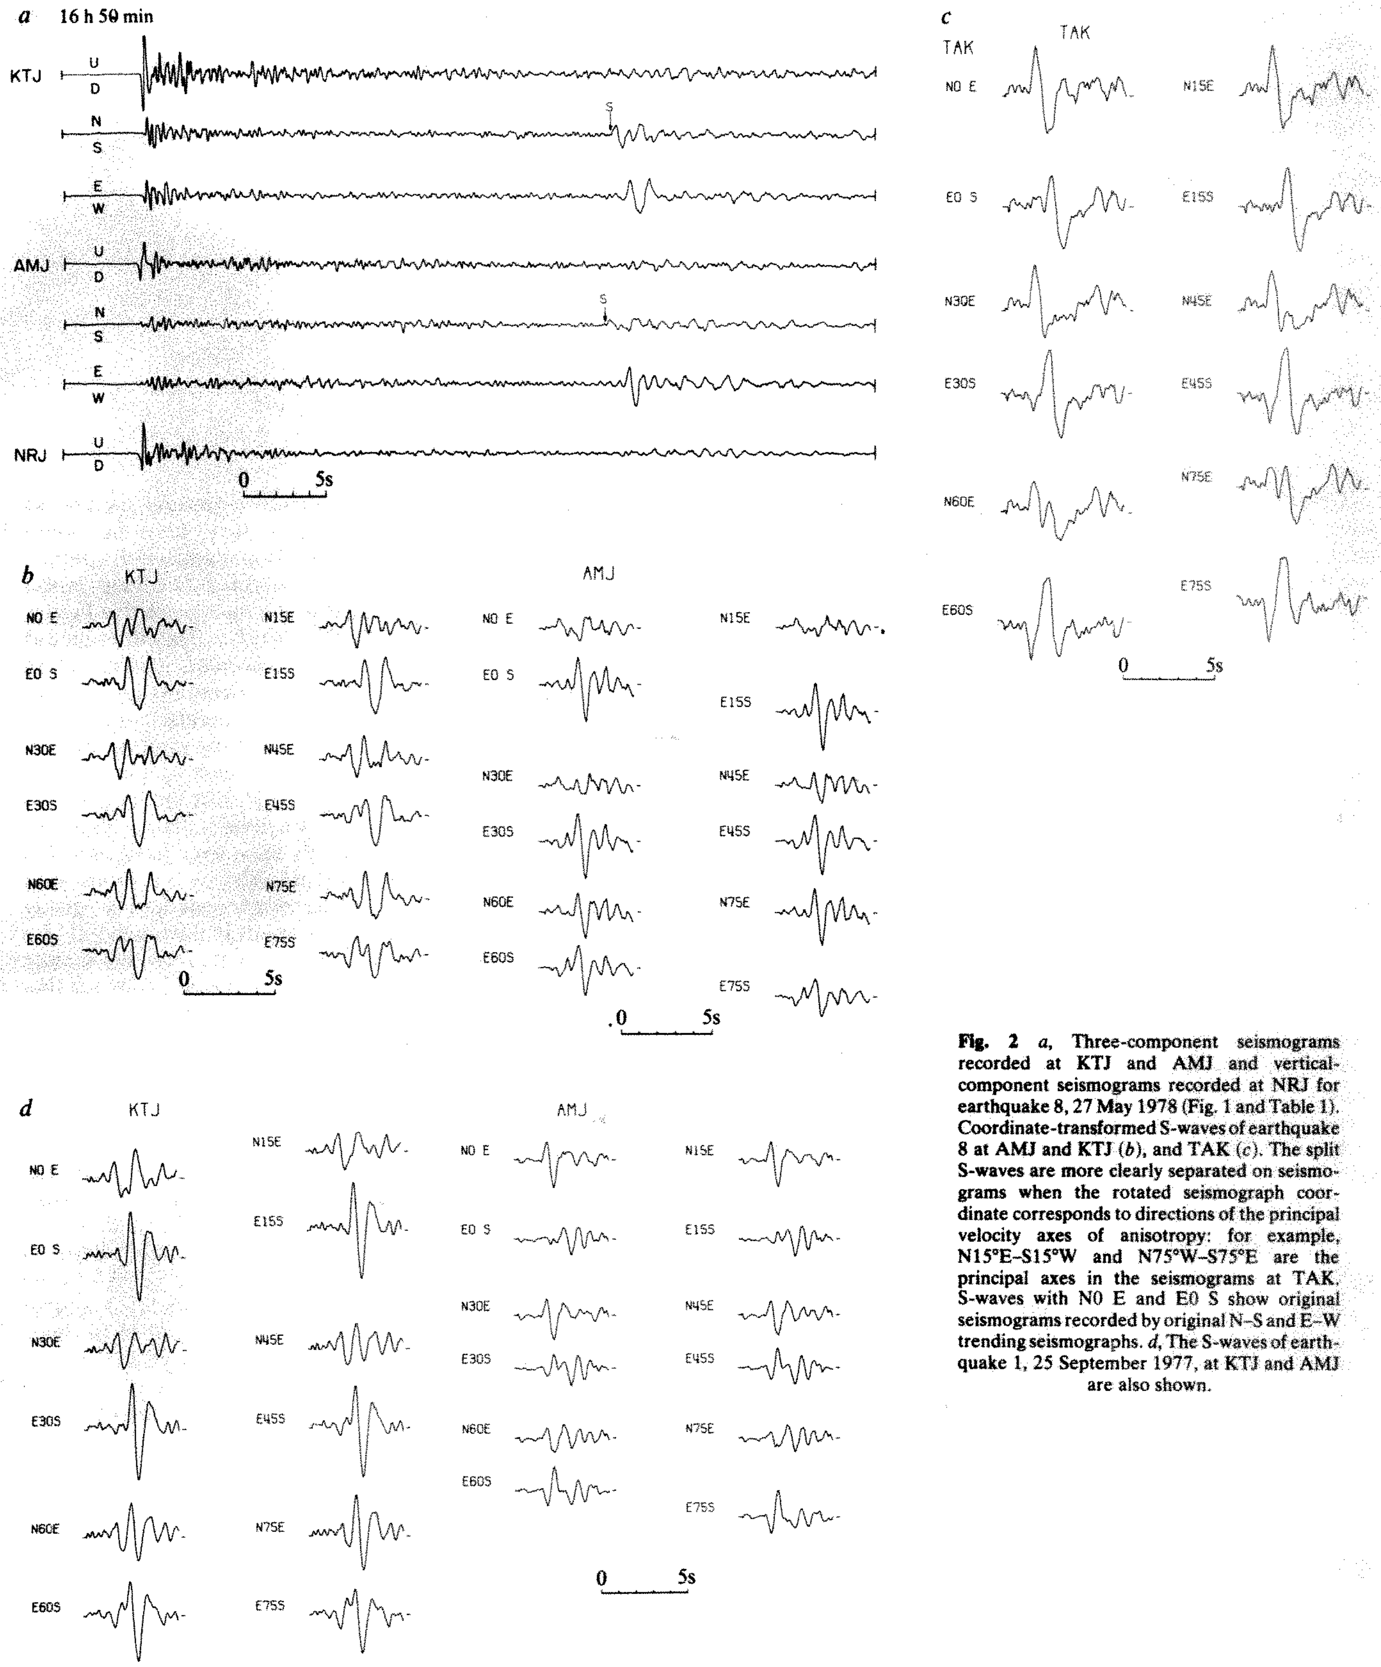

Fig. 2 *a*, Three-component seismograms recorded at KTJ and AMJ and vertical-component seismograms recorded at NRJ for earthquake 8, 27 May 1978 (Fig. 1 and Table 1). Coordinate-transformed S-waves of earthquake 8 at AMJ and KTJ (*b*), and TAK (*c*). The split S-waves are more clearly separated on seismograms when the rotated seismograph coordinate corresponds to directions of the principal velocity axes of anisotropy: for example, N15°E–S15°W and N75°W–S75°E are the principal axes in the seismograms at TAK. S-waves with N0 E and E0 S show original seismograms recorded by original N–S and E–W trending seismographs. *d*, The S-waves of earthquake 1, 25 September 1977, at KTJ and AMJ are also shown.

observed at AMJ, KTJ and TAK for deep earthquakes which occurred outside the Takayama area. These results suggest that the anisotropic medium is not distributed near the source or the receiver station, but rather at some intermediate location along the ray path as shown in Fig. 4. These arguments would be consistent with an anisotropic body ~50–100 km in both horizontal and vertical extents at depths ~100–200 km. The corresponding velocity difference between the two shear waves is ~2–4%. The travel times of the S-wave with the faster velocities associated with the splitting are identical to those of S-waves from the standard travel timetable of the Japan Meteorological Agency[12]. The travel times associated with the minimum velocities are thus delayed ~1 s relative to the standard time.

Preferred orientation of microcracks or liquid inclusion, or individual minerals may cause such an anisotropy of the S-wave[11,13-15]. At present, it is difficult to interpret the anisotropy. We, however, hypothesize that this anisotropy is related to a magma reservoir because AMJ, KTJ and TAK are located near volcanoes inside the volcanic front[16] (Fig. 1). It seems possible, therefore, that S-waves from the deep earthquakes pass through deep magma reservoirs beneath volcanoes (Fig. 3). If thin elliptical inclusions trending north–south exist within magma reservoirs, then a velocity anisotropy of S-waves could be caused with the maximum velocity axis NS.

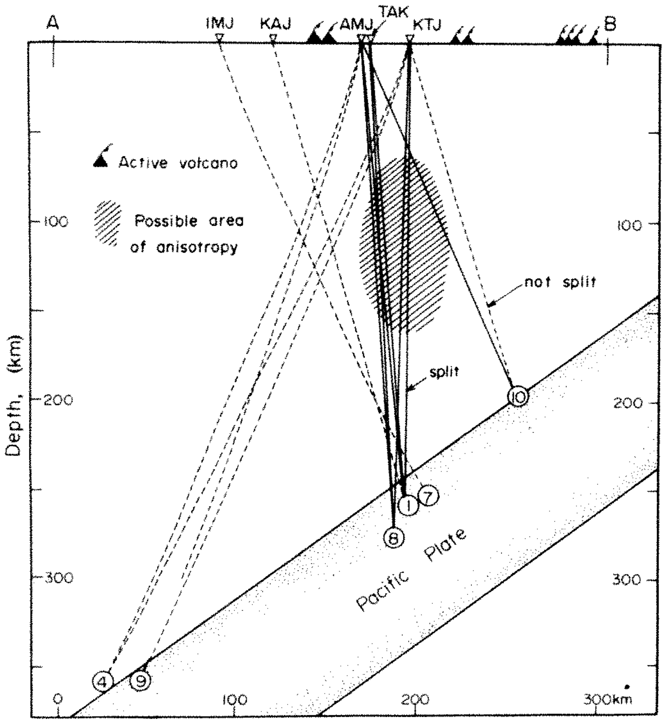

Fig. 3 S-wave ray paths for earthquakes 1, 4, 7, 8 and 10 projected on the plane A–B (Fig. 1). Solid rays denote those associated with the S-wave splitting (arrival time difference >0.4 s). A possible area of anisotropy is inferred from a combination of these ray paths.

We thank the Observation Center for Earthquake Prediction, Nagoya University and the Hokuriku Observatory of Kyoto University for providing the seismographic records and use of their facilities, and Professors K. Aki and S. Crampin, and Mr F. Yamazak for helpful comments.

Restrictions on the compositions of mid-ocean ridge basalts: a fluid dynamical investigation

Herbert E. Huppert

Department of Applied Mathematics and Theoretical Physics,
University of Cambridge,

R. Stephen J. Sparks

Department of Earth Sciences, University of Cambridge,
Downing Place, Cambridge CB2 3EW, UK

The nature of the melts parental to mid-ocean ridge basalts has been vigorously debated. Opinions vary between those considering the parental magma to be magnesia-rich (picritic basalt) with 15–20% MgO and those arguing that the parental melts are compositionally related to the most primitive liquids erupted at mid-ocean ridges (MgO ~ 9–11%). This difference of between 5 and 11% in MgO content represents a temperature interval of 100–250 °C. The actual MgO content places constraints on the thermal conditions at the mantle source. The high-magnesia liquid theory is supported by melting experiments on mantle and basalt samples[1-3] and by petrological studies of ophiolite complexes[4]. However, this theory does not seem to be immediately consistent with the fact that no glasses or aphyric rocks of these compositions have ever been sampled from the sea floor. Indeed the most primitive glass compositions that occur as inclusions in olivine megacrysts and as glassy margins to pillow lavas have MgO contents in the range 9–11%. Models of generating low MgO partial melts from the mantle have been proposed. For example, Presnall *et al.*[5] consider that melting at cusps in the peridotite mantle solidus could generate such melts. We outline here a fluid dynamical model for a basaltic mid-ocean ridge magma chamber supplied by high-magnesia melt from the mantle. The model predicts that high-magnesia extrusives will not be erupted, that ultramafic cumulates should occur at the base of the oceanic crust, that lava compositions will be restricted to MgO contents < 10% and that magma mixing will be a common feature of sea-floor basalts[6].

Before presenting the model we emphasize a fundamental feature of the moderate to low pressure evolution of picritic to tholeiitic basalt by crystal fractionation[7]. Figure 1 shows the dependence of density of high-magnesia melts on MgO content as crystallization occurs, calculated by the method of Bottinga and Weill[8]. As an example, we use the estimate of Elthon[4] for the parent magma for the oceanic crust (MgO ~ 17·8%) and generate successive residual liquids by crystallization of olivine (Fo_{90}). As olivine crystallizes out the density of the residual liquid decreases despite the declining temperature. The residual liquid reaches the density minimum *A* and the liquid joins a cotectic (perhaps olivine-plagioclase or olivine–plagioclase–pyroxene). Subsequent crystallization, dominated by plagioclase and pyroxene, generates residual liquids of progressively increasing density, due to iron-enrichment accompanied by low degrees of silica enrichment. Similar relationships between density and composition have been documented from several suites of mid-ocean ridge basalts[7], although the exact position of the minimum point *A* may change slightly from case to case. The variation of magma density with composition is complicated by the effects of suspended crystals, but in general the effect of suspended crystals will accentuate the relationships shown in Fig. 1 (ref. 7) by increasing the magma density at a fixed temperature.

It is significant that the most primitive glasses yet recovered from the sea floor occupy the density minimum shown in Fig. 1 (9–11% MgO)[6,7,9,10]. Mid-ocean ridge basalts are all more

0028–0836/80/270046–03$01.00

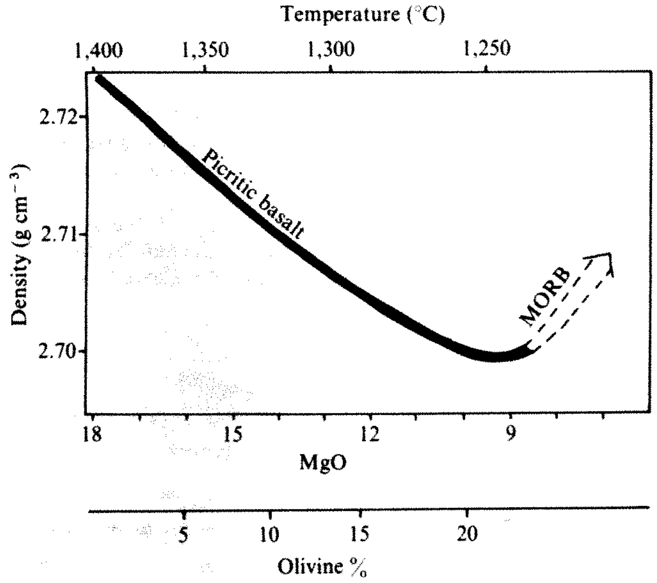

Fig. 1 Variation of melt density with MgO content in picritic liquids. The estimate of Elthon[4] is used as an example of the parental magma to the ocean crust with MgO ~ 17.8% and generated a succession of liquid compositions down to MgO = 10% by removal of forsterite (Fo_{90}). The approximate percentage of olivine removed in generating the successive liquids is indicated by the lower scale. Liquidus temperatures were estimated approximately from the experimental data of Krishnamurthy and Cox[17]. The density minimum at A is illustrated with the approximate trend of mid-ocean ridge basalt density with MgO content for MgO < 9% (after ref. 7).

evolved than this composition and show abundant evidence for mixing between evolved liquids and more primitive liquids (with MgO 9–11%)[6,9–11].

Figure 2 shows our model of a magma chamber containing typical mid-ocean ridge basalt into which a new influx of hot, but denser, picritic-basalt melt is intruded. The concept of an open-system magma chamber periodically replenished by new melt from depth[12] is now widely accepted as the most probable situation existing beneath the mid-ocean ridges, although the exact geometry and location of mid-ocean ridge magma chambers is still uncertain[13]. The temperature contrast between the two magmas may be 100–200 °C, depending largely on the MgO content of the picritic basalt. Investigations of an analogous system[14] where a hot salty layer of water underlies a cold freshwater layer indicates that the dense fluid will remain at the base of the chamber. Between the two layers there is a non-turbulent interface across which heat and salt are transferred by molecular rather than turbulent processes. Unless the densities of the two layers are virtually identical, no physical mixing occurs across the interface, although each layer convects vigorously. We suggest that this form of motion can also occur in magmas where the ratio of diffusivity of mass to that of heat is typically $< 10^{-5}$.

We have adapted the empirical and theoretical results of studies on the salt/water system to the picrite/basalt system in a magma chamber. A detailed treatment of the problem, which has several geological implications in addition to the situation described here, will be presented elsewhere. We summarize here the results pertinent to the problems of mid-ocean ridge magma genesis. Vigorous convection occurs in the two layers (Fig. 2*b*) and heat transfer through the interface between the two layers results in rapid cooling of the lower layer.

Our calculations indicate that the temperature of the lower layer as a function of time, $T(t)$, can be expressed as

$$T(t) = T(0) + \{[\Delta^{-7/3} + 7\,A(0.5 + r)t/3] - \Delta\}/(1 + 2r)$$

where $T(0)$ is the initial temperature, Δ is the initial temperature difference between the layers and r is the ratio of the thickness of the lower layer to that of the upper layer. The expression takes account of the heat of crystallization for olivine using a value of 200 cal g^{-1}. The constant A is dependent on the physical properties of the fluids.

$$A = 0.32(g\kappa^2\alpha^7/\nu)^{1/3}/(h\sigma^2)$$

where g is the gravitational acceleration, κ is the thermal diffusivity, α is the coefficient of thermal expansion, ν is the kinematic viscosity, h is the thickness of the lower layer and σ is the density contrast between the layers due to the difference in MgO contect divided by the mean density.

Typical values of the physical properties are: $\kappa = 10^{-6}\ \mathrm{m^2\,s^{-1}}$; $\alpha = 5\times10^{-5}\ \mathrm{K^{-1}}$; $\nu = 10^{-3}\ \mathrm{m^2\,s^{-1}}$; $\sigma = 2\times10^{-2}$. Figure 3 shows the cooling history of the lower layer for values of h between 3 and 300 m with an upper layer thickness of 4 km, an initial upper layer temperature of 1,255 °C and an initial lower layer temperature of 1,385 °C. We observe that the lower layer cools to thermal equilibrium with the upper layer in a time scale of a few months to a few years. The reason for the rapid cooling rates is the intense turbulent convection that occurs for large Rayleigh numbers[14]. Typically, the initial Rayleigh number of the lower layer exceeds 10^9.

Another consequence of the turbulently convecting flow regime is that olivines precipitated from the lower picrite layer will be kept in turbulent suspension throughout the cooling of the lower layer. In all plausible models we calculate that the mean turbulent velocities[15] are in the range 1–5 cm s^{-1}, whereas the free-fall velocities of olivine crystals of 1–5 mm diameter (typical dimensions in ultramafic cumulates and olivine–phyric lavas) in magnesia-rich liquids are in the range 10^{-2}–10^{-3} cm s^{-1}. The olivine settling rates only become comparable to the turbulent velocities when the temperature difference becomes small (< 1 °C).

The model predicts (Fig. 2) that the lower picritic basalt will not mix with the upper basalt layer and that it will cool rapidly in

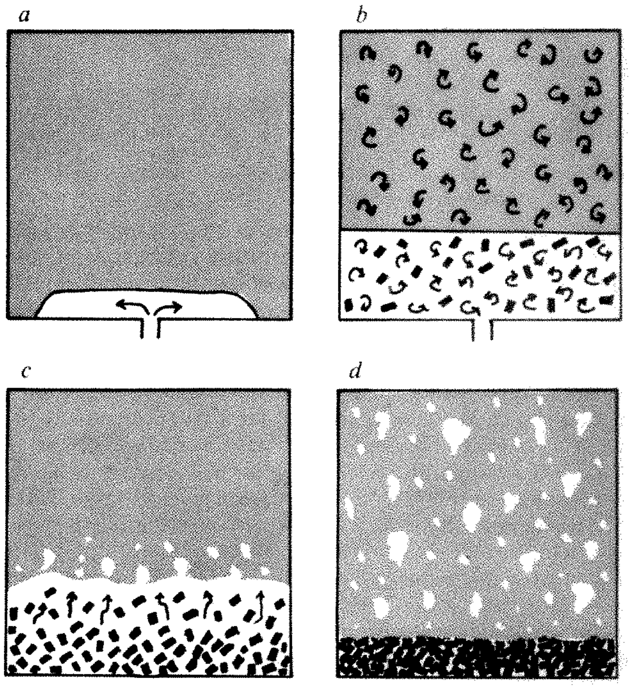

Fig. 2 Schematic model for the behaviour of a new influx of picritic melt into a MOR magma chamber (not to scale): *a*, intrusion of hot, dense picrite into reservoir of fractionating basalt; *b*, stable stratification into two layers which equilibrate thermally by turbulent convection with growth of olivine in lower layer; *c*, convection dies in lower layer at the end of cooling history allowing for olivine settling and separation of low density interstitial basaltic melt; *d*, Cumulate olivine layer formed at base of chamber as low density interstitial melt mixes convectively with heated upper layer.

a period of a few years at most. During its cooling to thermal equilibrium with the upper layer, the picrite will be highly turbulent and olivines precipitated from the liquid will remain in suspension until a late stage when the temperatures of the two layers are nearly equal. Provided that the upper layer is volumetrically large, the lower layer will transform into a mixture of suspended olivine in a basalt liquid. This basaltic liquid will be more primitive than the upper layer which has increased slightly in temperature. In many of our calculations, the residual liquid composition in the lower layer is estimated to occur near to the density minimum shown in Fig. 1. Note that the lower layer will in fact increase in bulk density as it crystallizes, as long as the olivines are kept in suspension. For example, the bulk density of liquid A plus 20% olivines in suspension is 2.82 g cm^{-3}. The dense lower layer remains in existence as long as the convection is sufficiently vigorous to suspend the olivine crystals.

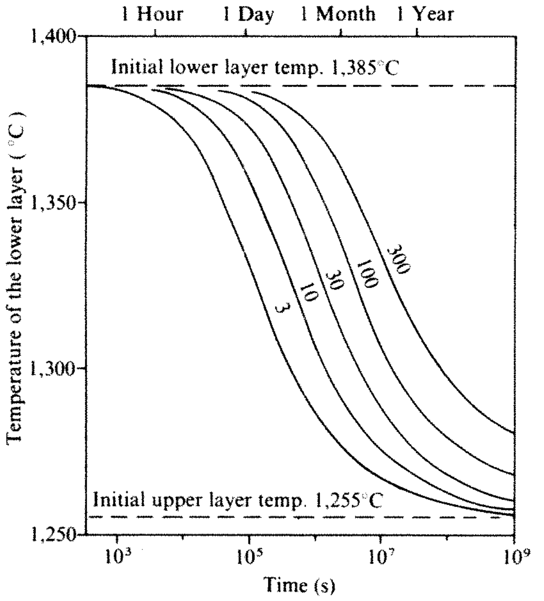

Fig. 3 Temperature of the lower layer as a function of time for various thicknesses (*h*) in metres of the lower layer for an upper layer 4 km thick.

Once convection has died down in the closing stages of cooling, theory[16] predicts a concentration gradient of olivines will be generated in the lower layer when the free-fall velocity and convective velocities become comparable (Fig. 2*c*). Only a slight concentration gradient is required to nullify completely the density instability caused by the slight temperature gradient at this late stage, leading to a transition to stable stratification of the lower layer. We predict that the layer will pass rapidly to a stage of *en masse* sedimentation of suspended olivine. A substantial amount of basaltic liquid will segregate as the olivines sediment (Fig. 2*c*). For example, if a picrite layer, 100 m thick, contained 18% MgO at 1,400 °C and the upper layer, 2,000 m thick, contained basalt with MgO = 9% at 1,250 °C, the lower layer would evolve to a suspension of 20% olivines in a basalt liquid at an equilibrium temperature of 1,264 °C and 10% MgO. Sedimentation of the olivine to a dense close-packed mode (60% olivine) would liberate ~80% of the remaining basaltic liquid, generating a cumulate layer 33 m thick (Fig. 2*d*). The olivines would be relatively uniform in composition as they have grown in conditions approximating equilibrium crystallization in the turbulent layer. Such features are found in the homogeneous olivine cumulates observed at the base of ophiolites. Further adcumulus growth (as is common in ultramafic cumulates) would drive out further basaltic liquid component.

Thermal equilibration between the two layers (Fig. 2) would require that the upper layer has increased in temperature. In many cases the upper layer would be more evolved and denser than the basalt liquid derived from the lower layer as illustrated in the example calculation above. We conclude that the basalt liquid squeezed out during olivine sedimentation in the lower layer will be buoyant in the upper layer and will mix with it convectively (Fig. 2*d*). In this way the compositions of basalts which can erupt at the surface are restricted in composition as they periodically become mixed with basalt close to the density minimum.

Volcanic rocks cored on Hess Rise, western Pacific Ocean

T. L. Vallier*, K. E. Windom†, K. E. Seifert† & Jörn Thiede‡

Large aseismic rises and plateaus in the western Pacific include the Ontong-Java Plateau, Magellan Rise, Shatsky Rise, Mid-Pacific Mountains, and Hess Rise. These are relatively old features that rise above surrounding sea floors as bathymetric highs. Thick sequences of carbonate sediments overlie, what are believed to be, Upper Jurassic and Lower Cretaceous volcanic pedestals. We discuss here petrological and tectonic implications of data from volcanic rocks cored on Hess Rise. The data suggest that Hess Rise originated at a spreading centre in the late early Cretaceous (Aptian–Albian stages). Subsequent off-ridge volcanism in the late Albian–early Cenomanian stages built a large archipelago of oceanic islands and seamounts composed, at least in part, of alkalic rocks. The volcanic platform subsided during its northward passage through the mid-Cretaceous equatorial zone. Faulting and uplift, and possibly volcanism, occurred in the latest Cretaceous (Campanian–Maastrichtian stages). Since then, Hess Rise continued its northward movement and subsidence. Volcanic rocks from holes drilled on Hess Rise during IPOD Leg 62 (Fig. 1) are briefly described here and we relate the petrological data to the origin and evolution of that rise. These are the first volcanic rocks reported from Hess Rise.

Hess Rise is a triangular-shaped bathymetric high that is bounded on the west by the Emperor Seamount chain, on the north-east by the Emperor Trough, and on the south by the Mendocino Fracture Zone. A clear sequence of magnetic anomalies has not been discovered on Hess Rise, but it is believed to lie entirely within the Cretaceous magnetic quiet

0028-0836/80/270048-03$01.00

zone and thereby is younger than early Aptian (~111 Myr old) in age. Our drilling results[1] and previous plate reconstructions[2,3] indicate that Hess Rise formed in Aptian or early Albian time south of the early Cretaceous palaeoequator and moved progressively northward as part of the Pacific Plate.

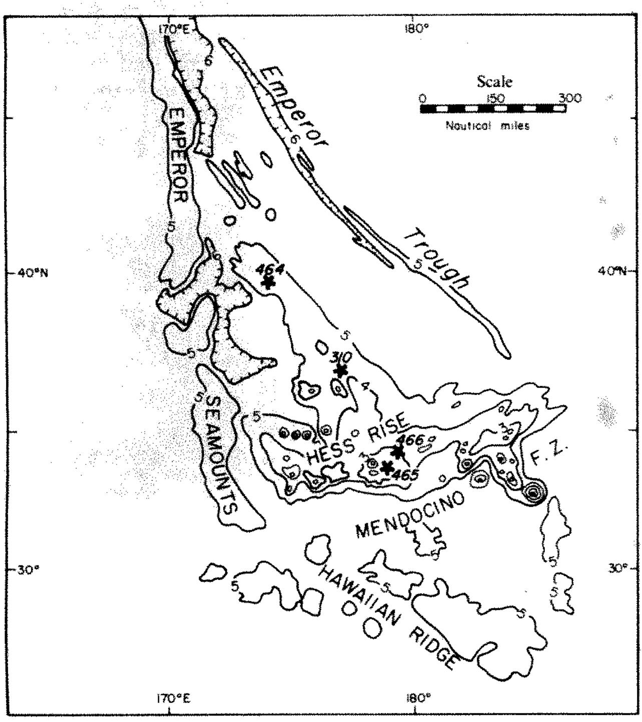

Fig. 1 Bathymetric chart of Hess Rise showing sites drilled and the major bathymetric features. Site 465 cores penetrated trachyte beneath upper Albian limestone and Site 466 cores contained alkali basalt clasts in Upper Cretaceous chalk. Site 464 cores penetrated altered tholeiitic basalt beneath lower Albian limestone. Site 310, drilled on DSDP Leg 32, did not penetrate igneous rocks. Contour intervals are in kilometres.

We recovered 16 cm of highly altered tholeiitic basalt from beneath Lower Albian (uppermost Lower Cretaceous) sediments at Site 464 on northern Hess Rise, 24 m of altered trachyte from beneath Upper Albian sediments at Site 465 on southern Hess Rise, and alkali basalt clasts in Upper Cretaceous (Campanian–Maastrichtian) sediments at Site 466 on southern Hess Rise. Petrological interpretations are based on the petrographical data from 68 thin sections, X-ray diffraction analyses of altered phases, whole-rock chemical analyses of 18 trachyte samples from Site 465 and three basalt samples from Site 464, and microprobe analyses of feldspar phenocrysts from Site 465 trachytes and clinopyroxene phenocrysts from Site 466 basalt clasts. The X-ray fluorescence and instrumental neutron activation analysis data for rocks from Sites 464 and 465 are given in Tables 1 and 2. Clinopyroxene data determined by microprobe analyses of basalt clasts from Site 466 are given in Table 3. Figures 2 and 3 are plots of rare earth element (REE) data.

The basalt from Site 464 is deeply altered as indicated by the high total water contents (7.12–8.05%), high K_2O contents, and abundant smectite minerals. The most convincing evidence that these are tholeiitic basalt, characteristic of mid-ocean ridge basalt (MORB), rather than alkalic basalt is the REE pattern (Fig. 2). The pattern is relatively flat at about 15 times the chondrite abundance and corresponds to a transitional type MORB[4]. In contrast, alkalic basalts show considerable light REE enrichment relative to heavy REE. Studies on the alteration of tholeiitic basalt by seawater[5–7] show that basalt increases in the amounts of H_2O^+, total Fe, K, and Ti and decreases in the abundances of Ca, Mg, and Si which are consistent with our results.

Table 1 Compositional ranges and averages of major and minor element oxides as determined by X-ray fluorescence, instrumental neutron activation analysis, and wet chemical techniques

	Trachyte (Site 465)		Basalt (Site 464)	
Oxide	Range	Average	Range	Average
SiO_2	58.07–60.81	59.66	45.58–46.75	46.16

* Fe_2O_3 is total iron for Site 465 analyses only.

Site 465 data ($N = 18$) are from southern Hess Rise trachyte and Site 464 data ($N = 2$) are from northern Hess Rise basalt.

Subaerial eruption of trachyte flows at Site 465 is suggested by large (>5 mm diameter) vesicles, red iron oxide staining in some flow units, and the absence of glassy flow margins. The trachytic textures are defined by flow-alined feldspar laths and microlites in smectite-replaced glassy groundmasses. Plagioclase feldspar has a compositional range of An_{28} to An_{43} as determined by electron microprobe. Some plagioclase is completely replaced by potassium feldspar, possibly during a late-stage magmatic event.

Table 2 Trace element ranges and averages as determined by X-ray fluorescence and instrumental neutron activation analysis

	Trachyte (Site 465) (p.p.m.)		Basalt (Site 464) (p.p.m.)

For trachyte, $N = 18$; for basalt, $N = 3$.

Chemical data for trachyte samples from Site 465 (Tables 1 and 2) show that the oxides and elements have small ranges of values. Most data trends are consistent with either differentiation effects or high temperature alteration. For example, MgO decreases as K_2O increases and K_2O increases with SiO_2 as expected for differentiation. However, both K_2O and SiO_2 decrease as H_2O^+ increases and MgO increases as H_2O^+ increases. These data are consistent with effects caused by high-temperature alteration[8,9]. Rare earth data for the trachyte samples are plotted in Fig. 3. The REE patterns are consistent with patterns for differentiated alkalic rocks. The heavy REE, particularly Lu, also decreases with increasing H_2O^+. Despite their alteration, the trachytes from Hess Rise are chemically similar to trachytes from oceanic islands, particularly the Tristan da Cunha group[10], and are also similar to end members of differentiation trends discovered in rocks from other oceanic rises and plateaus[11–14].

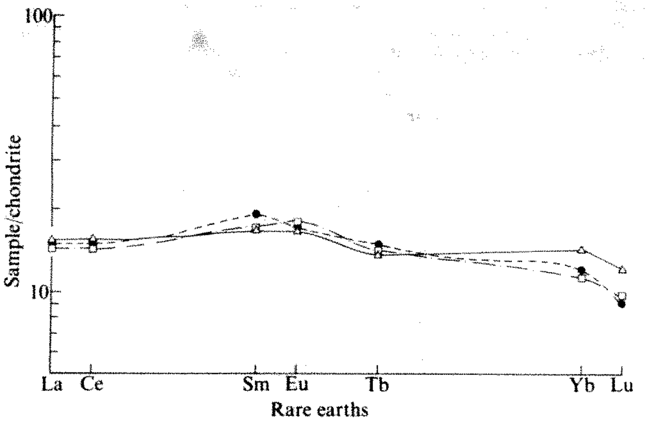

Fig. 2 Normalized plot of rare earth element abundance in basalt of Site 464. This plot is typical of tholeiitic basalt. △, 464-34-CC, 11 cm; ●, 464-34-CC, 19 cm; □, 464-34-CC, 22 cm.

Alkali basalt clasts were recovered from Upper Cretaceous (Campanian–Maastrichtian stages) sediments at Site 466. The rocks have phenocrysts of olivine (completely replaced), clinopyroxene, and plagioclase enclosed in altered glassy groundmasses. The alkalic nature of the rocks is suggested by the high calcium contents of clinopyroxene phenocrysts (Table 3). Plots of the molecular percentages En–Fs–Wo place the pyroxenes in the salite and high-calcium augite fields. Stratigraphic and petrological data from the clasts indicate that erosion of alkalic basalt islands occurred at least 25 Myr after the main volcanic pedestal had formed. It is apparent that some uplift and faulting took place in the late Cretaceous, but the reason for the tectonic activity is not known.

The age, as determined by overlying and associated biogenic sediment, and petrology of the volcanic rocks have important tectonic and petrological implications. Combined with our interpretations based on shipboard data[1] and recognition of plate-associated lateral and vertical movements[2,3], we can present some preliminary conclusions with regards to the geological history of Hess Rise.

Table 3 Clinopyroxene chemistry of two alkali basalt clasts in Upper Cretaceous sediment, Site 466, southern Hess Rise.

Hess Rise, at least in part, is a subsided oceanic volcanic archipelago that was buried by younger pelagic sediments. Active volcanic activity probably ended before late Albian time, although the presence of alkali basalt clasts in the Upper Cretaceous strata at Site 466 may indicate later volcanism. The age difference between oldest sediment cored at the northern (464) and southern (465) sites (early Albian and late Albian–Cenomanian respectively) is consistent with passage of the rise over a mantle hot spot, but this hypothesis needs additional testing.

The volcanic rocks we recovered from Hess Rise represent only the uppermost part of the pedestal; therefore, we do not know the nature of the underlying volcanic succession. Judging from studies of older parts of deeply eroded oceanic islands and seamounts, of rocks erupted from mid-ocean ridges, and of our data from sites on Hess Rise, we presume that the oldest volcanic rocks are tholeiitic basalt that were extruded at a spreading centre in Aptian or early Albian time. Younger intraplate, or off-ridge, volcanism commenced after the sea floor had migrated from the ridge axis and subsequently built a large archipelago. After volcanic activity ceased, the archipelago continued moving northward. Most of the archipelago had subsided beneath sea level by the time it crossed the biological high-productivity zone of the mid-Cretaceous equator[1]. Tectonic activity, probably mostly block faulting, raised parts of the old archipelago above sea level where subaerial erosion provided clasts that became incorporated in the Upper Cretaceous strata at Site 466. Synchronous volcanic activity may have occurred. Hess Rise continued to subside during the Cenozoic as it moved northward and is now a prominent bathymetric high in the western Pacific.

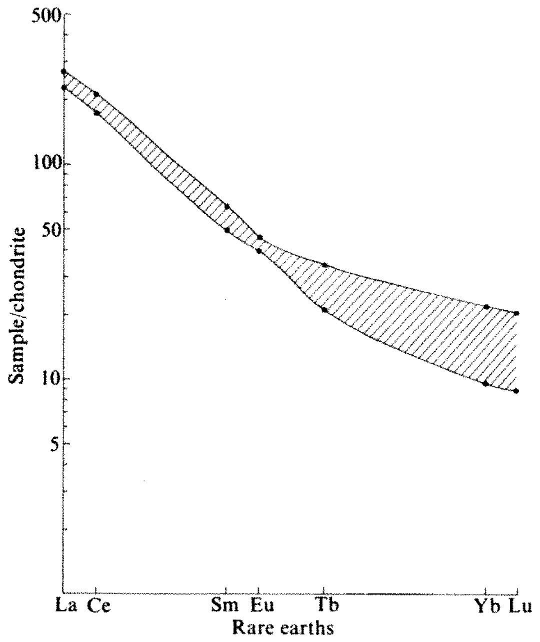

Fig. 3 Normalized plot of the total range of rare earth element abundance in Site 465 trachyte.

We thank Rodey Batiza and Florence Lee-Wong for helpful reviews. We thank the shipboard scientific staff on the Glomar Challenger for assistance during Leg 62 of the International Phase of Ocean Drilling.

Unique amino acid composition of Red Sea brine

D. E. Ingmanson

Sea Grant, A-032, University of California, La Jolla, California 92093

M. J. Dowler

Natural Science Department, San Diego State University, San Diego, California 92182

The lack of evidence from terrestrial environments supporting the chemical evolution model has resulted in scientists looking elsewhere in the Solar System and in space for evidence. We have suggested that the Atlantis II Deep brine (21°22′N by 38°05′E) located in a submarine rift at the bottom of the Red Sea is a promising environment possibly containing terrestrial evidence for chemical evolution[1]. We have also reported finding a thiocyanate concentration of 2.4×10^{-5} M in the Atlantis II Deep brine[2]. We report here the discovery of an unusually large concentration of glycine in the Atlantis II Deep brine and virtually no other dissolved free amino acids. We further suggest four possible explanations for the unique amino acid composition of Red Sea brine. Our methods of location, sampling and storage of the brines have been discussed elsewhere[2].

Several investigators have analysed seawater and other saline solutions for their dissolved free amino acid composition[3-6]. Because in deep ocean waters the dissolved free amino acid concentration is extremely low[6], great care must be used in the sampling, storing and analysing the samples. Special precautions in our work included the following measures. All water used was double distilled in glassware. All glassware was acid (nitric acid/sulphuric acid, 1:2 by volume) washed and rinsed repeatedly with double distilled water. Before use, all inorganic compounds were heated at 450 °C for over 12 h to remove organic contaminants. Preparation of the reagents for chromatography entailed the following steps. Ammonium hydroxide was prepared by bubbling ammonia gas through acid-washed tubing, a water trap to remove any amino acids, and finally into water to produce 3 M NH_4OH. Hydrochloric acid reagent was made by two successive azeotropic distillations producing 6 M HCl.

Separation of the amino acids from the brine was accomplished by a liquid-exchange chromatography procedure using a copper–Chelex 100 (BIO-RAD) resin column and an ammonium–Chelex 100 column[4,6]. For column preparation and separation, these steps were followed in the order indicated:

(1) 25 ml of 3 M NH_4OH were passed through 10 ml of Cu^{2+}–Chelex 100;
(2) the column was rinsed with water until *p*H 9.8 was reached;
(3) 0.3 ml of 1 M NaOH was added to 10 ml of brine. The solution was brought up to 100 ml with water and poured onto the column;
(4) the column was flushed with water until Cl^- free as measured visually using $AgNO_3$ solution;
(5) amino acids were eluted with 25 ml of 1.5 M NH_4OH;
(6) 20 ml of 1.5 M NH_4OH were passed through 5 ml of NH_4^+–Chelex 100;
(7) the eluant amino acid solution was passed through the NH_4^+-Chelex 100 column to separate Cu^{2+} from the eluant;
(8) the column was chased with 5 ml 1.5 M NH_4OH;
(9) the sample was lyophilized. 2 ml of double glass distilled water was added, the solution was centrifuged, the supernatant removed and relyophilized.

Analysis was performed using a Beckman 121 MB amino acid analyser equipped with a model 126 data system. Samples were applied to a 0.28 × 20 cm column with Beckman AA-10 resin using a standard sodium citrate program (Beckman) with ninhydrin detection in a single column system.

Red Sea brine samples and several kinds of controls were all analysed for amino acids using identical procedures. The controls included many duplicates of 5 M NaCl synthetic brine, non-brine Red Sea water from a depth of 500 m, a solution of known amounts of amino acids, known contaminated solutions, the ammonium hydroxide reagent, the double glass distilled water and the hydrochloric acid used in preparing the resins. The synthetic brine and ammonium hydroxide revealed a glycine contamination level of <50 pmol per 10 ml. The water and acid were below the detection levels of the system. Recovery of known amino acids averaged ~50%. Known contaminated solutions showed a wide variety of amino acids.

The Atlantis II Deep brine samples yielded a mean glycine concentration of 1,090 nmol l^{-1} based on 11 analyses. About 10 nmol l^{-1} or less of serine was also detected. No other dissolved free amino acids were detected. The non-brine Red Sea sample showed a glycine concentration of ~122 nmol l^{-1}.

Previous reports of amino acids in deep ocean water suggest that a wide variety of dissolved free amino acids are present in most cases, but the total concentration levels are always below 100 nmol l^{-1} (ref. 6). Surface ocean water samples are reported to contain ~1,000 nmol l^{-1} with glycine comprising ~200 nmol l^{-1} (ref. 5).

How can the presence of high amounts of glycine and virtual absence of other amino acids be explained? As the glycine concentration is higher than that found in highly productive surface coastal waters, even though the brine is apparently sterile, an additional source must be sought. We suggest that one plausible source is an abiotic origin involving a Strecker synthesis of amino acids from aldehydes and cyanide. Because the methane content is known to be high, and formaldehyde is easily derived from methane, one can then explain the high glycine concentration. Why glycine is virtually the only amino acid found is unclear. Some investigators have invoked the properties of clays to explain unique amino acid distributions[8,9]. As relatively large volumes of samples are needed to check carbon isotope ratios, we have not yet determined the $^{12}C/^{13}C$ ratio which could shed light on the origin of the glycine. There are several other plausible explanations for our results. The most obvious is that there is biological contamination of the brines and/or our procedures. The Atlantis II brine has been reported sterile[7]. As the amino acid distribution of our control brine indicates no contamination and bacteriological assays done on water from the same sampler were negative (R. Cuhel, personal communication), we consider this explanation unlikely. Another explanation might involve chemical contamination of our sample. Glycine has been reported to bleed from or through Chelex 100[6]. If this were the explanation for our data, why were there such repeatable small amounts of glycine in the synthetic control brine? A third alternative is that the abundant bacteria above the Atlantis II brine decompose organisms and the amino acids leach into the brine where they accumulate. Perhaps there is some chemical compound in the brine that selectively removes all dissolved amino acids except glycine from the brine, or alters other amino acids to form glycine. However, there is no evidence to support this.

If amino acids are synthesized in geothermal systems, this might provide the nutrient base for some of the unique, highly productive regions surrounding deep-sea springs.

We have demonstrated the value of further exploration of Red Sea hot brines and especially the Atlantis II Deep brine from the perspective of chemical evolution. This should be done as soon as proposals have been made to mine commercially the rich heavy metal deposits in the sediment beneath the brines.[10].

Size distribution of Amazon River bed sediment

Carl F. Nordin Jr*, Robert H. Meade*, William F. Curtis*, Nivaldo J. Bósio† & Paulo M. B. Landim†

* US Geological Survey, Denver, Colorado 80225
† Departamento de Geociências, Universidade Estadual Paulista, Rio Claro, Sao Paulo, Brazil

The first recorded observations of bed material of the Amazon River were made in 1843 by Lt William Lewis Herndon of the US Navy, when he travelled the river from its headwaters to its mouth, sounding its depths, and noting the nature of particles caught in a heavy grease smeared to the bottom of his sounding weight[1]. He reported the bed material of the river to be mostly sand and fine gravel. Oltman and Ames took samples at a few locations in 1963 and 1964, and reported the bed material at Óbidos, Brazil, to be fine sands, with median diameters ranging from 0.15 to 0.25 mm (ref. 2). We present here a summary of particle-size analyses of samples of streambed material collected from the Amazon River and its major tributaries along a reach of the river from Iquitos in Peru, ~3,500 km above Macapá, Brazil, to a point 220 km above Macapá[3].

The field work was done aboard RV Alpha Helix. Samples were collected with pipe dredges[3], or with a US BM-54 bed material sampler[4], dried aboard ship, and transported to the US Geological Survey laboratories in Denver, Colorado, for particle-size analysis by sieving, or by pipette–visual accumulation tube methods[5].

Herndon's observations were remarkably accurate; the bed of the Amazon is mostly fine sand. Many of our samples contained small percentages of fine gravel; these were especially prevalent at locations where there were local outcrops in the abutting terraces, or where conditions favoured hydraulic sorting; for example, on the outsides of bends, downstream from confluences with some of the major tributaries, where there are zones of high shearing both in the flow and at the bed with exceptionally high turbulence, or in very narrow sections with high velocities. Figure 1 shows a comparison of particle-size distributions of material collected in a deep hole just below the confluence of the Rio Negro and the Rio Solimões, and of material collected 131 km upstream and 74 km downstream of the confluence. The striking differences in size distribution are apparently due to hydraulic sorting at the confluence in combination with local outcrops of fine gravel in the Alter do Chão formation.

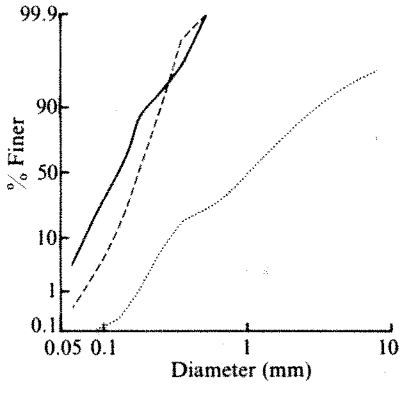

Fig. 1 Hydraulic sorting at the confluence of the Rio Negro and Rio Solimões results in the local deposits of gravel. The water depth was 54 m. Curves are coded as follows: ...., confluence of the Rio Negro and Rio Solimões; ----, Rio Amazonas, 74 km downstream of the confluence; ———, Rio Solimões, 131 km upstream of the confluence.

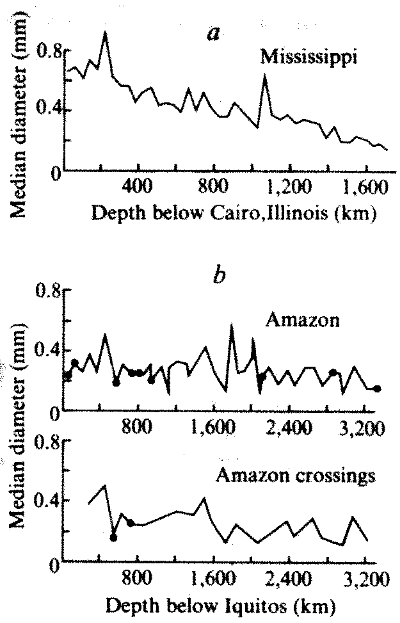

Fig. 2 Variation with distance of median particle size: *a*, for the Mississippi River; *b*, for the Amazon River. Median sizes shown for Mississippi are averages of sands (median diameters 0.06–2.00 mm) for 40-km reaches of river. Median sizes shown for Amazon are mostly individual samples; ●, average values where two or more samples were collected in a cross-section.

In most alluvial streams, bed material becomes finer and more uniform in a downstream direction. Figure 2*a*, for example, shows the trend of decreasing particle size for bed material of the Mississippi River along a 1,600-km reach below Cairo, Illinois[6]. The mean particle diameter along the reach is reduced from ~0.7 to 0.2 mm.

No such striking reduction in particle size was found for the Amazon River between Iquitos and Belem. A plot of the median diameters of bed materials from our 1977 samples against distance downstream from Iquitos, Fig. 2*b*, shows no significant trend. To eliminate the effects of local hydraulic sorting, we systematically collected some of our samples on the crossings between bends. When these data are plotted by themselves (Fig. 2*b*), a slight trend towards decreasing particle size is apparent.

At several cross-sections where we measured the suspended-sediment discharge[7,8], we collected five or more samples of the bed at equally spaced intervals across the sections. The average curves (Fig. 3) show no appreciable differences in particle-size distributions. Cross-channel variation in particle size at several cross-sections was at least as great as downstream variations encountered along the entire 3,300-km reach.

A sorting coefficient, σ, was computed for each sample:

$$\sigma = 1/2\left(\frac{d_{50}}{d_{16}}+\frac{d_{84}}{d_{50}}\right) \qquad (1)$$

where the subscript represents per cent finer. For example, d_{50} is the particle size for which 50% by weight is finer. Values of σ ranged from 1.18 to 2.59, with 70% of the values falling between 1.20 and 1.40. The highest value, 2.59, was for the

0028–0836/80/270052–02$01.00

sample taken at the confluence of the Rio Negro and Rio Solimões, the size distribution of which is shown in Fig. 1. When values of σ were plotted against distance, no significant trend was found. The bed material does not tend to become more uniform in the downstream direction, as it does in most other alluvial streams.

Although the median size and sorting coefficient of the sands on the bed of the Amazon mainstem are essentially constant in the 3,300-km reach we sampled, the composition of the sands in the same reach changes significantly. To the unaided eye, the sands collected near Iquitos appear darker than those collected farther down the river, because of a larger proportion of dark mineral grains and rock fragments. Heavy-mineral suites also differ.

Landim *et al.*[8] report that sands in the first 1,300 km or so downstream from Iquitos are rich in unstable minerals, such as hypersthene, augite and amphibole; these indicate a predominantly Andean source. Sands in the lower 2,000 km contain fewer unstable minerals and higher proportions of zircon and tourmaline. This change in mineral composition is unlikely to represent only the progressive decomposition of unstable Andean minerals during transport or during temporary storage in alluvial deposits, because such decomposition would be accompanied by attrition and a reduction in particle size along the channel. We hypothesize that the change in composition represents a combination of the decomposition of the Andean minerals and a dilution of that mainstem material by sands brought in by tributaries from the Precambrian shield areas north and south of the Amazon. Thus, any reduction in size of material from the Andean sources by attrition along the mainstem below Iquitos is offset by the addition of material from tributaries draining the Precambrian shield areas.

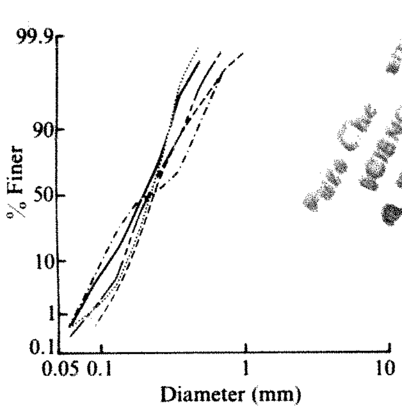

Fig. 3 Average particle-size distribution curves for cross-sections where five or more samples were collected. The curves are coded as follows: ————————, Rio Maranõn, 25 km below Iquitos; ----, Rio Solimões at São Paulo de Olivença, 757 km below Iquitos; ———, Rio Solimões near Santo Antonio do Içá, 909 km below Iquitos; ...., Rio Solimões at Manacapuru, 2,086 km below Iquitos; -·-·-·-·-, Rio Amazonas at Óbidos, 2,827 km below Iquitos.

A family of regression equations describing the density distribution of dispersing organisms

R. A. J. Taylor

Department of Entomology, The Pennsylvania State University,
University Park, Pennsylvania 16802

I have previously shown[1] that some of the published regression equations for describing the decline of density of insects with distance from a centre of dispersal were each special cases of a more general equation:

$$N = \exp(a + bx^c) \tag{1}$$

where N is density at a distance x from a centre of dispersal and a, b, and c are parameters. Equation (1) is a good description of the dispersal of most insects so far investigated[1]. To describe any single set of data, a simpler expression can often be found to fit, but this approach will lead to as many theories of migration as there are equations. To describe all sets of data by a single generalized model may require greater complexity than equation (1), and more parameters. I present here such a generalization, which may lead to a unified theory.

The decline in density with distance is characteristically concave, being steep near the origin, and having a long tail, but more rarely the relationship is convex in form (for example, *Meligethes aeneus*[1,2]); permitting the exponent in equation (1) to vary enables both forms to be fitted by the same equation. But a problem with equation (1) is that as c approaches zero a singularity occurs which is difficult to interpret, leading as it does to $N = \exp(a+b) = $ a constant. When c approaches zero it is appropriate to adopt the logarithmic equation,

$$N = \exp(a + b \ln x). \tag{2}$$

The relationship between c and the residual variance after fitting equation (1) is a continuous function, except in the region of $c \sim 0$. As c approaches zero, equation (2) has been found to be a good fit for one set of data (*Glossina palpalis* and *G. tachinoides*[1,3]) of the eight previously examined, and the residual variance was the value which preserved the relationship between c and residual variance after fitting equation (1).

Early models used to describe dispersal have usually been derived from the normal distribution and are thus closely related to the diffusion equations of physics. In these models it is assumed that particles, or in this case, insects, separate at a constant velocity known as the coefficient of diffusion D, and for a given period. When applied to living organisms this assumes that their behaviour is fixed and is unaffected by the presence of others: an assumption with little justification[4].

The regression equation related to the diffusion equation is the so-called 'half-normal',

$$N = \exp(a + bx^2) \tag{3}$$

in which b is inversely proportional to the coefficient D. By assuming that D is proportional to x^{2-c}, equation (1) is obtained. With D proportional to distance x, the rate of diffusion must be inversely proportional to density, a relationship which can be interpreted biologically. A large number of animals released at a point are likely to interact with one another, changing their behaviour in a density-dependent fashion; high densities experienced during rearing or collection may lead to longer periods of activity. They also increase contacts between individuals which may, in turn, reduce the initial speed of movement away from the release

Homo sapiens	22	3.17	-0.01	0.03	-0.93	12	2.8050	353.80
Peorian loess	10	2.66	-0.05	9×10^{-4}	-0.43	12	1.3775	125.71

Equation (5) fitted to dispersal data of 14 species, and also that of the deposition of Peorian loess in central North America. (Significance levels all less than 0.001.) The data are all of average numbers obtained at a distance from a point source except for the tsetse* data which are from a line source, and standardized for density (see ref. 23). The *Drosophila* data are of the combined data of Dobzhansky and Wright[1] as given in Wallace[24]. d.f. = degrees of freedom, r.m.s. = residual mean square.

point, thus decreasing the diffusion coefficient. As the number of contacts increases with the number released and a very large number of dispersing insects is needed to get sufficient recaptures for analysis, such experiments are likely to decrease the diffusion coefficient in the early stages of dispersal. Once an insect has left the central concentration, its diffusion coefficient may rise to some characteristic level determined by its earlier environmental history; the amount of interference required for a given effect is also likely to be a species characteristic.

This complex behaviour makes the diffusion process envisaged by Pearson[5] and Dobzhansky and Wright[6] seem unlikely; yet the prediction that the variance of distance flown should be linearly related to the time spent flying was apparently upheld by Dobzhansky and Wright's experiment[6]. Their discovery that the diffusion coefficient was constant only for a given experiment did not deter their faith in the model, but the fact that the coefficient varied between experiments[7] casts some doubt on the validity of the normal distribution as a basis for the model. With the potential for such varied behaviours in different species, it seems essential to increase the numbers of model parameters. While this may present problems in statistical estimation, it does make possible a rational search for behavioural interpretation that is not possible with the normal model[8].

The distribution from which equation (1) presents a form appropriate for regression analysis is a generalization of the Γ distribution (when $\gamma=0$), and which also includes the Weibull distribution ($\alpha=0$), and the half-normal ($a=\frac{1}{2}$, $c=2$, $\gamma=0$), and which has the probability density function[9],

$$p(x)=\frac{c(x-\gamma)^{c\alpha-1}}{\beta^{c\alpha}\Gamma(\alpha)}\exp\left(-\left[\frac{x-\gamma}{\beta}\right]^{c}\right). \qquad (4)$$

Equations (1) and (4) are related by ($\gamma=0$), ($\beta^{-c}=-b$), ($\alpha=1/c$), and ($c/\beta\Gamma(1/c)\equiv\exp(a)$). If the condition that ($\alpha=1/c$) is relaxed, a second term in x is obtained, and defining equivalent parameters gives,

$$N=\exp(a+bx^{c}+d\ln x) \qquad (5)$$

where ($\gamma=0$), ($\beta^{-c}=-b$), ($c\alpha=d+1$), and ($c/\beta^{c\alpha}\Gamma(\alpha)\equiv\exp(a)$). Equation (5) has equations (1) and (2) as special cases; equation (1) is obtained by setting $d=0$ and equation (2) when either b or $c=0$. In view of this relationship, the $\ln x$ term of equation (5) clearly becomes dominant as b or c approaches

Residual sums of squares after fitting the four regression equations to the 15 sets of data.

*The *F*-ratio is the comparison of equation (5) with the next best fitting equation indicated by an asterisk.

†Significance shows that the somplete four-parameter equation is required for adequate description of the dispersal data ($P<0.001$). As expected, equation (5) has the minimum RSS for all data, but not necessarily the lowest mean square residual.

NS indicates no significant improvement in fit by using equation (5); SS = sums of squares. RSS = residual sums of squares.

zero, and shows why $N=\exp(a+b\ln x)$ is an appropriate alternative equation preserving the symmetry between c and residual variance. Thus the description of Morris' data of tsetse dispersal[3] is not qualitatively different from the other seven sets investigated in ref. 1.

Using literature data for several taxa, I attempted to determine the usefulness of these equations for description of animal dispersal from a point source. Table 1 shows the results of fitting equation (5) to data of 14 animal species and also, for comparison, one set of data of the aerial displacement by wind of grains of Peorian loess in central North America[10]. Table 1 shows that all the data fit the model well, and also that they can be separated into three types; two data sets have d comparatively large (*Meligethes* and *Parus*) suggesting that the fourth parameter has a large influence, and three sets in which c is small (*Glossina*, man and soil), supporting the logarithmic equation (2): of the remainder, approximately half have very small b but these coincide with large c.

To confirm that equations (1) and (2) are indeed special cases of equation (5) when b, c or d are small, all three equations were fitted to the data, with, for comparison, the 'half-normal' equation (3). Table 2 shows the residual sums of squares after fitting the four equations. The last column shows the F-ratio for improvement obtained by fitting equation (5) over the next best fitting equation, and equation (1) always fits better, usually significantly better than equation (3). Note that only man and the tsetse fly data conform to the same model as the soil. What features do man and tsetse have in common with air-blown soil? It has been suggested that all behaviour is the resultant of two opposing tendencies, to approach and to separate, and that the distributions we see of organisms in space are the sum of these two opposing behaviours[11]. The distribution of Peorian loess is probably also the result of characteristics of the grains which tend to promote or inhibit displacement by wind, for example, surface texture and mass. I do not suggest that the forces promoting displacement in animals are the same as for wind-blown soil, but that there are analogous forces acting in both cases.

Whatever those forces are, the same functional relation connecting them to the specific behaviour of the dispersing particle (soil, spores and seeds as well as actively moving animals) should apply. The equation presented here is a good candidate for such a function, even though at this stage the parameters cannot be identified. However, it is likely that the segregation of the data sets into two groups described by equations (1) and (2) does reflect a real behavioural difference in movement. To determine what that behaviour might be will necessitate analysis of the parameters and this requires far more density–distance data than is available.

Cameral liquid transport and buoyancy control in chambered nautilus (*Nautilus macromphalus*)

Lewis Greenwald*, Peter D. Ward† & O. E. Greenwald*

*Department of Zoology, Ohio State University, Columbus, Ohio 43210
†Department of Geology, University of California, Davis, California 95616

Studies of cephalopod buoyancy[1] show that transport of cameral liquid by the shallow water cuttlefish (*Sepia*) can be explained by a reduction of the liquid's osmotic pressure, followed by osmosis out of the chamber. This mechanism seems insufficient to explain chamber emptying in the chambered nautilus (*Nautilus macromphalus*), which is frequently found below 240 m, the depth beneath which simple osmotic emptying cannot function[2,3]. At 240 m, the hydrostatic pressure forcing water into the chambers of the nautilus shell exceeds the maximum osmotic emtying pressure. Because deep water experiments were not feasible, it was our aim to determine whether nautilus could transport cameral liquid against osmotic pressure gradients, and to consider mechanisms that could account for transport against both osmotic and hydrostatic gradients. These possible mechanisms include enhanced siphuncular blood concentration (possibly caused by a countercurrent multiplier in the siphuncle[4]) which could 'draw' water from chambers below 240 m, and 'local osmosis'[6], resulting from enhanced solute concentrations in siphuncular intercellular spaces. Physiological and ultrastructural evidence for the latter is presented here.

To expose the siphuncle to osmotic pressure differences tending to draw water into a chamber, we drilled a hole into a 20-ml chamber and removed any liquid. Then we added 5 ml of NaCl-enriched seawater (either 1.3 or 1.9 osmolal). To give the animals an 'incentive' to empty their chambers, we drilled a hole in an adjacent chamber and filled it with seawater, causing the animal to sink to the bottom of the aquarium (1 m deep).

After 10–15 days we measured volumes and osmolalities of liquid remaining in the experimental chambers. Of 13 animals, 12 transported some liquid out (the animal that did not was omitted). For nine animals with 1.3-osmolal solutions in their chambers, the rate was 159 μl d^{-1} ± 80 (95% confidence interval), and for three animals whose chambers contained 1.9 osmolal solutions, 218 μl d^{-1}. The osmolality of heart blood of these and other animals was 1.062 (range 1.054–1.069, 17 animals); the osmolality of the seawater was 1.045. By the end of the experiment the osmotic pressure of the experimental cameral liquids had fallen to 1.262 and 1.770 osmolal, respectively, still well above the blood concentrations. Siphuncular blood samples were not obtained.

Thus the siphuncle transports liquid by some mechanism other than simple osmotic flow. This transport against osmotic gradients, as well as transport against hydrostatic gradients, such as would occur below 240 m, could be explained by local osmosis, which requires a cellular architecture of intercellular spaces or basolateral infoldings of the transporting cells[7]. According to Denton[5], siphuncular cells are "packed with mitochondria" and the basal and lateral membranes of these cells are "folded to form canaliculi". This description recalls other transporting cells thought to use local osmosis[8]. Our observations of siphuncular cells (Fig. 1) are consistent with this description. Our micrograph is from a siphuncle that was emptying cameral liquid (1.7 osmolal) against the osmotic gradient at a rate of 310 μl d^{-1}. The numerous mitochondria along the lateral infoldings (canaliculi) suggest that solute-coupled water transport occurs at these small infoldings rather than at the level of the large basal infoldings. Neither large basal infoldings nor canaliculi are present in siphuncles that

0028–0836/80/270055–02$01.00

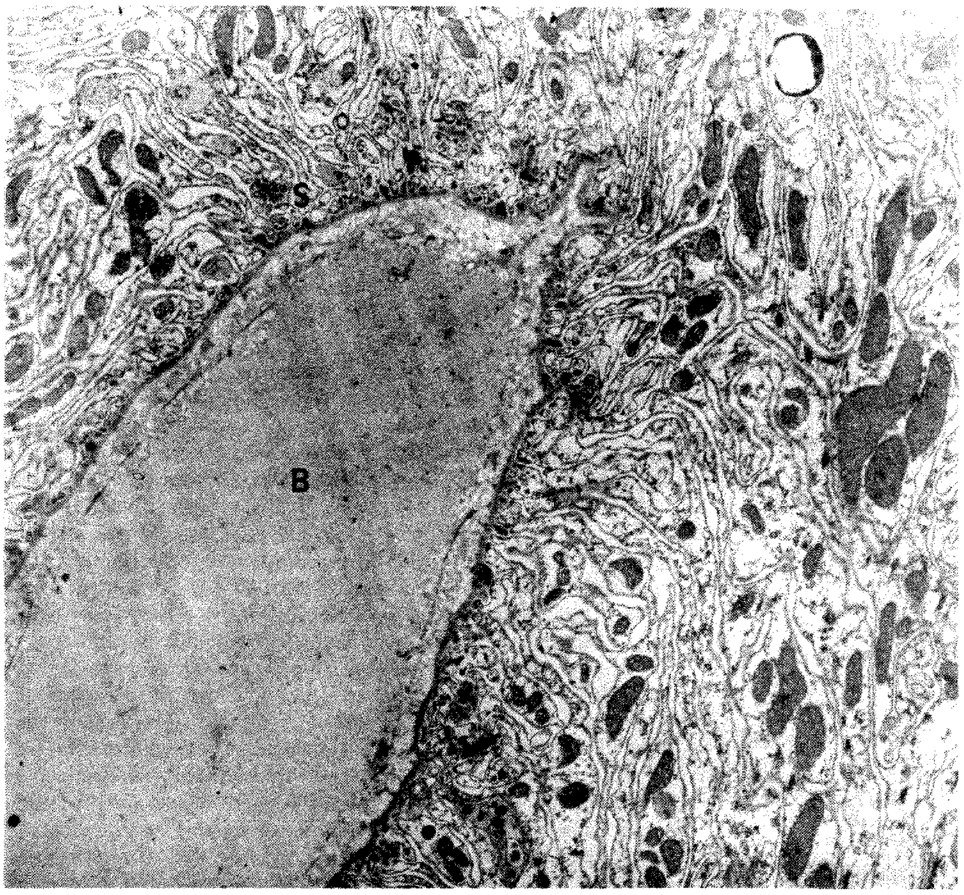

Fig. 1 Low power electron micrograph (×5,000) of a siphuncle cell. The large basal infolding (B) can be seen as well as the network of small channels (S) that lead into the large basal infolding. Numerous mitochondria (M) can be seen in the cytoplasm between the small channels.

have not yet begun to empty cameral liquid.

Nautilus adjusts its rate of emptying and consequent buoyancy development to meet its needs. When we did not flood incentive chambers and the animals were buoyant, as they become in the laboratory, emptying of hyperosmotic solutions was slow (Fig. 2). These animals increased their emptying rates when incentive chambers were flooded, to make the animals sink. Other animals that had been emptying rapidly (and had flooded incentive chambers) decreased their emptying rates when we emptied and plugged the incentive chambers to make the animals float.

This work was supported by NSF grant PCM 7823624 to L.G. and P.D.W. We thank Professor E. J. Denton for helpful criticism, Drs Yves Magnier, Director of the Aquarium of Nouméa, New Caledonia, and Paul de Boissezon, Director of the ORSTOM Laboratory in Nouméa where this work was done.

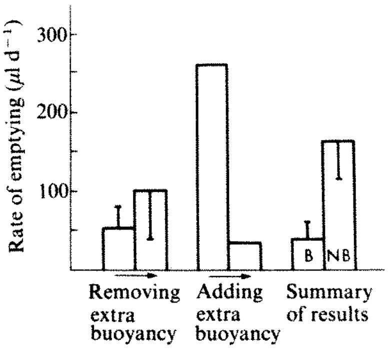

Fig. 2 Rates at which cameral liquid was emptied from experimental chambers of nautilus in different conditions. See text for explanation. The lines extending from the means are the 95% confidence intervals. The difference in emptying rates between all buoyant (B) and non-buoyant (NB) animals (last panel) is highly significant ($P < 0.01$, Student's t test).

Ovipositing butterfly (*Pieris brassicae* L.) distinguishes between aqueous extracts of two strains of *Cannabis sativa* L. and THC and CBD

The ovipositing female butterfly has proved a useful tool for separating closely related strains of various plant species. Using the large white (*Pieris brassicae*), we have been able to distinguish between the Turkish and Mexican strains of *Cannabis sativa*, and demonstrate that the butterfly is sufficiently sensitive to differentiate between purified THC (tetrahydrocannabinol) and CBD (cannabidiol) – two substances which taste and smell alike to the human observer.

*Eggs counted in only 2 and 5 of these trials, respectively. †Eggs counted in 10 trials; egg batches counted in 14 trials. ‡Egg batches counted in 23 trials. §No. of egg batches including singles. Results obtained from female ovipositing in dual choice chamber. Experiments performed by L. Lundgren. ND, not determined.

We sprayed cabbage leaves with aqueous extracts (soups) of plants which do not serve as normal hosts for *P. brassicae*. The ovipositing female will lay sparingly on most of these leaves, totally reject a few, and sometimes lay as freely as on controls sprayed with cabbage extract or tap water. Cabbage (*Brassica oleracea*, greyhound strain) and *Cannabis sativa* (Turkish strain containing predominantly CBD (UNC 354) and Mexican strain containing predominantly THC (UNC 347))[1] were grown under glass at Ashton from seed produced in the UK. Leaves for the experiments were cut from the same plant, matched for size and position on the stem. Butterflies from Brian Gardiner's Cambridge strain[2] of *P. brassicae* were reared at Ashton.

Aqueous extracts were prepared by macerating 5 g of *Cannabis* (or other) foliage in a domestic blender for 5 min, and adding 5 oz tap water. The blender was not allowed to warm up. The resulting opaque green fluid was filtered through Whatman No. 1 paper, and a measured amount was sprayed on to each cabbage leaf. Maceration probably liberates unusual volatiles from *Cannabis*, cabbage and any other plant, and such extracts from its own food plant may slightly alter the butterflies' reaction to a leaf (Table 1). In other experiments volatiles were removed by heating the extract slowly after filtration for 30 min until all the characteristic odour had evaporated, leaving only a generalized 'green' or 'vegetable' odour. Lost fluid was replaced by an equivalent amount of tap water, and refiltered to remove green matter that had precipitated during heating; the resulting fluid was a clear brownish yellow. Ethanolic solutions containing 1% CBD and 1% THC were also tested by spraying on to the surface of cabbage leaves.

Two leaves were offered simultaneously to free-flying ovipositing females in a large greenhouse (4.5 × 7.5 m). Placed on reversed flower pots (6–12 inches apart), they were left *in situ* from 1000 h to 1400 h. These pots, with leaves, were transposed at intervals to avoid position effects. In sunny weather the leaves were resprayed twice during the 4-h period. Females were used on the second day of egg laying which resulted in a high proportion of small egg batches.

Aqueous extracts of *Cannabis sativa* sprayed on to the normal host plant drastically reduced egg laying by *P. brassicae*, but the Mexican THC strain proved far more repellent than the Turkish CBD strain. Table 1 shows that, matched against a control sprayed with tap water, egg batches are outnumbered 22:1 on leaves sprayed with Mexican strain, but only 3:1 with Turkish strain.

If well steamed, extracts of both plants, but more especially the Turkish strain, lost their principal oviposition deterrent. In several trials (Table 2) leaves treated with steamed Turkish soup, and once or twice with Mexican soup, attracted more oviposition than the controls, confirming that the steam of volatiles of both plants contained the more active deterrents.

Since slight repellent qualities were usually retained by steamed extract, and some cannabinoids, although in reduced amounts, would occur in the aqueous residue, we tested THC and CBD (dissolved in ethanol) against various controls and each other (Tables 2, 3) and found that 2–3 times as many eggs were laid on leaves sprayed with CBD than THC.

The ovipositing large white is known to react to a variety of visual and sensory cues, including the presence of mustard oils in foliage, egg batches on both leaf surfaces, feeding larvae and injuries to the plants[3]. It is nevertheless surprising to find that

Table 2 Oviposition on cabbage sprayed with steamed aqueous extracts (soups) from leaves of *Cannabis sativa*

Strains of *Cannabis* and spray used	No. of trials	No. of egg batches (excluding singles)	No. of eggs laid	No. of times first choice of ovipositing female	Remarks

ND, not determined.

this butterfly can distinguish between the aqueous extracts of two such similar strains of a plant species which does not, in nature, serve as a host. It seems that the major deterrent factors are in the volatiles emanating from these solutions; however, after steaming the extract, there remain non-volatile elements (which have not been identified) in the residue, which influence the ovipositing behaviour of the butterfly. It is therefore interesting to find that the large white can distinguish between two very similar cannabinoids (differing from each other only by a ring closure which changes a substituted terpinoid (CBD) into a dibenzopyran (THC). Although present in small quantities these probably constitute two of the non-volatile repellents in the plants, and the relative unattractive nature of the THC could contribute to the greater repulsive qualities of the Mexican strain.

It is difficult to determine whether the initial choice of a leaf is made after merely a close approach or a rapid or brief contact. It will be seen (Table 2) that out of 26 trials the Mexican extract leaf was only once selected for ovipositing before the Turkish extract leaf. Recognition of a leaf sprayed with CBD and THC occurred after, rather than before 'touch down'.

The tendency for females to lay larger batches (containing more eggs than the controls) on certain CBD-treated leaves (Table 4) suggests that there may be an ovipositing stimulant, but not an attractant, in this substance. There is no doubt that several different factors contribute to the production of large egg batches, quite apart from the age and past history of the females concerned.

The few results we obtained with Mexican steamed extract in 1979 (Table 2) differed from those of other years. Thus, after heating and steaming, the residue retained much of its original repellent quality. Possibly the THC concentration was higher. Moreover, the spring had been exceptionally cold, and in an unheated greenhouse all the plants suffered. Indeed it would be surprising if the secondary plant substances—always disconcertingly variable[1,4]—were similar in all respects to those found in the previous crops.

We thank Lennart Lundgren for help with the dual choice chamber, Brian Gardiner for butterflies and M. G. Rowan for material and advice.

A curiosity of light adaptation

J. D. Mollon & P. G. Polden

University of Cambridge, Department of Experimental Psychology, Downing Street, Cambridge CB2 3EB, UK

By standard psychophysical procedures[1] it is possible to arrange that visual discriminations depend only on signals originating in the violet-sensitive receptors of the eye. A person's vision then shows several characteristic properties: differential sensitivity is lower than when the green- and red-sensitive cones contribute to detection, spatial and temporal resolution is poorer, and a number of anomalies of adaptation reveal themselves[1–9], including the saturation that we have demonstrated when violet targets are presented on steady blue or violet adapting fields[10]. 'Saturation' refers to the empirical finding that as the intensity (I) of the short-wavelength field increases, the threshold intensity (ΔI) for detecting a violet target rises much more rapidly than is described by Weber's law ($\Delta I/I$ = constant). These earlier results (replicated here; see Fig. 2, right-hand data), were obtained in what would conventionally be regarded as equilibrium conditions, in that thresholds were measured after 4 min of adaptation to the steady field. Here we examine a very odd aspect of the phenomenon: the threshold reaches its saturated state only after passing through a much lower value[11,12].

Figure 1 shows (for 3 observers) the time course of the threshold for a 436-nm target during the first 3 min after the onset of a composite adapting field. The latter consisted of a 440-nm component of $10^{10.6}$ quanta s^{-1} deg^{-2} and a 575-nm component of $10^{11.7}$ quanta s^{-1} deg^{-2}. The second, yellow, component would traditionally be termed an 'auxiliary field' (ref. 1, p. 198); it serves to suppress the red- and green-sensitive cones. The left-most data points of Fig. 1 represent the threshold 1 s after the onset of the composite field; the threshold is elevated relative to its dark-adapted value (not shown). Thereafter the threshold falls (as would normally be the case during the first few seconds of light adaptation), passes through a minimum, and then rises with remarkable speed.

For observers J.D.M. and D.D. the function at its steepest has a slope of 1 dB s^{-1}. To record accurately these rapid changes in sensitivity we have revived a special psychophysical method described by Cornsweet and Teller[23]. An ordinary staircase procedure[12], such as is traditionally used to track a changing threshold, would require a very large step size if it were to track faithfully the extremely rapid changes seen in Fig. 1; but then the precision of the estimate at any given delay (Δt) would be low. The modified procedure (called here the 'method of a thousand staircases') is designed to obviate this difficulty. In the present example, the observer receives 13 exposures to the adapting fields, each exposure, or run, lasting 3 min and successive runs being separated by 15-min intervals to allow the visual system to recover. During each run, test flashes (and accompanying warning tones) are presented at 3-s intervals. On the first run of the series the test flashes are all presented at the same intensity and the observer indicates by pushbuttons whether he has seen each flash. The response corresponding to each value of Δt is stored by the computer that controls the experiment. On the next run the computer adjusts the intensity of the flash at a given Δt according to the response previously given at that Δt but independently of responses given earlier in the current run. The new response at each Δt is now stored and is used to determine the flash intensity at that Δt on the third run; and so on. The adjustments between runs are made according to the rules for a single staircase[13], but what is unusual is that a large number (here 60, but in principle unlimited) of staircases are being maintained concurrently, each staircase corresponding to a single Δt. The final thresholds plotted in Fig. 1 are based on the intensity levels visited at a given Δt in the last eight runs.

Figure 2 places the phenomenon of Fig. 1 in context. Consider first the data to the right. These constitute an increment–threshold function ('threshold-vs-intensity' (t.v.i.) curve) for 436-nm targets presented on a 440-nm field and were obtained in steady-state conditions, in that measurements at each intensity of the field were preceded by 4 min of adaptation to the field. A fixed yellow (575 nm) auxiliary field of $10^{11.2}$ quanta s^{-1} deg^{-2} was present throughout. The broken line has a slope of unity and corresponds to Weber's law. The thresholds deviate upwards from this line, showing the operational saturation described earlier. At the highest intensity of the 440-nm field, another class of cones becomes responsible for detection[10] and the function flattens. A conventional, random double-staircase procedure[13] was used to obtain these data.

In the central panel of Fig. 2, log threshold is plotted as a function of Δt, with the intensity of the 440-nm field as parameter. These data were obtained by the method of a thousand staircases and they show how the threshold reaches its final 'equilibrium' value. The broken lines project the

0028–0836/80/270059–04$01.00

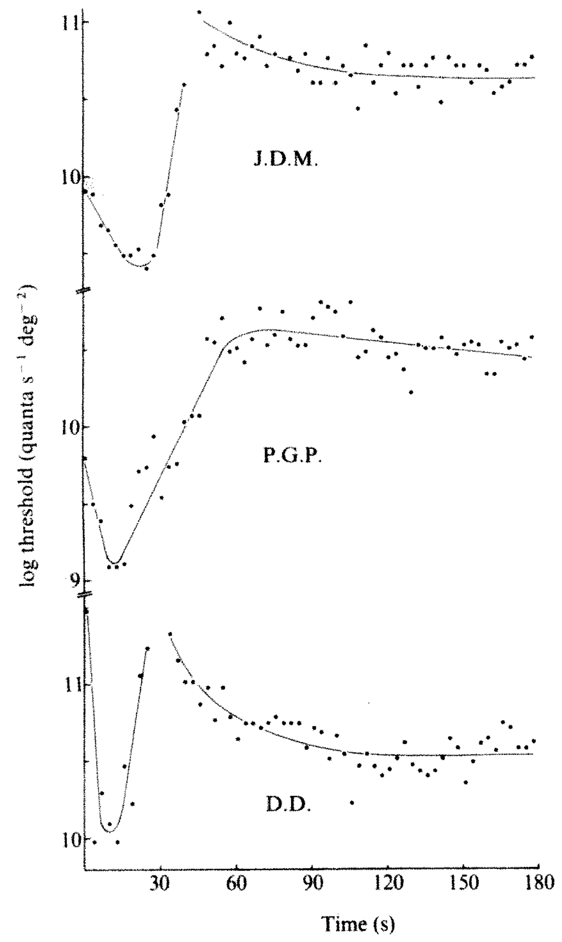

Fig. 1 Variation of log threshold intensity for detecting 436-nm flashes during the first 3 min of adaptation to a composite adapting field consisting of a 440-nm component at an intensity of $10^{10.6}$ quanta s^{-1} deg^{-2} and a 575-nm component at an intensity of $10^{11.7}$ quanta s^{-1} deg^{-2}. (The nominal chromaticity coordinates of this composite field are $x=0.45$, $y=0.47$.) The target flash subtended 1 deg of visual angle, was delivered to the centre of fovea and had a duration of 200 ms; the steady adapting fields were concentric with the target flash and subtended 6.5 deg. Target flashes were presented at 3-s intervals, each being preceded by a warning tone. A period of 2 min of dark adaptation preceded the onset of the fields. The solid lines are interrupted at values of Δt at which insufficient light was available to measure a threshold. Observers are denoted by initials.

asymptotic threshold levels to their rightful places on the t.v.i. curve. The 575-nm field remained the same intensity throughout and was combined in different sessions with different intensities of the 440-nm field.

The behaviour of the threshold changes systematically with small changes in the intensity of the 440-nm field. In all cases, the threshold passes through a minimum before rising again, but the more intense the field the earlier the minimum occurs and the steeper the slope of the rising part of the function. The latter trend can be seen in the data of Stromeyer *et al*[12]. Ancillary evidence suggests that for $\Delta t > 45$ s the upper limit to the family of functions in Fig. 2 depends on detection by a recovering long-wavelength mechanism (see also ref. 12, Fig. 14). At the lower field intensities, the functions resemble those given by Augenstein and Pugh[8] for light adaptation to long-wavelength fields alone. The left-most panel of Fig. 2 is discussed below.

Hitherto, we have treated the 575-nm field merely as an auxiliary field, serving to adapt the long- and middle-wavelength cones. If we assume that the spectral sensitivity of the short-wave receptors is approximately that of the psychological mechanism Π_3 (ref. 1, p. 18), then in our conditions the 575-nm field will contribute never more than 1% to the total number of photons absorbed in those receptors. Yet Fig. 3 demonstrates that this field (and thus probably a signal originating in the long- and middle-wavelength cones) is crucial to the temporal variation in sensitivity. In the control condition of this experiment (solid circles, Fig. 3) the onsets of the fields were simultaneous as before, but in the experimental condition (open circles) the onsets were uncoupled, the onset of the 575-nm field being delayed by 40 s relative to that of the 440-nm field. The delay chosen is equal to a Δt at which the threshold would have passed its minimum if the onsets of the fields had been simultaneous. Yet 40 s of pre-adaptation to the violet field has little effect on the function: the onset of the delayed yellow field finds the threshold close to the value for $\Delta t = 1$ s in the control condition and the threshold then passes through its curious oscillation as before; the rising part of the function is displaced along the abscissa by a delay (47 s) that is slightly greater than the imposed delay of the yellow field. Because it seems to matter only slightly whether or not the retina has been pre-exposed to the 440-nm component, the phenomenon must depend substantially on a signal originating outside the short-wavelength receptors. However, the 440-nm component (and thus, probably, the adaptive state of the violet-sensitive receptors) must be independently important, as variation in its intensity produces the family of functions seen in Fig. 2. The 7-s discrepancy noted in the present results may be attributable to the difference in the adaptive state of the short-wavelength receptors.

We relate the present phenomenon to a general model of the short-wave mechanism[14,15], in which it is supposed that signals originating in the short-wavelength receptors are transmitted only via chromatically opponent pathways[16-18] and that the sensitivity of the psychophysically defined short-wavelength mechanism depends on (1) the adaptive state of the short-wavelength receptors and (2) the balance of short- and long-wavelength signals reaching a chromatically opponent site. A crucial assumption is that a chromatically opponent channel is most sensitive to input perturbations when it is close to the centre of its operating range; as it is 'polarized' (that is, driven to one or other end of its operating range by, for example, a saturated blue or a saturated yellow field), incremental or decremental inputs are increasingly attenuated. In our experiments, yellow fields alter the measured sensitivity to short-wavelength targets primarily by altering the polarization of the opponent site, for they negligibly stimulate the short-wavelength receptors. The violet fields act both at short-wavelength receptors and at the opponent site, but, in the presence of the yellow field, contribute negligibly (<5%) to absorptions in the long- and middle-wavelength cones. Note that the most sensitive state of the opponent channel almost certainly does not correspond to the condition of equal rates of isomerization in the three classes of receptor; there is good evidence that the signal from the violet-sensitive receptors is disproportionately weighted in its contribution to this channel[19].

As a working hypothesis we suppose that the present phenomenon arises from a temporal variation in the signal delivered to the opponent site from the long- and middle-wavelength cones. A 575-nm field of $10^{11.2}$ quanta s^{-1} deg^{-2} has a troland value of $10^{5.0}$ and will bleach approximately 85% of the pigment in these cones[20]; most of the change in the proportion of unbleached pigment will occur in the first minute after onset of the field[21]. During this time the signal reaching the opponent site from these cones will presumably fall rapidly, owing both to bleaching and to other processes of receptor adaptation (see, for example, ref. 22). The photo-sensitivity of the short-wavelength cones is not known but our calculations suggest that they will not be substantially bleached by our 440-nm field. So we assume that during light adaptation to our composite field the signal from the long- and middle-wavelength cones is changing more rapidly than

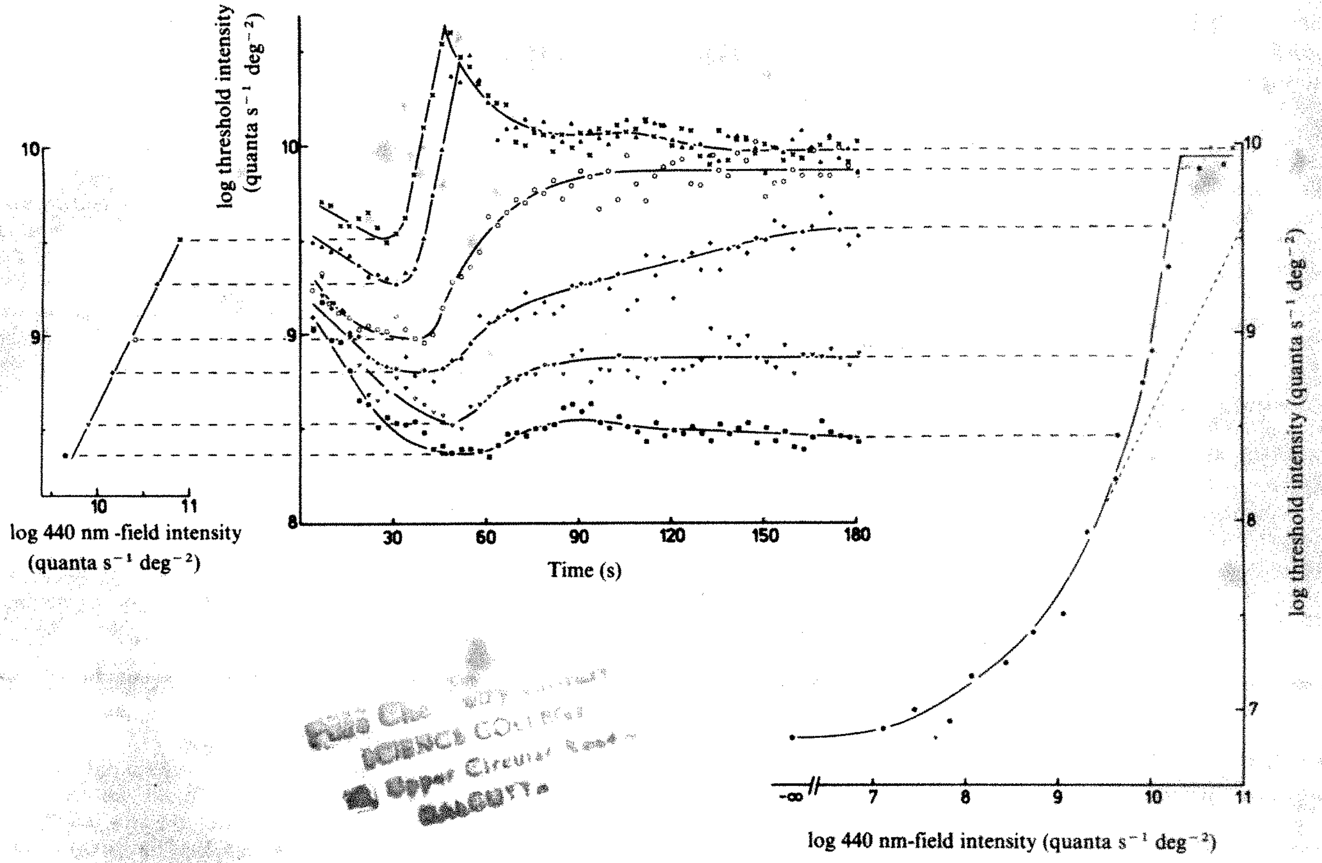

Fig. 2 Right-hand side: a conventionally obtained increment–threshold function for 436-nm test flashes presented on steady 440-nm fields of increasing intensity. A 575-nm auxiliary field of fixed intensity ($10^{11.2}$ quanta s^{-1} deg^{-2}) was present throughout. Thresholds were measured using a randomized double-staircase procedure and the plotted values are based on a sequence of 32 responses obtained between 3.5 and 5.5 min after onset of the composite adapting field, earlier responses being used to place the staircases close to the estimated threshold. Stimulus parameters were as for Fig. 1. Observer: J.D.M. Centre: temporal course of the threshold for detecting 436-nm test flashes during the first 3 min of adaptation to a series of composite fields consisting of a fixed 575-nm component of $10^{11.2}$ quanta s^{-1} deg^{-2} and 440-nm components of intensities: × $10^{10.88}$, ▲ $10^{10.63}$, ○ $10^{10.39}$, + $10^{10.14}$, ▽ $10^{9.88}$, ■ $10^{9.64}$ quanta s^{-1} deg^{-2}. Two experimental sessions were devoted to each of the latter values and the order of sessions was randomized. Left-hand side: minimal thresholds as a function of the log intensity of the 440-nm field. The solid line has a slope of unity.

that from the short-wavelength cones. The opponent site passes from being polarized in the yellow direction to being polarized in the other direction and the threshold, correspondingly, falls, passes through a minimum, and then rises again.

A further feature of the parametric results of Fig. 2 (central panel) is compatible with the hypothesis outlined above. The minima of the several functions should correspond to instants at which the opponent site is in the same (maximally sensitive) state. Differences between the minimal thresholds must then depend only on variations in sensitivity at more distal sites in the channel that carries the signal. In the left-most panel of Fig. 2 we plot the minima against the intensity of the 440-nm field: these values, unlike the asymptotes (right-most panel), obey Weber's law closely. As Weber's law (whatever its ultimate explanation) characterizes the threshold for large achromatic targets presented on bright steady fields, it is the behaviour that might be predicted when we hold constant the state of the opponent site. In other experiments we have held constant the 440-nm component of the field and varied the 575-nm component: in this case the minimum threshold, though reached at different values of Δt, varies little in its absolute value, as would indeed be predicted if (1) sensitivity at the distal site is predominantly set by the 440-nm component and (2) the minima represent equivalent states of the opponent site.

Is the hypothesis supported by the observer's

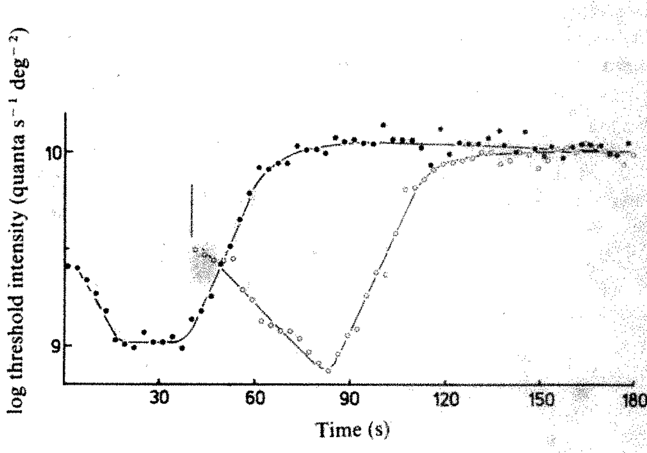

Fig. 3 Solid points: variation of log threshold intensity for detecting 436-nm test flashes during the first 3 min of adaptation to a composite adapting field consisting of a 440-nm component at an intensity of $10^{10.4}$ quanta s^{-1} deg^{-2} and a 575-nm component at an intensity of $10^{11.2}$ quanta s^{-1} deg^{-2}. Observer: J.D.M. Open points: results obtained when the onset of the 575-nm component of the field was delayed by 40 s. All points are plotted relative to the time of onset of the 440-nm component of the field. The onset of the delayed yellow field is indicated by a vertical bar.

phenomenological experience? Assuming that it is the central region of the field that is most relevant, the CIE chromaticity coordinates of the composite fields used for the measurements of Fig. 2 range from $x = 0.47$, $y = 0.50$ to $x = 0.36$, $y = 0.32$; but these chromaticities are not a good guide to the appearance of intense stimuli in transitional conditions. Formal phenomenological reports were obtained in separate runs in the conditions of Fig. 2. At onset, all fields were 'dazzlingly' bright and they varied in hue from 'yellow' to 'pale violet' according to the intensity of the 440-nm field. In all cases, after about 10 s, the field darkened strikingly and turned a grey or slate blue colour. After 60 s the colour was always pinkish, and, after 120 s, greyish. The sudden darkening always occurred a few seconds before the independently measured loss of sensitivity, and the value of Δt at which it occurred varied less with field intensity than did the point of minimum threshold. We therefore hesitate to relate the phenomenology to the processes, probably retinal, revealed by the sensitivity measurements; and the reader will have noticed that throughout this article we have avoided the term 'blue–yellow opponent channel'.

Visual acuity is better for letters in rows than in columns

R. D. Freeman

School of Optometry, University of California, Berkeley,
California 94720

The spatial resolving capacity of the visual system is usually measured with charts containing letters of different sizes displayed in horizontal rows or, less often, in vertical columns. Although previous studies suggest that acuity may not be equal for these two arrangements[1–7] it is implicitly assumed in clinical tests that orientation of an array of letters is of no consequence to the measurement. The work reported here shows that this assumption is incorrect. While undergoing an examination in an eye clinic, I noticed that letters of a given size seemed more difficult to identify when they were arranged in vertical compared with horizontal arrays. Subsequently, I tested a group of subjects using letters presented pseudo-randomly with different inter-letter spacings, in rows or columns. Subjects were required to identify letters from left to right or from top to bottom in each isolated row or column. A significantly higher number of errors was made for letters in columns than for those in rows. The effect does not depend on order or direction of letter presentation, and it is not found when acuity determinations are made using a non-letter test symbol. To explore the conjecture that the effect could be associated with previous experience, two additional groups of subjects were tested. First, bilingual Chinese, whose first language is read in both horizontal and vertical arrays, were tested using Chinese characters and English letters. Second, acuity determinations were made with young children who could identify letters but did not read. In each case, acuity was not significantly different for horizontal or vertical presentations, a finding consistent with the notion that learning may influence the development of visual resolution.

The tests were carried out with slides containing pseudo-random combinations of eight letters—E, H, R, N, O, X, D and V—arranged in groups of columns or rows. Each letter appeared once at a given inter-letter separation (see below). The slides were mounted in frames for use in a standard vision chart projector. Before the tests, the refractive condition of each subject was carefully determined. Subjects were rejected if a visual anomaly or considerable refractive error was found. Using appropriate ophthalmic lenses if required, subjects monocularly viewed letters that each initially subtended an anticipated threshold level of 4 arc min at the eye. (A 7.1-mm letter viewed at 20 ft subtends 4 arc min and if correctly read, an acuity of 20/15 is indicated.) Letters were presented in a column or row and all eight letters were shown at each of five inter-letter separations (2, 4, 8, 16, and 32 arc min). For each subject, the zoom lens on the projector was adjusted so that letters were small enough to be near threshold, as estimated by approximately 75% correct identification. Letters of all separations were then systematically presented in columns or in rows and subjects were asked to identify them from top to bottom or from left to right, respectively. Half of the subjects were tested using columns followed by rows and the other half were tested in the reverse order. No differences were found related to order of presentation. Ten letters were used at each inter-letter spacing, but only the inside eight were scored to avoid possible complications of edge effects at the ends of each row or column.

Results for 11 subjects, given in Fig. 1*a*, show that for both columns and rows, the error rate increases with decreased separation between letters, as could be anticipated from previous work[8]. However, in addition, the mean error rate is clearly higher for columns than for rows of letters and the overall difference is highly significant ($\chi^2 = 26.12$, $P = 0.0062$).

What can account for this difference in acuity between horizontal and vertical arrays of letters? An optical explanation of the effect can be ruled out immediately. The subjects used did not have high amounts of ocular astigmatism, and the moderate or small astigmatic errors found were of both vertical and horizontal types. In either case, these errors were fully corrected with lenses. Furthermore, when grating test targets are used to determine acuity, no differences are found between vertical and horizontal orientations[9,10]. This applies also to laser-created interference-fringe gratings for which the effect of the eye's optics are essentially bypassed[10].

One must therefore propose an alternative explanation for the effect found here and an obvious possibility is that the development of visual acuity for arrays of letters is associated with learned patterns of reading. Specifically, because we learn to read rows of letters, finest acuity develops correspondingly for horizontal displays. Because we also learn to read from left to right, acuity may be superior for this direction compared

0028-0836/80/270062-03$01.00

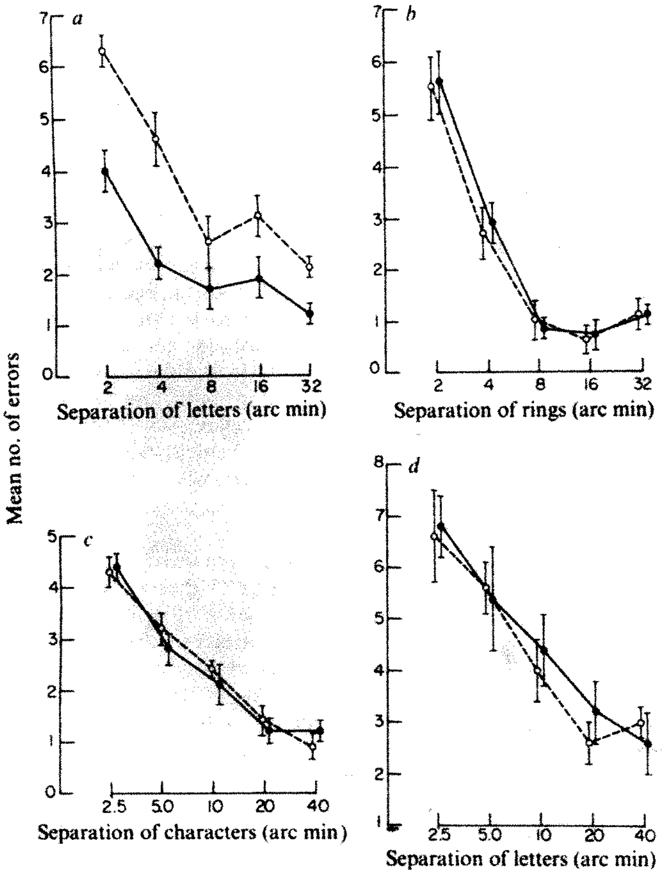

Fig. 1 Results are given for visual acuity tests using letters with adults (*a*) or children (*d*), Chinese characters with Chinese subjects (*c*), or Landolt rings (*b*), presented in vertical columns (open symbols, dashed lines) or horizontal rows (filled symbols, solid lines). Each point represents the mean number of errors for eight presentations at given inter-letter (or character or ring) separations. Vertical bars represent ±1 s.e.m. Abscissae are scaled logarithmically.

with the reverse. To examine this possibility, a second group of subjects, most of whom were included in the first group, was tested with the same letter chart used before. Only, in this case, letters were identified from right to left in rows or from bottom to top in columns. Results were very similar to those shown in Fig. 1*a*, with a significantly higher number of errors found for columns than for row arrays. The acuity effect is therefore selective for orientation but not for direction. If there is a direction-selective component, a more sensitive measure which might incorporate temporal factors is required for its study.

The hypothesis linking visual acuity development and experience applies to letters that must be recognized. For simpler acuity targets that require detection only, learned reading habits do not apply and therefore, differences between rows and columns would not be expected. To determine this, acuity was measured using Landolt rings, which contain a gap at the top, bottom, left or right whose subtense is 1 arc min at 20 ft. These were presented in rows or columns with inter-ring separations, just as in the previous case. The same group of subjects, whose letter acuities are shown in Fig. 1*a*, were tested using Landolt ring targets and the results are given in Fig. 1*b*. Clearly, there is no difference between acuities for rings in rows as compared with columns. In both cases, the data show a very high mean error rate for closely spaced rings, suggesting that this type of detection task may be more difficult than letter identification when test arrays are dense. It thus seems that acuity differences between rows and columns of test objects may apply specifically to letters; this is consistent with the idea that they are related to learned reading patterns.

It would be possible to test this notion more directly by measuring acuity of subjects whose language is read and written primarily in vertical rather than horizontal arrays. In this case, acuity would be expected to be reduced for rows instead of columns of letters. However, there are apparently no common languages that are arranged only in vertical columns. On the other hand, modern Chinese is read and written in both columns and rows so that no bias would be expected on the basis of learned reading patterns. Ideally, it would be best to test Chinese subjects who do not read or write English. This was not practical, but it was possible to measure acuities of bilingual Chinese subjects for whom English is a second language learned during teenage years. Following thorough refractions, acuities were determined using eight standard Chinese characters, chosen for simplicity, which each subtended 5 arc min initially. Inter-character separations were 2.5, 5, 10, 20 and 40 arc min. In addition, acuities were also determined with this group using the English letter chart. The results for characters, presented in Fig. 1*c*, clearly show that there are no acuity differences between rows and columns (confirmation is provided by the χ^2 statistic). Results with this same group using English letters showed a tendency for an increased number of errors for column arrays, but this trend is not significant (χ^2 statistic).

Although unlikely, it could be argued that there are inherent racial differences in visual resolving capacities between these Chinese subjects and the American group tested previously. The possibility is easy to rule out, however, by measuring acuity for English letters using Chinese–American subjects who have never learned to read or write characters. Five subjects in this category were tested with the same chart as used for the initial group of Americans. The results were virtually identical to those for the latter group and it may thus be concluded that inherent racial factors are not involved in the findings described here.

One additional group of subjects was tested. If an acuity bias for horizontally arranged letters develops as a result of learned reading patterns, subjects who know the alphabet but do not yet read should not demonstrate a difference between rows and columns of letters. Five children, aged 4–5 y, were refracted and then shown the eight letters used on the chart to insure that they could identify them. Acuities were then determined, the results for which are shown in Fig. 1*d*. As might be expected, variability is greater than that for the other groups, but there are no consistent differences between rows and columns.

Taken together, the results of this study suggest that visual acuity performance for letters is related to reading patterns learned in childhood. The finding which is not compatible with this idea is that the acuity difference between rows and columns holds for right to left identification as well as the reverse. It is possible, of course, that a directional effect could be found using different tests. In any case, the neural mechanism that underlies the relatively high acuity for horizontal arrays may be concerned primarily with fixation. For example, contours adjacent to a letter that interfere with its resolution[11,12] may be more effectively masked in row arrays. The advantage of horizontal letter displays, in terms of acuity, may be relevant to other work showing that reading speed is slower[3,4] and word or pseudo-word identification poorer[5–7] for vertical compared with horizontal arrangements of letters. Further study is required to determine the relative importance of factors such as spacing and numbers of letters in a given array. In addition, it would be interesting to know if eye movement patterns differ for reading in row as opposed to column arrangements.

I thank Dr G. Kaprielian for help with this study, Dr C. Chan for constructing Chinese characters and Dr Doris Lin for help with Chinese translations. This work was supported by Research Career Development Award EY00092 and grant EY01175 from the USPHS.

Eye movement in strabismic cats

Max Cynader* & Laurence Harris

Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4JI

Strabismus is a common clinical condition in which the visual axes of the eyes do not intersect on the object being viewed[1]. As such, the ability to achieve single binocular vision by fusing the images of a single object in the two eyes is lost. In most cases of strabismus, one of the two eyes is clearly deviated and the other eye is used for fixation, although in some cases each eye is used alternately for fixation[2,3]. While much attention has been devoted to the motor capabilities of the deviating eye in strabismus[1–3], little attention has been given to the visuomotor competence of the other eye. We report here that, if one eye of a kitten is made to deviate by surgery, the visuomotor capacities of the other, 'normal', eye are affected. A reduction in the ability to follow the movement of a large striped drum is observed with binocular viewing, even when stimuli are viewed monocularly with the normal eye. This means that anomalous visual input from the deviated eye during stimulation is not the cause of the reduced oculomotor capacities.

Divergent strabismus was induced in three 10-day-old kittens by severing the medial rectus muscle of the right eye. The left eye was not touched. The kittens were then reared normally in a well-lit laboratory environment until they were 8–12 months old. At this time the normal undeviated eye of the cat was prepared for eye movement recording by implanting a magnetic search coil according to the technique of Robinson[4]. In addition, head restraining tubes were attached to the skull by means of dental acrylic[5]. Surgery was performed under Alfathesin anaesthesia and the animals were allowed at least 2 weeks to recover before recording began. The eye movements of the three strabismic cats were compared with those of three normal cats studied with the same techniques.

We primarily studied eye movements evoked in response to visual and vestibular stimuli in the horizontal plane. When a large striped drum is rotated about a cat, a characteristic pattern of eye movement called optokinetic nystagmus (OKN)[6] is evoked with a time course resembling a sawtooth. The slow phase of this response matches the velocity of the drum in normal cats and thus compensates for the motion of the drum and permits clear vision. Figure 1 compares the velocity of the slow corrective phase of optokinetic nystagmus (measured in the nondeviating eye) of strabismic cats with that of normal cats as a large striped drum is rotated about the animal at various velocities. The results show that the normal cat is able to match the velocity of his eyes to that of the drum rather well over most of the velocity range tested.

By contrast the velocity match of the apparently normal eye of the strabismic cat with that of the drum is much less accurate. For all drum velocities above 4° per s, the eye rotated more slowly than did the drum. This lessened response to visual stimulation is unlikely to be due to any generalized deficit in oculomotor capacity, due, for example, to mechanical impediments which might have resulted from implantation of the eye coil or from the early surgical procedures on the other eye. The eye movement responses to vestibular stimulation as assessed by rotating the cat sinusoidally in the dark were the same in normal and strabismic cats. In both normal and strabismic cats, the vestibulo-ocular reflex was able to compensate for the head and body movement induced by rotating the cat[5,7]. Thus, the deficit in oculomotor capabilities seems to be specifically related to the response to visual stimuli.

The results illustrated in Fig. 1 were obtained with both eyes open and did not permit assessment of the contribution of vision with each eye to the reduced oculomotor response of the nondeviating eye. Accordingly we measured optokinetic responses of the 'normal eye' to visual stimuli presented through either eye. The interpretation of the monocular stimulation findings (Fig. 2) is rendered more difficult by the finding that monocularly-viewed stimuli moving medially (that is, rightward viewed through the left eye) were more effective at eliciting OKN than lateral-directed stimuli even in normal cats[8]. This difference in the effectiveness of medial and lateral-directed stimuli was also observed with monocular stimulation of the nondeviating eye in the strabismic cats. It is clear, however, that the efficiency of OKN was decreased markedly for both medial and lateral stimulus motion, relative to that of the normal animals. This defect in monocularly-evoked OKN rules out anomalous visual input through the deviating eye during the stimulation period as a possible cause of the reduced OKN observed with binocular stimulation. Visuomotor performance mediated by stimuli presented through the deviating eye was also severely impaired. Figure 2*b* shows optokinetic responses of the nondeviating eye to visual stimuli viewed monocularly through the deviating eye. These data show that reduced OKN followed stimulation of the deviating eye when stripes moved in either direction. The

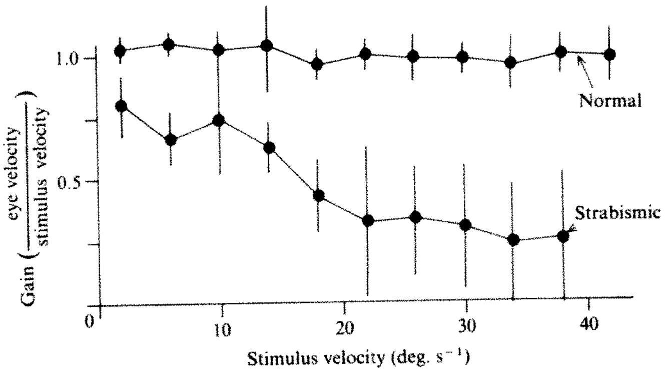

Fig. 1 The gain of optokinetic nystagmus as a function of drum speed for the normal and strabismic cats. The gain of the response is the velocity of the slow phase[6] of the optokinetic response divided by the velocity of the drum. A gain of 1 indicates perfect following of the drum by the eyes. The gain of the normal cats is close to 1 over most of the velocity range tested while that of the strabismic cats is markedly lower. The drum consisted of a large cardboard cylinder 90 cm in diameter on which high contrast black and white vertical stripes (period 20°) were painted. Background luminance was 0.1 cd m^{-2}.

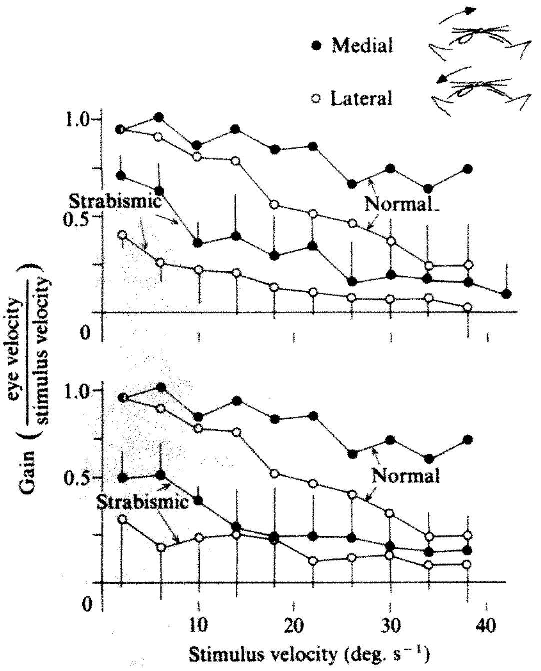

Fig. 2 *a*, The gain of the slow phase of optokinetic response in normal and strabismic cats when stimuli are viewed with the nondeviated eye only. The gain of the reflex is lower for laterally-directed high velocity drum movement than medially-directed movement in both the normal and strabismic cats. The gain in both directions is considerably lower for the strabismic cats than it is for normal cats even though the strabismic animals viewed the stimulus through the nondeviated eye. In normal cats, the gain of the reflex is the same regardless of whether the monitored eye or the other eye alone views the stimulus, as would be expected from Hering's Law[16]. *b*, Responses to drum motion when the strabismic animals view through the deviating eye alone are compared with those of normal cats viewing monocularly. The deficits observed in the visuomotor capacities of the strabismic cats are similar regardless of which eye views the moving stimulus. The standard deviations (s.d.) have been omitted from the curves representing responses of the normal cats for clarity. A typical value for the s.ds in this case is 0.15. Drum parameters are as in Fig. 1.

deficits of OKN were similar with stimulation of either the deviating eye or the nondeviating eye.

The present results show that the visually-evoked eye movements mediated through an apparently normal eye can be altered by surgical exodeviation of the other eye. The eye movement deficit seems to be specific to visual stimulation as vestibular stimulation evoked normal oculomotor responses. The mechanism underlying this reduced visuomotor competence remain unknown but several anomalies identified in various parts if the visual system in strabismic cats[9–11] help towards its understanding. We have recently recorded visual responses in the nucleus of the optic tract (NOT) of strabismic and normal cats[11]. Our findings in this structure, which has an essential role in optokinetic nystagmus[12,13], indicate marked changes in binocular connectivity among NOT neurones following surgically-induced strabismus. These neural changes may provide a basis for the visuomotor deficits found in the strabismic cats. It would be interesting to see if similar defects exist in the normal eye of human strabismics, particularly in view of the recent findings suggesting defects on OKN in the normal eye of amblyopic humans[14,15].

Genetic control of sensory connections in *Drosophila*

Philippe Vandervorst & Alain Ghysen

Laboratoire de Génétique, Université Libre de Bruxelles, 67 rue des Chevaux, 1640 Rhode-St-Genèse, Belgium

The function of the nervous system depends on the formation of a net of appropriate connections. This process must be at least partly under genetic control, yet the genetic analysis of the development of specific nerve connections has so far made little progress (reviewed in ref. 1). This is in part because of the immense complexity of the connective net. The problem is simpler in the case of insect secondary neurones which are derived from the epidermis and send their axons centripetally towards the central nervous system[2]. The arrangement of sense organs on the body surface is very reproducible in many cases, so that given neurones can be recognized unambiguously in different individuals. In *Drosophila*, the genetic analysis of development has so far concentrated on the epidermis. The genetic control of segmentation is relatively well understood[3,4] and it has been found that segments are progressively subdivided in smaller developmental units called compartments[5]. This led to the speculation that sensory neurones belonging to different compartments might have different properties[6]. Here we show that the stimulation of mechanoreceptor bristles at different positions on the notum and legs of *Drosophila* specifically evoke different behavioural responses. This specificity depends on the segmental and in some cases on the compartmental identity of the bristle, but not on the site of entry of the axon into the central nervous system.

Decapitated flies remain alive and standing for up to 20 h. They remain motionless if left undisturbed, although they are able to stand up if overturned, or to walk a few steps if pushed. The tickling of single bristles induces several reactions: wing scissoring, withdrawal of the stimulated body part, and vigorous cleaning by a leg. The latter reaction was analysed in more detail, for it provides a specific and easily scored response. The response evoked by the different macrochaetes on the humerus and notum is quantified in Fig. 1. The microchaetes on the notum were also examined, but their small size and high density makes it impossible to stimulate them individually. It appears from Fig. 1 that the notum is divided in two regions, one where all the bristles evoke a response of the first (and to some extent of the second) leg, and the other which stimulates the third leg. It should be noted that no bristle evoked specifically a response of the second leg, but that such a response was observed in many cases as an alternative to the response of the first leg, mostly after the latter had already responded repeatedly to

0028-0836/80/270065-03$01.00

continuing stimulation of a given bristle. In order to characterize the specificity of the response further, we have analysed two mutations which result in the development of a supernumerary notum at an ectopic location. The mutation *wingless* transforms the wing to a notum in mirror image symmetry to the normal notum[7]. In this case the axons from the ectopic bristles join those from the normal bristles and enter the thoracic ganglion at the normal place[8]. We have confirmed that the ectopic bristles induce the same response as their normal homologues[8]. The double mutation *bithorax*^{3} *postbithorax* transforms the bare, vestigial metanotum into a mesonotum bearing the whole complement of notal bristles[9]. Here the axons from the ectopic bristles enter the thoracic ganglion much posterior to the normal place[10]. The stimulation of these ectopic bristles gives a pattern of responses which is identical to the pattern of the normal mesonotum both in the specificity and in the frequency of the responses (Fig. 2).

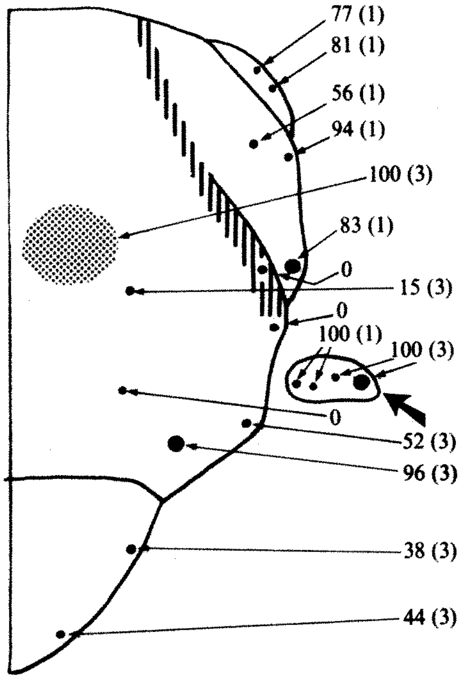

Fig. 1 Frequency and specificity of response to stimulation of the bristles on the notum and tegula. Flies of wild type Canton S strain were exposed to ether, decapitated and left to recover for 1–2 h in a moist environment. Stimulation was achieved by gently touching individual bristles with a hair. A micromanipulator was used in some cases. The numbers give the proportion of flies (out of 48) where a given bristle evoked a cleaning movement by a leg. The numbers in parentheses indicate which leg responded (1: prothoracic leg, 3: metathoracic leg). Bristles represented by large dots were selected for the analysis of the homoeotic situation in Fig. 2. The tegula is drawn at the side of the notum (arrow). The dotted area represents the region where groups of microchaetes were stimulated. The dashed stripe separates the zones which evoke responses of the first and third legs respectively.

The bristles on the legs were also characterized (Table 1). As for the microchaetes on the notum, most of the leg bristles are too small and dense to be stimulated individually. However it appeared that groups of microchaetes on the anterior and posterior regions of the first and third legs give different responses, and therefore the bristles of the two regions have been listed separately in Table 1. We have attempted to define more precisely the limit between the leg bristles which give an 'anterior' response and those which evoke a 'posterior' response in the case of the femur and tibia of the first and third legs. The results are shown in Fig. 3; the figure also shows the boundaries separating the anterior and posterior developmental compartments of these legs[11]. The coincidence between the sensory and the compartmental boundaries is obvious.

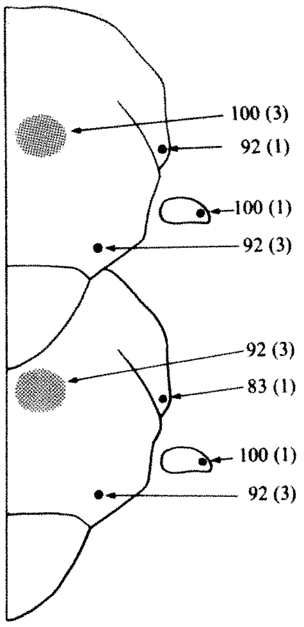

Fig. 2 Frequency and specificity of the responses in the mutant bx^3pbx/Ubx^{105}. The normal mesonotum is above, the transformed metanotum is below. The bristles marked by large dots on Fig. 1 have been selected because they give a high frequency of response. The numbers are as in Fig. 1, except that 12 flies were analysed.

There is a second situation where an apparently homogeneous population of bristles is divided by a compartmental boundary. The limit between the thorax and wing compartments runs through the tegula, a sclerite at the base of the wing. It is remarkable that within this small area, two of the bristles evoke an intense response of the first leg while two others induce a movement of the third leg (Fig. 1, arrow). However, in this case the identity between sensory and compartment boundaries cannot be assessed, since the exact position of the compartment boundary has been reported as variable within the tegula[12].

Table 1 Frequency and specificity of responses to stimulation of leg bristles in wild-type *Drosophila*

	wtd	2nd	contra
AFe 1	83		33
PFe 1	13	92	
ATi 1	63		46
PTi 1	71	21	4
AFe 2	100		
PFe 2	100		
ATi 2	100		
PTi 2	100		
AFe 3	33	88	4
PFe 3	71		15
ATi 3	79	21	
PTi 3	63		25

The left column indicates the stimulated area. AFe and PFe: anterior and posterior femur; ATi and PTi: anterior and posterior tibia; 1, 2 and 3: first, second and third legs. The next three columns represent the three responses which have been scored. wtd: withdrawal of the stimulated leg; 2nd: cleaning of the stimulated leg by the second (mesothoracic) leg; contra: cleaning of the stimulated leg by the contralateral leg. The numbers represent the per cent of flies (out of 48) where a given stimulation evoked a given response. The numbers add up to more than 100 because the stimulation of a given set of bristles may evoke different responses.

Our results on wild-type flies indicate that the connections established by a sensory neurone depend on its position in two different ways. In the case of the legs, the specificity of the response clearly depends on the segmental identity of the neurones. Furthermore, within each leg, groups of bristles with different specificities can be detected. In those cases where a detailed analysis could be done, the limit between groups of bristles which evoke different responses appeared to coincide with the position of the anterior–posterior compartment boundary. The same is probably true in the case of the tegula, although the position of the compartment boundary is not as precisely defined as it is in the legs. These results show that the choice of a given pattern of connections depends on the segmental and compartmental identity of the neurone. Recent experiments have shown that the establishment of a given projection in the central nervous system also depends on the developmental history of the sensory neurone in the locust[13], and on the segmental and compartmental identity of these neurones in *Drosophila*[14].

In the case of the notum, the different specificities of the anterolateral and dorsoposterior bristles must depend on something other than the compartmental identity since all these bristles belong to the same compartment. In this case, the decision to establish a given type of connection appears to depend on the position of the bristle along the anteroposterior (and possibly mediolateral) axis of the body. A similar dependence of the evoked behavioural response on the position of the sense organ along a body axis has been reported in the pupa of *Sphinx ligustri*[15]. Our results indicate that the neurones retain their specific pattern of connections even when they enter the central nervous system at an abnormal place. This may be related to the fact that ectopic or misrouted neurones which enter the central nervous system at an abnormal place can nevertheless establish a normal projection[10].

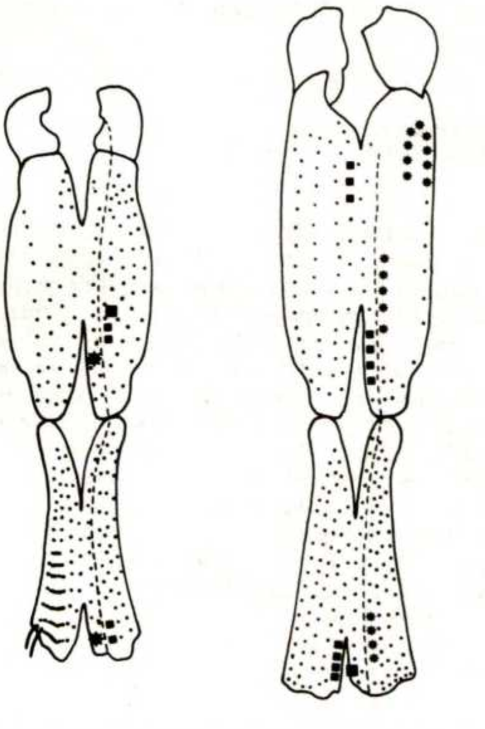

Fig. 3 Response of single bristles or rows of bristles on the prothoracic (left) and metathoracic (right) legs. All the leg bristles are represented by dots. Bristles which induce a withdrawal of the leg or a cleaning response of the contralateral leg are marked with asterisks, bristles which induce a cleaning movement of the mesothoracic leg are marked with solid squares. The broken line shows the position of the anterior–posterior compartment boundary. The chaetotaxy of the legs and position of the boundary are from ref. 11.

The behavioural approach used in this work was originally suggested by Don Ready. We thank R. Thomas for support and critical reading of the manuscript. This work was carried out under a contract between the Belgian government and the University of Brussels. P.V. is supported by the IRSIA; A.G. is chercheur qualifié of the FNRS.

Testosterone-sensitive neurones respond to oestradiol but not to dihydrotestosterone

K. M. Kendrick & R. F. Drewett

Department of Psychology, University of Durham,
Durham DH1 3LE, UK

Testosterone is aromatized to oestradiol in the brain, and it has been suggested that its effects on the brain are produced by this metabolite[1]. Oestradiol does indeed restore sexual behaviour in castrated rats[2,3], but it is much more effective if combined with a second metabolite, dihydrotestosterone[4,5]. This may be because the two hormones have a synergistic effect on the brain; or because the central effect of oestradiol synergises with the peripheral effects of dihydrotestosterone (which include stimulation of penile development). Evidence that the corticomedial amygdala (CMA) and the preoptic area of the rat brain are both involved in the control of sexual behaviour led us to examine the neurones of the stria terminalis that connect the two[6,7]. These neurones are hormone-sensitive; their absolute refractory period is lengthened by castration and reduced again by testosterone. So we have investigated the aromatization hypothesis further by examining the effect of oestradiol and dihydrotestosterone on these testosterone-sensitive neurones. Oestradiol has exactly the same effect as testosterone; dihydrotestosterone has no effect, whether it is given alone or in combination with oestradiol.

Thirty-two virgin, adult male Wistar rats (400–650 g) were divided at random into four groups of eight and castrated under ether anaesthesia. Eight weeks or more after castration, rats in each group were assigned to treatment with (1) 5 µg oestradiol benzoate (OB), or (2) 1 mg 5α-dihydrotestosterone propionate (DHTP), or (3) 1 mg DHTP + 5 µg OB, or (4) oil vehicle alone. These doses were chosen because they restore full sexual behaviour in the castrated male rat when OB and DHTP are given in combination[4,5], but not when each is administered alone[2–5]. Treatments were administered as two daily 0.1-ml subcutaneous injections, for 18–22 d. The hormones were provided for us in unlabelled, coded bottles, and we did not know which animal received which treatment until the experiment was finished and the code was broken.

For electrophysiological recording the animals were anaesthetized with urethane (1.3 g per kg, intraperitoneally)

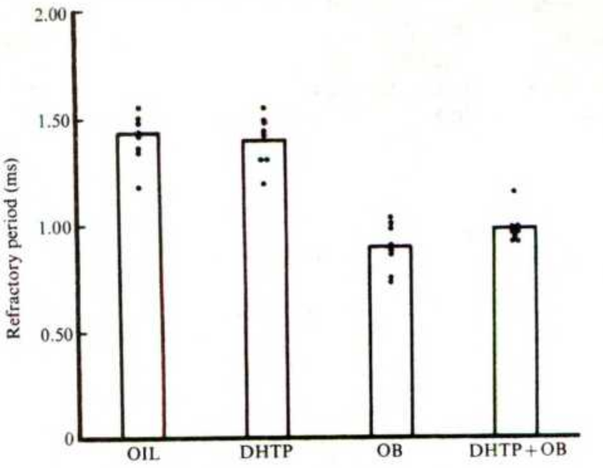

Fig. 1 Absolute refractory period of CMA neurones projecting to the MPH in castrated rats treated with oil (69 neurones from eight rats); DHTP (74 neurones from eight rats); OB (80 neurones from eight rats), or DHTP+OB (87 neurones from eight rats). Figure gives the overall mean and individual means (dots).

and mounted in a conventional stereotaxic frame (Kopf Instruments). Coordinates for electrode placement were the same as given in refs 6 and 7. A monopolar stainless steel electrode, insulated to within 0.5 mm of the tip, was used to stimulate the medial preoptic-anterior hypothalamic area (MPH) with cathodic monophasic pulses (current 50–500 μA; duration 0.5 ms). Glass micropipettes filled with 0.5 M sodium acetate plus 2% pontamine blue were used to make single-unit extracellular recordings from CMA neurones. No recording electrode was used in more than one animal. At the end of each experiment a small current was passed through the stimulating and recording electrodes to facilitate histological localization. The rats were perfused *in situ* with a 10% formol saline to which a small amount of potassium ferrocyanide had been added. Brains were mounted in paraffin wax, sectioned at 15 μm and stained in cresyl violet and luxol fast blue.

Absolute refractory periods were determined in a total of 310 CMA neurones stimulated antidromically from the MPH. The criteria for antidromic invasion and the method for estimating the absolute refractory period of CMA neurones were the same as in refs 6 and 7. The results were analysed as follows. The refractory periods for all neurones isolated in a given rat were reduced to a single mean. These means (eight for each of the four groups) were then analysed by analysis of variance, followed by the Scheffé test[8].

Results are shown in Fig. 1. Overall analysis of variance showed that the groups were significantly different ($F = 56.80$, with d.f., 3, 28; $P < 0.001$). The Scheffé test showed that oestradiol significantly reduced the refractory period (oil compared with OB, $P < 0.001$). Dihydrotestosterone (unlike testosterone[6,7]) had no effect when given alone (oil compared with DHTP was not significant) and no additional effect when given in combination with oestradiol (OB compared with DHTP+OB, not significant.)

The mean absolute refractory period for neurones in the group of gonadally intact rats in our earlier experiment was 1.01 ms, with 95% confidence limits of 0.89 and 1.13 ms; the mean for the group of castrated rats was 1.61 ms with 95% confidence limits of 1.37 and 1.85 ms. The mean absolute refractory periods for the OB and the DHTP+OB groups in this experiment (0.90 and 0.98 ms) are therefore within the 95% confidence limits of our earlier intact group and those for the group treated with DHTP (1.40 ms) are within the 95% confidence limits of our earlier castrated group. These comparisons demonstrate that the refractory periods for CMA–MPH neurones in animals that are castrated but treated with oestradiol are not significantly different from those in gonadally intact animals.

Thus, our results show that oestradiol has the same effect on a population of testosterone-sensitive forebrain neurones as testosterone itself, as would be predicted from much indirect evidence. Dihydrotestosterone, on the other hand, has no effect on these neurones, and does not enhance the effect that oestradiol has on them.

Although we have not excluded the possibility that higher doses of dihydrotestosterone might have such an action, these results suggest that in behavioural experiments with the two hormones in doses comparable to our own, the increased sexual behaviour that is induced by dihydrotestosterone is not attributable to an action of the hormone on forebrain neurones comparable with that of testosterone and oestradiol. There is independent evidence that dihydrotestosterone has a different site of action, for the stimulating effect of testosterone on spinal sexual reflexes is mimicked by dihydrotestosterone, but not by oestradiol[9].

Activity-dependent extracellular K^+ fluctuations in canine Purkinje fibres

Richard P. Kline*†‡, Ira Cohen*, Robin Falk* & Joel Kupersmith†

*Department of Physiology and Biophysics, SUNY, Stony Brook, New York 11794

†Departments of Pharmacology and Medicine, Mount Sinai School of Medicine, CUNY, New York, New York 10029

Cardiac Purkinje fibres are important in cardiac electrophysiology and pathology due to their specialized role in the ventricular conducting system, and their properties as a second cardiac pacemaker[1]. Changes in extracellular K^+ activity (K_0) affect the conduction velocity[2] and the natural automatic rate of the Purkinje fibre[3]. Both anatomical[4] and electrophysiological[5,6] studies of the Purkinje fibres have demonstrated the possibility of K_0 fluctuations in the narrow intercellular clefts. We investigated, using K^+ selective electrodes, the effect of the K_0 fluctuations observed during activity in canine Purkinje fibres. Summation of K_0 fluctuations during single action potentials leads to elevation of baseline K_0 during rapid trains. However, unlike in ventricular muscle where depolarization is seen[7,8], membrane potential in non-automatic Purkinje fibres hyperpolarizes in response to rapid beating. Prolonged depletions of extracellular K^+ following long periods of overdrive are associated with slowly changing membrane currents, which markedly influence automaticity, action potential duration, and membrane potential.

Free running canine Purkinje fibres were removed from left and right ventricles and perfused in well oxygenated Tyrode solutions containing the following, 4 mM KCl, 2 mM $CaCl_2$, 130 mM NaCl, 1 mM $MgCl_2$, 0.4 mM NaH_2PO_4, 12 mM $NaHCO_3$, and 6 mM glucose. *p*H was maintained at between

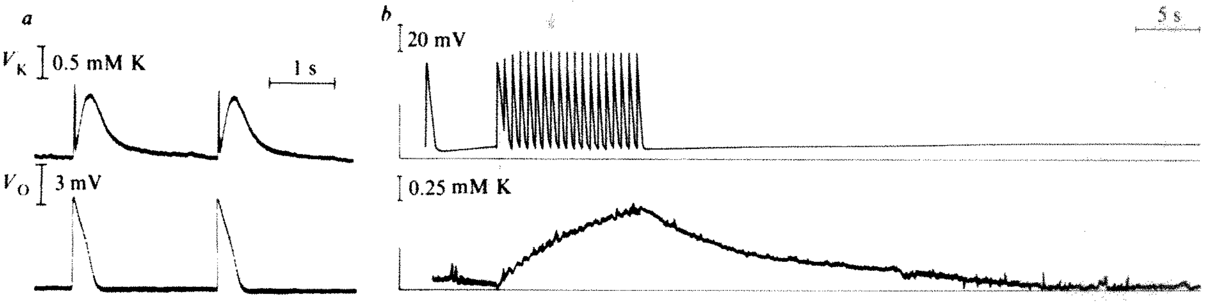

Fig. 1 (*a*), Top trace. (V_k) is the differential output of the two K^+ electrode barrels and represents the K_0 fluctuations during two single beats. The initial spike on this trace is an artefact due to the inability to reject stimulus voltage. Bottom trace: (V_0) is simultaneous output of the K^+ electrode reference barrel (37 °C). (*b*), Top trace. (V_m) is membrane potential measured with a conventional intracellular microelectrode. Bottom trace: (V_k) is differential output of K^+ electrode and represents K_0. No beat to beat accumulations are seen with this electrode tip position. K_0 accumulates slowly during 10 s of stimulation at 1 beat per 600 ms (37 °C).

'.2 and 7.4; the temperature was kept stable at the levels ndicated.

Double barrel K^+ sensitive electrodes (Corning liquid ion xchanger 477317) were constructed from theta glass double hannel tubing and calibrated for selectivity and response time sing methods previously described[7]. To measure K^+ activity evels, the output of the Tyrode-filled reference barrel (V_0) was ubtracted from the output of the K^+ selective barrel ($V_k + V_0$). The differential channel output (V_k) represents the K^+ activity evels, which for small changes vary approximately linearly with K^+ activity.[8]

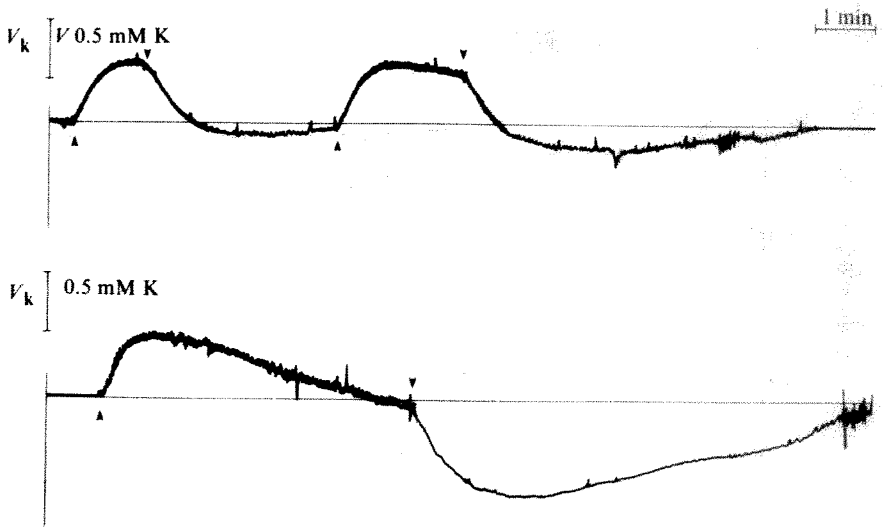
Due to the somewhat slower response time of the K^+ elective barrel (20 ms), capacitive compensation was used to peed this barrel while a variable 'roll off' filter (Bloom) was sed to slow the reference barrel output before differential mplification. Common mode rejection of the two barrels was djusted to within 0.1% by a variable gain circuit.

K^+ electrode experiments were performed on the largest of he canine Purkinje fibres to facilitate manipulation of the lectrode and minimize the effect of tissue dimpling. Voltage lamp experiments were performed using the two-microelectrode voltage clamp method[6] on the short fibres of arrow radius (length, 1.5 mm; radius 0.15 mm). These fibres were dissected into short sections while being continually perfused with a high calcium (4 mM) Tyrode solution. In these mall fibres, clamp steps could be applied with acceptable evels of current magnitude and a good spatial homogeneity[9]. These fibres have K^+ currents similar to those described in ungulate[10].

To measure K_0 fluctuations, K^+ electrodes were slowly inserted through the sheath of the fibre bundle under constant observation through a dissecting microscope. To minimize tissue distortion, electrodes were made with fine tips (1–2 μm in total outer diameter). In fact, frequently cells were inadvertently punctured while the K^+ electrode was being advanced, such that normal action potentials were measured with the reference barrel, along with very high K^+ activity levels (but no beat to beat fluctuations) on the differential output. On withdrawal (or further advance) of the electrode tip, there was an abrupt fall in measured K^+ levels. At the same time, potential on the reference barrel returned to within several millivolts of ground level. One criterion for determining that the K^+ electrode was located extracellularly was that measured K^+ activity levels during quiescent equilibrium states were near bath levels, and were responsive to changes in bath K^+ levels[8].

Figure 1*a* shows K_0 accumulation measured during a single action potential. This beat to beat fluctuation occurs only when the electrode is near a cell membrane. The accumulation developed rapidly during the plateau of the action potential and then began to subside during fast repolarization. There is an initial rapid fall of K_0 which may have been influenced by the effect of active uptake processes on the narrow cleft spaces. During rapid beating, in addition to the K_0 fluctuations during single beats, there is an overall accumulation as beats occur progressively earlier during diastolic decay of K_0 (ref. 8). The post train decay of K_0 now exhibits a slow tail following the initial rapid decline, where the time constant of the slow

Fig. 2 K_0 fluctuations (V_k) during and after 1, 2 and 5 min periods of overdrive at 1 beat per 300 ms. K_0 undershoot of the baseline implies extracellular K^+ depletion. Solid arrow 'up' indicates start of stimulus drive; arrow 'down' indicates stimulus drive off (37 °C).



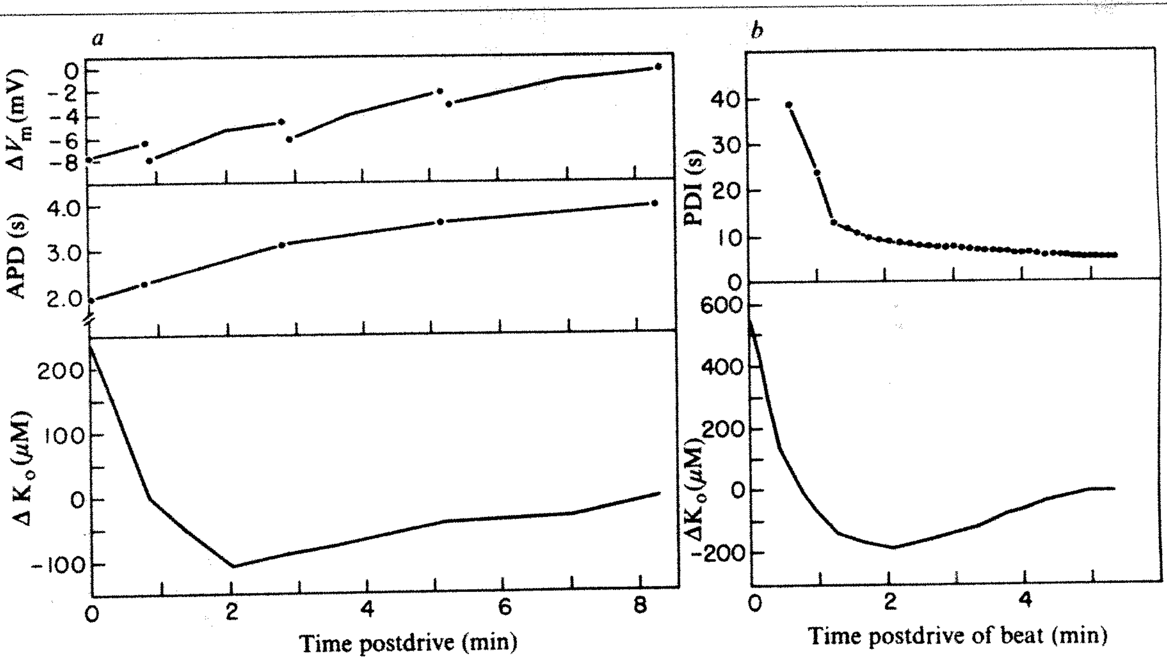


Fig. 3 (*a*), Return of V_m and action potential duration (APD) to control values following overdrive, plotted with simultaneously measured K$^+$ depletion. The '0' value on the K$_0$ axis corresponds to baseline levels of K$_0$(22 °C). (*b*), Comparison of return of automaticity with K$_0$ postdrive. Each point in the top panel represents a single action potential. Vertical axis is duration of previous diastolic interval (PDI) for each beat. (37 °C; difference in time course of undershoot in *a* and *b* is due to temperature difference.)

component reflects the diffusion relaxation time for the entire cylindrical preparation[7].

If the electrode tip is in a more superficial position in the fibre bundle, beat to beat accumulations are not seen. This is probably due to the longer diffusion pathway between the clefts and the electrode tip, and the resulting time average of observed K$_0$ levels[7]. As shown in Fig. 1*b*, K$_0$ accumulates progressively during 1 min of beating. We also measured intracellular potential (V_m) with a nearby conventional microelectrode, and found that the membrane hyperpolarizes during the K$_0$ accumulation.

With overdrive of more than 1 min, K$_0$ levels plateau and later slowly subside back to baseline. The most likely reasons for the decline in K$_0$ are stimulation of the Na$^+$-K$^+$ pump due to intracellular Na$^+$ accumulation[11,12] and decreased K$^+$ efflux per beat, due in part to action potential shortening (unpublished observation). When beating is terminated, K$_0$ levels fall rapidly and undershoot the baseline for a prolonged period. This prolonged postdrive undershoot is evidence of persistent Na$^+$-K$^+$ pump activity[11]. Figure 2 shows such K$_0$ accumulation and depletion associated with rapid stimulus trains of varying length (1, 2 and 5 min). The magnitude and duration of the K$_0$ undershoot increases with longer periods of overdrive[11]. Cooling the preparation to 22 °C also prolonged the undershoot.

With an intracellular microelectrode in a nearby cell, we monitored membrane potential (V_m) simultaneously with K$_0$ values. On cessation of stimulation following a period of overdrive, membrane potential is hyperpolarized and automaticity is suppressed. This phenomenon of overdrive suppression was originally described by Vassalle[13]. In addition, action potential duration is shortened following

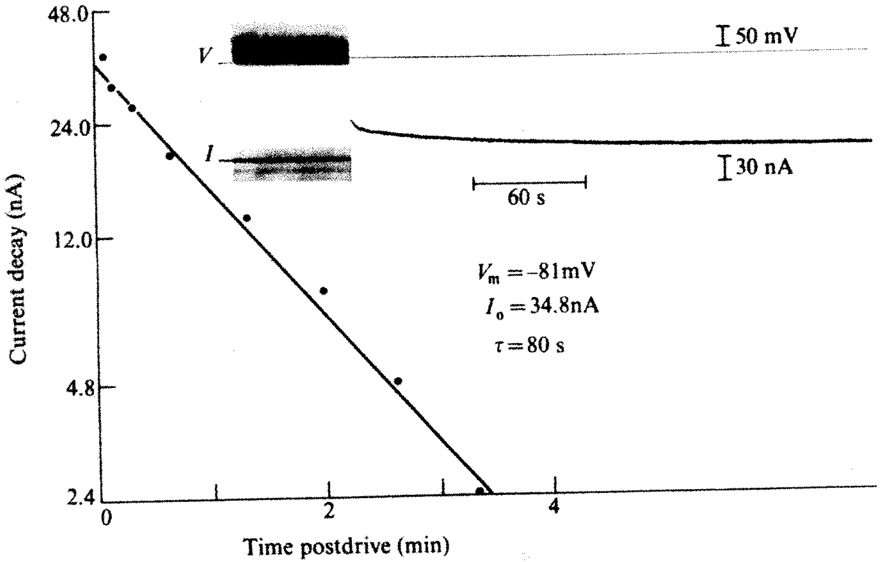

Fig. 4 Clamp current following overdrive (inset) is shown for 4 min voltage clamp to −81 mV (V, voltage trace; I, current trace).

drive. Figure 3*a* plots the postdrive return of action potential duration and membrane potential following a period of overdrive. Figure 3*b* plots the postdrive return of automatic activity versus K_0 for a spontaneously rhythmic fibre. The effect of overdrive on the membrane electrophysiological parameters gradually subsided during a period of minutes, and closely coincided with the duration of the K_0 undershoot.

As the post overdrive variations in these three parameters can be explained by a decaying outward current[13,14], we attempted to measure that current using the voltage clamp[15,16]. Following a similar period of rapid drive, we measured currents using sustained voltage clamp pulses at various holding potentials. Figure 4 (inset) shows the current recorded during a 4-min clamp pulse to −81 mV, following a period of overdrive. A decaying outward current is readily seen. The time constant of the current is 80 s, 1–2 orders of magnitude larger than the time constant of the pacemaker current (I_{K_2}) measured at this holding potential[10,17]. This slow current is dependent on there being a preceding period of overdrive, and is enhanced as the drive duration is lengthened.

However, the current does not seem to be independent of potential. As the postdrive clamp potential becomes more positive, the magnitude of the current decreases. Between −50 and −40 mV, the current becomes biphasic, and eventually at more positive potentials reverses polarity. The time constant of the decay of the slow current also seems to vary with potential. This may arise from :(1) contamination of an electrogenic pump current due to K_0 accumulation or depletion acting on other currents; (2) contamination of an electrogenic pump current by another time- and voltage-dependent current (I_x); (3) a direct effect on pump current of changing levels of K_0 in the clefts: (4) a dramatic dependence of passive ionic fluxes on post drive clamp potential, causing, for example, an increase in sodium loading at depolarized potentials; or, (5) a complicated dependence of pump current on membrane potential. Further experiments are needed to determine why slow current decay varies in this way with potential.

In summary, there is direct evidence for beat to beat changes in extracellular K^+ activity in canine Purkinje fibres. These fluctuations may provide some of the time dependence of the K^+ currents in both the plateau and diastolic potential ranges, by altering both the K^+ equilibrium potential and K^+ conductance [18]. It is also possible that transient changes in K_0 during extra-systoles and short periods of triggered automaticity may influence the following beats. Therefore, these activity-dependent fluctuations in K_0 and the associated membrane currents may be important factors affecting both the generation and maintenance of some ventricular arrhythmias.

Single acetylcholine-activated channels show burst-kinetics in presence of desensitizing concentrations of agonist

B. Sakmann, J. Patlak & E. Neher

Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen-Nikolausberg, Am Fassberg, FRG

High resolution measurements of the current through individual ion channels activated by acetylcholine (AChR-channels) in frog muscle have shown that these currents are discrete pulse-like events with durations of a few milliseconds[1,2]. Fluctuation and relaxation measurements of end-plate currents have led to the conclusion that the rate of channel opening increases with agonist concentration, and that the channel, once open, closes spontaneously[3–6]. Katz and Thesleff have shown, however, that in the continued presence of ACh, the initial end-plate current declines to an equilibrium value with a time constant of several seconds[7]. This reversible phenomenon is referred to as receptor desensitization. We report here that in the presence of ACh concentrations sufficient to cause desensitization, single channel current pulses appear in groups. From the temporal sequence of the pulses, we have derived estimates of the rates of activation and desensitization of the AChR-channel.

Experiments were performed on the extra-synaptic membrane of denervated fibres of frog (*Rana pipiens*) cutaneous pectoris muscle, using the extra-cellular patch clamp method for the application of agonist and to record membrane current[8]. AChR-channels in the extra-synaptic membrane are heterogeneous in their mean 'open times' (E.N. and B.S., in preparation). The predominant extra-synaptic AChR-channel has been described as having open times four to five times longer than the synaptic-type channel. However, about 10% of the channels we observed had properties comparable to subsynaptic AChR-channels. This report includes only measurements from channels of this latter type to facilitate comparison with previous measurements of end-plate currents.

Figure 1*a* shows the current recorded from a patch of membrane in the presence of 5 μM ACh starting less than 1 s after the agonist-containing pipette had been sealed on to the muscle fibre. The current switched randomly between the resting level and four equally spaced amplitudes, indicating that at least four channels were active. The progressive decrease in the number of amplitudes reached in the continued presence of ACh indicated a decrease in the number of open channels. This decrease characterizes the time course of receptor desensitization and results in complete inactivation of the current because of the low density of AChR-channels in the extrasynaptic membrane. However, after this initial desensitization, 'bursts' of single channel currents are observed at irregular intervals. Figure 1*b* shows a sequence of four such bursts recorded in the presence of 10 μM ACh about 30 s after the pipette had been sealed against the membrane. Initially the membrane is at the resting level. At time A, the current begins to fluctuate rapidly between the resting and another discrete level which in its amplitude corresponds to that flowing through a single open channel. At time B, about 800 ms later, the membrane current returns to the resting level. These rapid fluctuations define a current burst which is followed by an interburst interval during which the membrane is at the resting level. The sequence of bursts and interburst intervals becomes apparent in the presence of ACh concentrations >2 μM.

We interpret this pattern of current to reflect fluctuations of single AChR-channels between three states: closed, open and a desensitized, non-conducting state. At the beginning of the record shown in Fig. 1*b*, according to this model, all AChR-channels of the membrane patch under investigation are in a desensitized state. At time A, a single receptor-channel complex converts from the desensitized to the open/closed state. It then fluctuates rapidly between the open and the closed state and converts again to the desensitized state at B. However, the pattern of current shown in Fig. 1*b* is also reminiscent of the behaviour of single AChR-channels in the presence of channel-blocking substances[9]. Because some agonists themselves can block channels, the observed fluctuations of current during a burst could also reflect blocking of open channels by ACh molecules[10]. The two alternative mechanisms can be distinguished by their predictions for the agonist concentration dependence of the kinetics of fluctuations of current within a burst.

In the first interpretation, the rapid fluctuations are due to the changes of state: closed $\underset{\alpha}{\overset{\beta'}{\rightleftarrows}}$ open. In this two-state scheme β' and α are the rate constants of channel opening and closing respectively: α should be independent of the ACh concentration and can be measured as the reciprocal decay constant, τ_0^{-1}, of the distribution of the durations of current pulses (mean 'open time') during a burst. On the other hand, β', measured as the reciprocal decay constant, τ_C^{-1}, of the distribution of intervals between pulses, (mean 'closed time') should increase with the ACh concentration, because β' is an apparent rate constant, whose value is assumed to depend on agonist-binding steps preceding channel openings. In contrast, a channel-blocking mechanism would predict the opposite. The mean open time would shorten as the agonist concentration was raised, and the mean closed time would be independent.

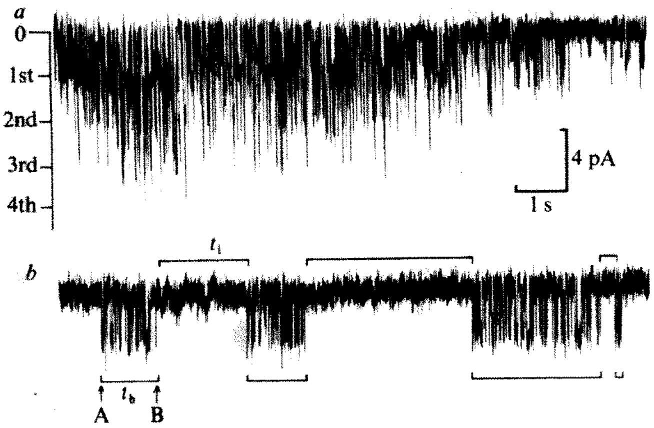

Fig. 1 Onset of desensitization and burst kinetics on small patches of extra-junctional membrane of chronically denervated frog muscle in the maintained presence of constant ACh concentrations. *a*, Record from a membrane patch starting when the agonist-containing patch pipette was sealed against the membrane. Four discrete levels of current can be resolved, as indicated roughly by the scale on the left. Individual step sizes are $\simeq 3$ pA, as expected for open ACh-activated channels at −130 mV membrane potential. The occurrence of currents reaching the fourth level indicates that at least four channels are active simultaneously. The maximum current amplitude reached decreases during this record until the membrane patch is at the resting level. ACh concentration was 5 μM; membrane potential, −130 mV; temperature, 11 °C. Inward current was downwards. The background noise, seen clearly on the resting level, caused some spread of the current amplitudes at each level. All records have been filtered at 500 Hz low pass. *b*, Bursts of current fluctuations follow the period of initial current inactivation. This record was started 34 s after the placement of the patch pipette and following a current pattern comparable to that shown in (*a*). The arrows marked A and B indicate the onset and cessation of fluctuations between the resting and the first current level and delineate that which is defined as a single channel current burst. Brackets indicate the measurement of t_b and t_i, burst duration and the inter-burst interval, respectively. Although occasionally bursts occur simultaneously, giving rise to currents reaching the second level (not illustrated), most bursts late in the record only reach the first level of current. This indicates that only a single channel is active. Conditions are the same as in (*a*), except that the pipette contained 10 μM ACh. The calibration scales apply to both traces.

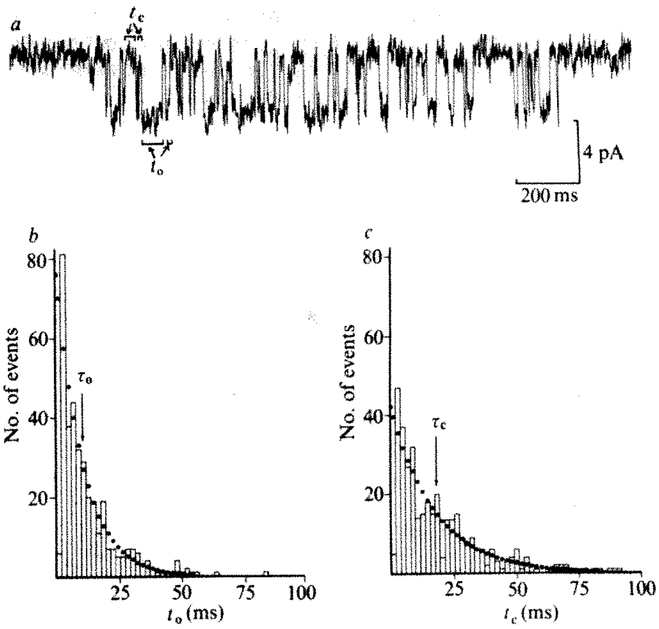

Fig. 2 Analysis of the rapid fluctuation of current during a burst. *a*, A single recorded burst in the presence of 10 μM ACh shown at higher time resolution than those in Fig. 1*b*. Brackets indicate the measurement of individual channel open times, t_0, and closed times, t_C. The membrane potential was −130 mV; temperature, 12 °C. *b* and *c*, Histograms of distributions of open and closed times measured during several sequential bursts at 10 μM ACh, −130 mV membrane potential and 12 °C. Records of currents were stored on an FM tape recorder, subsequently sampled and stored digitally on a PDP 11/34 computer. The sampling interval was 0.5 ms. Individual open and closed times were measured semi-automatically and stored to construct frequency-of-occurrence histograms. The histograms were fitted with single exponential curves, as indicated by the dotted line, using a least-squares fitting routine weighted for the statistical nature of the underlying events. The arrows indicate the best fit decay constants τ_0 and τ_C for the distribution of open and closed times, respectively. τ_0 was 10.6 ms and τ_C was 18 ms at 10 μM ACh.

We have, therefore, analysed quantitatively the distribution of open and closed times within bursts at various concentrations of ACh. Figure 2*a* shows a burst, illustrating the time course of the channel's conductance fluctuations. The distributions of open and closed times can be fitted by single exponentials (Fig. 2*b*, *c*), as expected for first-order kinetic processes. Figure 3*a* shows single bursts recorded in the presence of various concentrations of ACh and Fig. 3*b* summarizes our measurements as a plot of the values of τ_0^{-1} and τ_C^{-1} in double log scales as a function of ACh concentration. The mean open times are not measurably concentration dependent. Measurements at −90 mV and −130 mV show that mean open times increase with increasing membrane hyperpolarization. The e-fold increase per 65-mV change is close to the value reported for single channel measurements at low ACh concentration[1]. The rate constants of channel closing derived from these values are of the order of 100–250 s^{-1}, comparable to the values inferred from end-plate current fluctuation analysis[4]. Channel closed times decrease with agonist concentration. In the range of 5–50 μM ACh, the relation between τ_C^{-1} and ACh concentration is roughly described by a power law with an exponent of about 1.4. This suggests an increase of the apparent rate constant of channel opening from ~25 s^{-1} to ~500 s^{-1} in this concentration range. It is consistent with a reaction scheme that involves the binding of two ACh molecules preceding the opening of a single channel[5,6]. The intersections between the lines in Fig. 3*b* define the concentration of ACh for which the mean open time equals the mean closed time. These concentrations, 22 µM at −90 mV and 17 µM at −130 mV, are estimates of the apparent dissociation constants for channel activation by ACh in our conditions. These results support the hypothesis that the rapid current fluctuations during a burst reflect transitions of a single channel between the open and closed states. They rule out a channel-blocking mechanism.

The repeated appearance and disappearance of bursts of current, as illustrated in Fig. 1*b*, reflects fluctuations of AChR-channels between the open/closed and a desensitized state occurring on a much slower time scale than the open–closed transitions of the channel. At even lower time resolution, however, bursts seem to be an element of a pattern of current to which we refer as 'clusters' of several bursts (Fig. 4). Clusters are evident because the interburst intervals are much shorter than the mean intervals between the clusters.

Bursts and interburst intervals within a cluster vary stochastically in duration, and bursts become shorter at higher ACh concentrations. The separation of bursts is not always seen as clearly as in Fig. 1*b*, and in some cases it is difficult to define the beginning and end of individual bursts. However, at 20 µM ACh, bursts are clearly resolved (Fig. 4). The mean values of burst durations and interburst intervals at this concentration are 420 ± 12 ms and 180 ± 10 ms (± s.e.), respectively. Clusters of bursts have durations of several seconds and are separated by irregular intervals of several tens of seconds. For example, the cluster of eight bursts illustrated in Fig. 4 was recorded 18 s after the pipette had touched the muscle membrane; the next cluster occurred 23 s later. The duration of clusters is variable and decreases with increasing agonist concentrations. At 20 µM ACh, the average duration of clusters is 4.8 ± 2 s, whereas the average duration of the interval between clusters is 34 ± 4 s. A simple explanation for these observations is that the AChR-channel can exist in two different states of desensitization. Thus at 20 µM ACh, the sequence of bursts and burst intervals reflects the kinetics of a fast component of desensitization with apparent rate constants of $\simeq 2\,s^{-1}$ and $\simeq 5\,s^{-1}$ for the conversion to and from the desensitized state, respectively. The kinetics of a slow component are measured by the average duration of clusters and the average interval between clusters. At 20 µM ACh, the apparent rate constants are $\simeq 0.2\,s^{-1}$ and $\leqslant 0.03\,s^{-1}$ for the transitions between open/closed and this desensitized state.

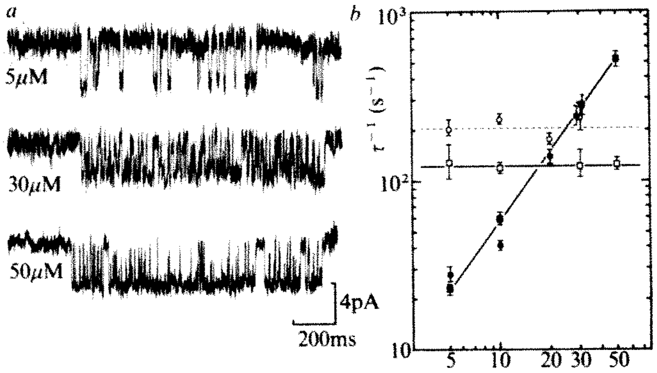

Fig. 3 Agonist concentration dependence of open and closed times during current bursts. *a*, Examples of bursts recorded in the presence of three different ACh concentrations as indicated on the left side of each record. All three records were taken at −130 mV membrane potential, 11 °C. As the ACh concentration increases, the duration of intervals between pulses of current decreases. At ACh concentrations $<20\,\mu M$ ACh, the channels are, during a burst, mostly in the closed state, whereas at $>20\,\mu M$ ACh, the channels are predominantly in the open state. *b*, Log log plot of the inverse of the best fit τ_0 and τ_C values, measured as shown in Fig. 2*b* and *c* against ACh concentration. Open symbols are values for the channel mean open times, τ_0, and closed symbols are for the channel mean closed times, τ_C. Circles were measurements at −90 mV, squares at −130 mV membrane potential. The solid lines were drawn through the −130 mV data, the dotted through the −90 mV. All lines were drawn by eye. Each point represents the best fit exponential to histograms made by summation of the histograms from many bursts in the same conditions. Standard error brackets refer to the calculated standard error of the best fit values of τ to their respective histograms. Channel open times are not measurably dependent on ACh concentration but increase with membrane hyperpolarization. The channel closed times are strongly dependent on ACh concentration: the slope of the line drawn was 1.4. No consistent change of mean closed times with changes in membrane potential was measureable.

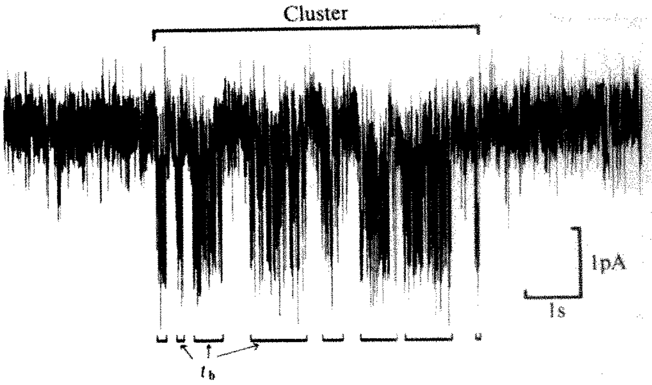

Fig. 4 Occurrence of single channel bursts in clusters as revealed at low time resolution. This record was obtained in the presence of 20 µM ACh 18 s after the establishment of the pipette-membrane seal. Membrane potential was −90 mV, 12 °C. At this slow sweep speed it is no longer possible to resolve individual pulses of current, but a clear grouping of bursts of pulses is apparent. The lower brackets indicate the durations of eight individual bursts, while the upper bracket illustrates the duration of a cluster. In frequency-of-occurrence histograms of the interval between current pulses, three widely separated exponential components are measureable. The fastest component respresents the distribution of channel closed times within bursts, the intermediate one the distribution of inter-burst intervals and the slowest component represents the time intervals between clusters. The wide separation of the means of the various interval distributions justifies the separation of groups of pulses into bursts and clusters.

The results demonstrate that at least three kinetic processes control the AChR-channel conductance state in the presence of desensitizing concentrations of ACh. The rapid fluctuations of current in the millisecond time range represent transitions of single AChR-channels between their open and closed states. The slow kinetic process, in the time range of several seconds, which is measured as the repeated occurrence of clusters, can tentatively be related to the onset of and recovery from desensitization as observed in measurements of end-plate current[11–13]. In addition, we have presented kinetic evidence for an agonist–receptor interaction that leads to a desensitized state of the receptor–channel complex in the intermediate time range of hundreds of milliseconds.

Effect of lesion of cortical dopamine terminals on subcortical dopamine receptors in rats

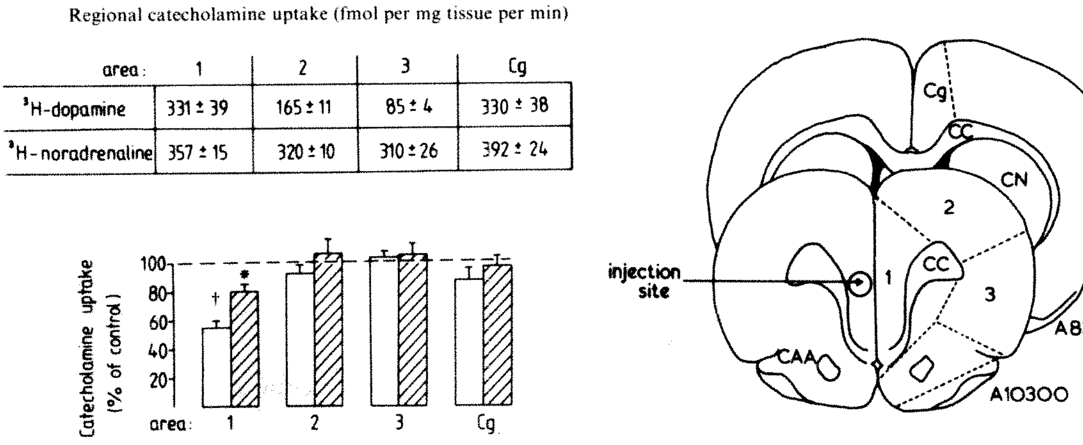
C. J. Pycock, R. W. Kerwin & C. J. Carter

Department of Pharmacology, Medical School, University of Bristol, Bristol BS8 1TD, UK

Since the demonstration of dopamine-containing nerve terminals within cortical regions[1,2], studies have confirmed the existence of a dopaminergic projection to the medial prefrontal cortex[3,4]. Cortical dopamine (DA) may be a functional neurotransmitter, as there are selective high-affinity receptor binding[5,6] and uptake sites[7,8] within this area, a DA-selective adenylate cyclase system[8,9], cells responsive to iontophoretically applied DA[10], and a pool of DA amenable to release *in vivo*[11] or *in vitro*[12,13]. Lesions of either midbrain cell bodies in the ventral tegmental area[14,15] or of frontal cortical areas directly[16], with subsequent loss of DA terminals from the medial prefrontal cortex, induce hyperactivity in rats[16], and enhanced behavioural responses to amphetamine[16,17]. Lesion of subcortical DA pathways results in the opposite effects, suggesting that frontal cortical DA systems may have an inhibitory role in motor behaviour[15,16]. Dopamine-dependent hyperactivity and stereotypy is believed to be mediated from extrapyramidal and mesolimbic DA-innervated sites[18]. We previously noted that loss of catecholamine terminals within the frontal cortex of the rat results in increased DA turnover and utilization in subcortical striatal and limbic regions after one week[19]. We now show evidence of both enhanced presynaptic and post-synaptic mechanisms in the terminal regions of the ascending nigrostriatal and mesolimbic DA pathways one month after destruction of DA terminals within the medial prefrontal cortex of the rat. The increased ^{3}H-ADTN and ^{3}H-spiperone binding, enhanced DA-induced stimulation of adenylate cyclase and potentiated uptake capacity for DA within striatum and nucleus accumbens may demonstrate a functional basis for the observed potentiated behavioural responses.

Destruction of catecholamine terminals within the area of the medial prefrontal cortex was performed by infusion of 6-hydroxydopamine (6-OHDA) into this site. Male Porton rats (220–250 g) were pretreated with the noradrenergic uptake blocker desmethylimipramine[20] (DMI, 25 mg per kg, intraperitoneally (i.p.), 30 min before lesion) to increase the relative toxic specificity of 6-OHDA for DA terminals. Animals were anaesthetized (chloral hydrate, 300 mg per kg), and immobilized in a Kopf stereotaxic frame. Two groups of rats received bilateral injections of either solvent (1.5 μl 0.1% nitrogen-bubbled sodium metabisulphite solution) or 6-OHDA (Sigma) (8 μg per 1.5 μl per 2 min) into the medial prefrontal cortex (coordinates A + 10.3; V + 1.0; L ± 0.8 mm)[21] (Fig. 1).

Four weeks after surgery, the spontaneous and (+)-amphetamine (1 mg per kg, i.p.)-induced locomotor activity of both sham and lesioned rats was tested in an open field. Remaining rats were killed for biochemical assessment of the effects of the 6-OHDA/DMI lesion. Paired corpus striatum, nucleus accumbens and the region of the medial prefrontal cortex were rapidly dissected out and regional concentrations of DA and noradrenaline (NA) were measured using a sensitive radiometric enzymatic assay with [^{3}H]-S-adenosylmethionine (15 Ci mmol^{-1}, Radiochemical Centre, Amersham) as the methyl donor[22]. The high-affinity benztropine-resistant[23] uptake of NA, and the DMI-resistant uptake of DA, within the lesion site and adjacent cortical areas were also compared (see Fig. 1). In addition, the DMI-resistant uptake of DA in the striatum and nucleus accumbens was measured in the two animal groups. Concentrations of the major DA metabolites homovanillic acid (HVA) and 3,4-dihydroxyphenylacetic acid (DOPAC) within striatum and nucleus accumbens were measured fluorimetrically[24], and the basal and dopamine (5–50 μM)-stimulated adenylate cyclase activity assayed in these regions according to the technique of Clement-Cormier and coworkers[25]. Further, (+)-butaclamol-sensitive ^{3}H-spiperone (20 Ci mmol^{-1}; Radiochemical Centre, Amersham) binding using a range of 100–2,000 pM radioactive ligand[27], and also the 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene (ADTN)-sensitive binding of ^{3}H-ADTN (4.9 Ci mmol^{-1}; Radiochemical Centre, Amersham) using a range of 5–40 nM radioactive ligand[28] were studied in striatal



Regional catecholamine uptake (fmol per mg tissue per min)

area:	1	2	3	Cg
^{3}H-dopamine	331 ± 39	165 ± 11	85 ± 4	330 ± 38
^{3}H-noradrenaline	357 ± 15	320 ± 10	310 ± 26	392 ± 24

Fig. 1 The site and effect of 6-OHDA lesions of the medial prefrontal cortex on regional frontal cortical high-affinity catecholamine uptake. Transverse sections of the rat brain, levels A8380 and A10300[21], indicate site of injection (bilaterally, area 1) and adjacent areas taken for regional assay (areas 2, 3 and Cg). For regional high-affinity catecholamine uptake, areas were dissected from the appropriate plane and tissue from both sides of each animal pooled and chopped in two directions at 0.2 mm intervals using a McIlwain tissue chopper. Slices were weighed (5–10 mg per tube) incubated at 37 °C in 2 ml oxygen-bubbled Krebs–Ringer bicarbonate buffer, *p*H 7.4 for 10 min. ^{3}H-DA (specific activity 5 Ci mmol^{-1}, Radiochemical Centre, Amersham) or ^{3}H-NA (specific activity 10.7 Ci mmol^{-1}, Radiochemical Centre, Amersham) were added to each tube to give a final concentration of 0.1 μM. For DA uptake, 0.5 μM DMI was present in the buffer to restrict any uptake into NA terminals[20]; for NA uptake, 1 μM benztropine was present to restrict any uptake into DA terminals[23]. Uptake was terminated after 5 min by rapid filtration on to Whatman GF/B filters, and, following washing with 15 ml ice-cold buffer, radioactivity was determined by liquid scintillation counting. Tissue and filter blanks were assessed by measuring the uptake of radioactivity at 0 °C. The results of the regional high-affinity catecholamine uptake were calculated as fmoles per mg tissue per min (upper trace). Uptake in 6-OHDA lesioned animals was expressed as a percentage of that obtained in sham-operated rats (lower trace); open columns represent DA uptake, hatched columns for NA uptake. Each point is the mean of six values; vertical bars denote standard errors. Cg, cingulate cortex; CN, caudate nucleus; CC, corpus callosum; CAA, anterior commissure.

Table 1 Changes in regional concentrations of noradrenaline and dopamine and its metabolites in cortical and subcortical sites in rats following 6-OHDA lesions of the medial prefrontal cortex

Substance tested	Medial prefrontal cortex		Striatum		Nucleus accumbens	
	Sham	Lesion	Sham	Lesion	Sham	Lesion
NA	0.84 ± 0.03	0.58 ± 0.12* (68)	—	—	—	—
DA	0.11 ± 0.02	0.04 ± 0.01† (38)	11.94 ± 0.87	12.61 ± 0.84 (106)	7.97 ± 0.85	9.35 ± 0.40* (117)
HVA	—	—	0.63 ± 0.06	0.77 ± 0.04* (124)	0.93 ± 0.08	1.31 ± 0.10† (141)
DOPAC	—	—	1.21 ± 0.09	1.87 ± 0.40† (155)	1.33 ± 0.14	1.94 ± 0.27* (146)

Lesioned animals were pretreated with DMI (25 mg per kg, i.p.) and 6-OHDA (8 μg in 1.5 μl) injected bilaterally into the medial prefrontal cortex. Sham animals received bilateral injections of vehicle (1.5 μl 0.1 % sodium metabisulphite solution) into the same site. Biochemical assays were conducted 30 days after surgery. Results are the mean of seven observations and are expressed as μg per g wet weight tissue ±1 s.e.m. Figures in parentheses indicate the per cent value of sham-operated concentrations.

and nucleus accumbens membrane preparations.

Total specific binding of ^{3}H-ADTN and ^{3}H-spiperone was significantly increased in the membrane fraction prepared from both striatum and nucleus accumbens examined from the 6-OHDA lesioned animals (Fig. 2). Scatchard analysis of the data indicated that this was due to an increase in receptor numbers in both regions for both ligands (ADTN: B-values for striatum, control 113 ± 10 fmol per mg protein compared to 146 ± 9 for lesioned group ($P < 0.05$); nucleus accumbens, control 78 ± 4 fmol per mg protein compared to 90 ± 5 for lesioned group ($P < 0.05$). Spiperone: B-values for striatum, control 0.81 ± 0.07 pmol per mg protein compared to 1.08 ± 0.09 for lesioned group ($P < 0.05$); nucleus accumbens, control 0.91 ± 0.05 pmol per mg protein compared to 1.33 ± 0.11 for lesioned group ($P < 0.05$)). Additionally, there appeared to be a small decrease in receptor affinity for ^{3}H-ADTN binding in the striatum (K_d values: control 0.87 nM, lesion 1.54 nM). There appeared to be no change in receptor affinity with dissociation constants ranging from 0.22 to 0.49 nM for ^{3}H-spiperone binding, or for ^{3}H-ADTN binding in the nucleus accumbens, the regression analysis showing that the slopes did not significantly deviate from parallelism between sham-operated and lesioned animals. All binding data represents mean ± s.e.m. of eight determinations.

Dopamine (5–50 μm) markedly stimulated adenylate cyclase activity in striatal and accumbens homogenates. This effect was significantly greater in 6-OHDA lesioned animals at all doses of DA giving maximal stimulation in the striatum ($P < 0.05$) and at the 20 μM dose of DA in the nucleus accumbens ($P < 0.05$, Fig. 3). Furthermore, the cortical lesions resulted in significant increase in the high affinity DMI-resistant uptake of DA in both extrapyramidal and mesolimbic sites. Accumulation of DA into striatal slices from 6-OHDA/DMI lesioned rats was $1{,}067 \pm 71$ fmol per mg tissue per min compared to 754 ± 70 fmol per mg tissue per min in vehicle-injected animals ($2P < 0.02$). Accumulation of DA into slices from nucleus accumbens was 649 ± 86 fmol per mg tissue per min in 6-OHDA/DMI lesioned rats: control animals accumulated 435 ± 32 fmol per mg tissue per min ($2P < 0.02$, $n = 10$).

We have previously reported the behavioural and biochemical sequelae of such lesions, 10 days after surgery[16,19]. Because the additional binding and uptake studies were performed 1 month after surgery, we repeated these experiments at this later time to verify the effects of the lesion. At 1 month these lesions enhanced spontaneous and amphetamine (1 mg per kg, i.p.)-induced locomotor activity in the perimeter squares of an open field compared to sham-lesioned animals (spontaneous, $P < 0.05$; amphetamine-induced, $P < 0.01$, $n = 8$). Similarly the biochemical parameters at 1 month paralleled those results reported at 10 days after surgery. Briefly 6-OHDA lesions of the medial prefrontal cortex reduced DA concentrations to 38 % ($P < 0.01$) and NA concentrations to 68 % ($P < 0.05$) within this site (Table 1). These results were supported by a 48 % decrease in high-affinity DMI-resistant DA uptake and a 21 % decrease in high-affinity benztropine-resistant NA uptake (Fig. 1). These significant changes in catecholamine uptake were only observed in the region of the medial prefrontal cortex (area 1), adjacent regions and the cingulate cortex showed no differences between 6-OHDA lesioned and sham-operated animals (Fig. 1). In addition to changes in cortical catecholamine content, significant increases (+17 %) in the DA content of the nucleus accumbens ($P < 0.05$), and HVA and DOPAC concentrations in both striatum and nucleus accumbens were recorded in 6-OHDA lesioned rats (Table 1).

Lesions of 6-OHDA of the medial prefrontal cortex produce significant loss of both DA and NA from this site, together with an apparent enhancement of subcortical DA systems as indicated by increases in concentrations of DA and its metabolites, in basal and dopamine-stimulated adenylate cyclase, in ^{3}H-ADTN and ^{3}H-spiperone receptor binding and enhanced high-affinity uptake of DA within the striatum and nucleus accumbens. The neurotoxic effects of the lesion seem to be confined to the medial prefrontal cortex as adjacent regions and the cingulate cortex showed no changes in high-affinity catecholamine uptake. The lesion was associated with an increase in both spontaneous and amphetamine-induced locomotor activity.

The biochemical data would suggest a facilitation of DA mechanisms within extrapyramidal and mesolimbic sites which would support the enhanced behavioural responses. This increase would seem to involve both pre- and postsynaptic mechanisms within the striatum and nucleus accumbens as indicated by the recorded increase in DA utilization (increased DA metabolite concentrations), DA uptake, and increase in adenylate cyclase and receptor number. The exact site of these receptor increases is not known as not all postsynaptic DA receptors seem to be linked to adenylate cyclase[29] and a recent report suggests only a poor correlation between ^{3}H-spiperone binding and DA-sensitive adenylate cyclase suggesting that two different populations of DA receptors may be involved[30]. Furthermore it has been suggested that the neuroleptic may also label central serotonin receptors which would obviously confuse interpretation of the results[31]. However, an identical binding pattern is observed in lesioned animals using ADTN, a rigid analogue of DA which is believed to bind specifically to DNA receptors[28].

Such an apparent increase in both presynaptic and postsynaptic neurotransmitter mechanisms seem paradoxical as a decreased presynaptic function is usually associated with an increased postsynaptic sensitivity[32] and vice versa[33]. Thus the appearance of increased activity at both pre- and postsynaptic sites is a novel situation which is very interesting because of its accordance with the post-mortem biochemical data seen in schizophrenia, where increases in DA concentrations in nucleus accumbens[34], and enhanced neuroleptic binding in both nucleus accumbens and striatum[35,36] have been a documented feature of this disease. On the basis of other reported data, such a unilateral increase in pre- and postsynaptic activity is not completely without precedent, as recent findings describe increased behavioural responses following chronic treatment with DA agonists[37,38].

The mechanism by which loss of catecholamine terminals within the prefrontal cortex induces supersensitivity within subcortical DA pathways is not known. It may reflect an increased number of active DA terminals in these sites, but whether such changes are purely a physiological consequence of reducing cortical DA function, or related to collateral sprouting[39] following damage to the mesocortical DA projection remains to be resolved. In a previous study we showed that such lesions will also bring about changes in other neurotransmitter functions within the basal ganglia[19]. It therefore seems that the frontal cortical catecholamine system may be intimately concerned with the regulation of subcortical DA pathways. The medial prefrontal cortex sends projections to the striatum[40], nucleus accumbens[41], ventral tegmental area[40], and to the substantia nigra[42], thus providing potential routes through which such control may be mediated. The development of supersensitive central receptor sites is of much interest to the clinician, and an increase in either affinity or number of subcortical DA receptors has been suggested in development of Parkinson's disease[43], schizophrenia[35,36] and the dyskinesias[44]. Indeed a recent report has presented evidence for the development of supersensitive striatal DA receptors in rats following chronic neuroleptic treatment[45], a situation that may explain tardive dyskinesias which often develop in this type of drug therapy. That an apparent supersensitive subcortical DA system can also develop after lesions of the prefrontal cortex may have far reaching implications as to the possible involvement of this site in the aetiology and management of neurological and psychiatric disorders hitherto attributed to dopaminergic function in subcortical areas.

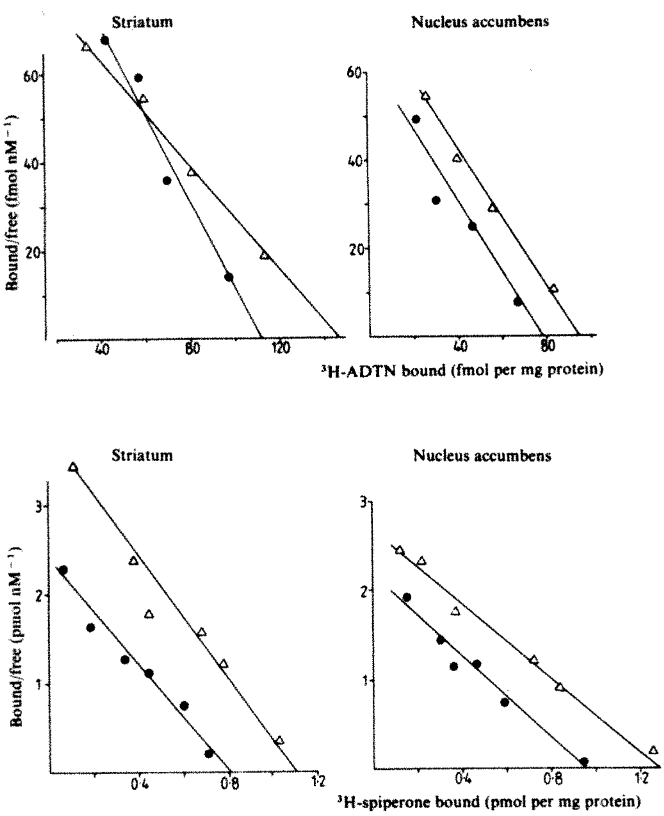

Fig. 2 Effect of 6-OHDA lesions of the medial prefrontal cortex on ^{3}H-ADTN (upper traces) and ^{3}H-spiperone (lower traces) binding to membrane fractions prepared from rat striatum and nucleus accumbens. Tissue pooled from nine sham-operated or nine 6-OHDA lesioned animals for each ligand, 30 days after surgery. Total specific ADTN binding was obtained by displacement with 1 μM ADTN[28] and total specific ^{3}H-spiperone binding was obtained by displacement with 1 μM (+)-butaclamol[27]. Data is shown as representative Scatchard plots of radiolabelled ligand receptor binding from sham-operated (●) and 6-OHDA lesioned animals (△), each point being the mean of quadruplicate determinations. At saturating concentrations of ^{3}H-spiperone specific binding typically represented 500 c.p.m.; nonspecific being typically 200 c.p.m. At saturating concentrations of ADTN specific binding was typically 900 c.p.m.; nonspecific being 400 c.p.m.

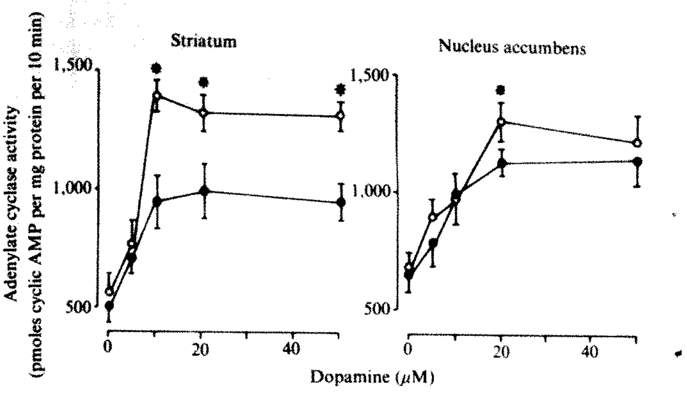

Fig. 3 Effect of 6-OHDA lesions of the medial prefrontal cortex on dopamine-sensitive adenylate cyclase activity in rat striatum and nucleus accumbens. Tissue pooled from six sham-operated or 6-OHDA lesioned rats, 30 days after surgery. DA-sensitive adenylate cyclase activity was determined according to the technique of Clement-Cormier *et al.*[25] and cAMP in the samples was assayed using the method of Brown *et al.*[26]. The results shown represent activity in tissue from sham-operated animals (●) and 6-OHDA lesioned rats (○) and represents the mean ± 1 s.e.m. of three determinations each assayed in triplicate. The data shown is obtained from a single assay and is one of several experiments carried out in identical conditions and giving similar results. Significant differences from sham-treated animals ($P<0.01$) are indicated by the asterisks and are determined non-parametrically from data pooled from two separate assays ($n=6$).

We thank Mrs Shirley Burns and Miss Sarah Pay for technical assistance, and Dr Tom Blackburn for supplies of ADTN. C.J.C. and R.W.K. are supported by the MRC.

Behavioural variants of rat neuroblastoma cells

Lloyd A. Culp

Department of Microbiology, Case Western Reserve University, School of Medicine, Cleveland, Ohio 44106

Study of the biological function of the cells of the nervous system has benefited from the isolation of cloned glial or neuronal tumour cell lines that can be induced to differentiate in culture[1–3]. Many of their differentiated properties reflect specific biochemical changes at the cell surface, and we have observed changes in cytoskeletal organization and glycosaminoglycan-containing proteoglycan content in the tissue culture substratum adhesion sites of neuroblastoma cells during neurite extension[4]. To assist in defining structure function relationships of cell surface components of rodent neuroblastoma cells, I have used two cell-surface-active agents to select for phenotypically-stable variants of these cells which display some unique properties and which will be useful for further biochemical and physiological analyses.

The first selection, based on sensitivity to detachment of these cells from the tissue culture substratum by the Ca^{2+}-specific chelator EGTA, is shown in Fig. 1 for cloned rat neuroblastoma B104 cells[3]. Variants were isolated that resist EGTA-mediated detachment from the tissue culture dish on conventional treatment [shaking at 37 °C for 30 min with 0.5 mM EGTA in phosphate-buffered saline (PBS)]. The selection was performed in two different ways. In the first approach (Fig. 1*a*), undifferentiated B104 cells were treated with EGTA, gently pipetted to detach loosely-adherent cells, and rinsed several times with PBS. Cells resisting this treatment (approximately 5×10^{-5} of the original cell number) were incubated for several hours in fresh medium and trypsin-subcultured into fresh dishes. After 2 weeks, several colonies developed at a final selection frequency of 1×10^{-5}; these colonies were subjected to the same selection protocol two more times before cloning. Most of the colonies from this selection were resistant to EGTA at 0.5 mM and displayed a highly elongated fibroblastic morphology. These cells are referred to as E_RA variants; higher EGTA concentrations or longer trypsinization are required to subculture them. Several clones were tested and showed properties similar to those of the E_RA 12 clone described here.

In an alternative procedure (Fig. 1*b*), cells in the original culture that resisted EGTA detachment were permitted to regrow into colonies in the original culture dish instead of being treated with trypsin and transferred to fresh dishes. The original dish was covered with cellular substrate-attached material (SAM), substratum adhesion sites which pinch off from the cell surface during EGTA-mediated detachment of the cells[6]; it has previously been shown that oncogenic virus-transformed fibroblasts respond differently to SAM-coated substrata compared to serum-coated substrata than do normal fibroblasts[7,8]. SAM-coated substratum permits selection of a different type of variant, termed E_RB, at a frequency of $\sim2\times10^{-5}$. Most clones displayed properties similar to the E_RB9 clone described here. Both variant types have been stable over 9 months of culture (25–30 passages).

A third selection method was based on the sensitivity of rat B104 cells to agglutination and killing by the lectin concanavalin A (Con A) using protocols similar to those found successful in generating Con A-resistant fibroblasts[5]. A confluent washed cell layer was treated with 20 μg ml^{-1} Con A for 16 h in serumless DMEM. The nonviable agglutinated cells were pipetted off the dish and the resistant cells (frequency of 5×10^{-6}) were permitted to regrow into colonies on the same

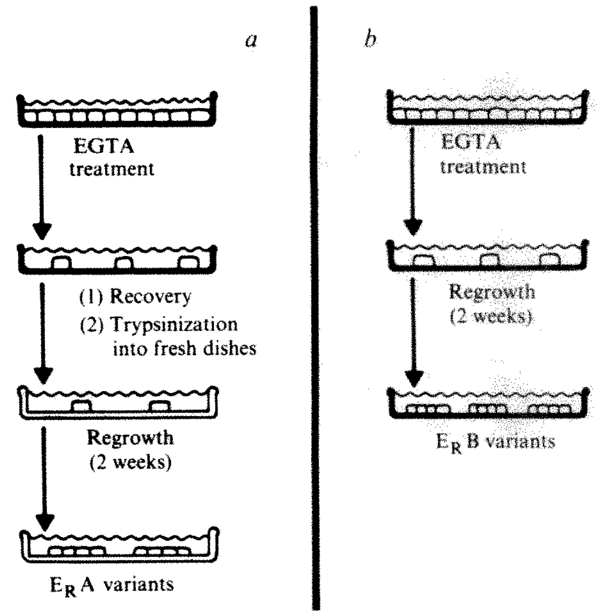

Fig. 1 Protocols for selection of EGTA detachment-resistant variants of rat neuroblastoma cells. Rat neuroblastoma cells (the B104 clone) were grown in 60 mm tissue culture dishes in DMEM (plus 7.5% fetal calf serum and penicillin and streptomycin) until they were just confluent ($\sim4\times10^6$ cells). In both selection protocols (*a* and *b*), the cell layer was rinsed twice with PBS and treated with 0.5 mM EGTA in PBS at 37 °C for 30 min by gentle shaking. Loosely-adherent cells were removed by gentle pipetting and the dish surface was rinsed twice with PBS. In protocol *b*, the dishes were refed with serum-containing medium to allow cell regrowth as a few sparse colonies on the SAM-coated substratum over a 2-week period. In protocol *a*, serum-containing medium was added back to the treated dishes for 4 h to permit recovery from EGTA-induced damage; the resistant cells were then trypsinized into fresh dishes to allow cell regrowth as a few sparse colonies over a 2-week period. Both of these protocols were repeated two more times before cloning of EGTA detachment-resistant cells.

Table 1 Growth and differentiation of variants

Property	Cell type and response			
	B104	C_R4	E_RA12	E_RB9
(1) Density-dependent inhibition of growth*	−(>6)§	−(>5)§	−(>4)§	+(1.2)
(2) Form neurites in serum-containing medium	−	−	−	+
(3) Form neurites in serumless medium†	+	+	−‖	+
(4) Form neurites on SAM-coated substrata‡	−	−	−	+

The designation + indicates that more than 25% of the cells responded; − indicates that less than 1% respond.

*As determined by multilayering of cells and continued high DNA synthesis in cultures after confluence of the culture had been achieved. The numbers in parentheses are saturating densities (cells per cm^2 $\times 10^{-5}$).

†At 50% confluence of the culture, the cell layer was rinsed twice with PBS and refed with DMEM lacking serum. Twenty-four hours later, the culture was microscopically evaluated for neurite formation.

‡SAM-coated substrata (on 60 mm tissue culture dishes) were formed by growing rat C6 glioma or rat B104 neuroblastoma cells to confluence, detaching them by EGTA treatment, and rinsing the SAM layer with PBS before inoculating 5 ml of serum-containing medium containing 5×10^5 cells. The cells were grown for 48 h before evaluating whether they had formed neurites.

§Cells are multilayered at this density.

‖These cells elongated and fused with neighbouring cells to form multinucleated syncytia.

dish. This selection was performed three more times with the lectin showing much less of a cytotoxic effect on each subsequent treatment. This variant is referred to as C_R4.

The growth properties and morphology of all four cell types were determined. The doubling time during exponential growth was similar for 'wild-type' B104, E_RA 12, E_RB9, and C_R4 cells (18–20 h). B104, E_RA 12 and C_R4 cells grew to a very high density with multilayering of cells (Table 1). E_RB9 cells differed in that they became density-inhibited when they formed a criss-cross array of neurites at higher density (Fig. 2*d*) without the cell body alignment characteristic of the parental B104 cells (Fig. 2*a*). They differed from the other cells in containing neurites at any cell density in serum-containing medium (Fig. 2*c*, *d*), except for an initial 12–24 h recovery from subculturing damage. These cells are essentially constitutive for neurite formation and are less spread over the substratum than the E_RA 12 (Fig. 2*e*) or 'wild-type' B104 cells. C_R4 cells tend to be somewhat epithelioid in appearance (data not shown).

The ability of these cells to form neurites was then tested in various experimental conditions (Fig. 2 and Table 1). The B104 cells only formed neurites when they were starved of serum for 24 h (Fig. 2*b*). They did not form neurites when grown in serum-containing medium on substrata coated with rat C6 glioma or neurite-containing B104 neuroblastoma SAMs (generated by prior growth of these cells to confluence and EGTA-mediated detachment). The E_RB9 cells contained neurites in all experimental conditions tested. The E_RA12 variant did not form neurites in any condition and underwent massive fusion within 24 h in serumless medium to form highly elongated 'myotube-like' syncytia containing many nuclei. Also, at low density in serumless medium (Fig. 2*f*), the syncytia only contained 2–4 nuclei; with cells approaching confluence, the syncytia contained as many as 20 nuclei. These elongated cells frequently spanned the entire microscope field, and there was no evidence of growth cone formation in these cells. There was no appreciable syncytia formation when these cells were in serum-containing medium. C_R4 cells were similar to B104 cells in their ability to form neurites in serumless medium but not in serum-containing medium or during growth on SAM-coated substrata (Table 1). Thus, the selection protocol based on EGTA-mediated detachability and regrowth

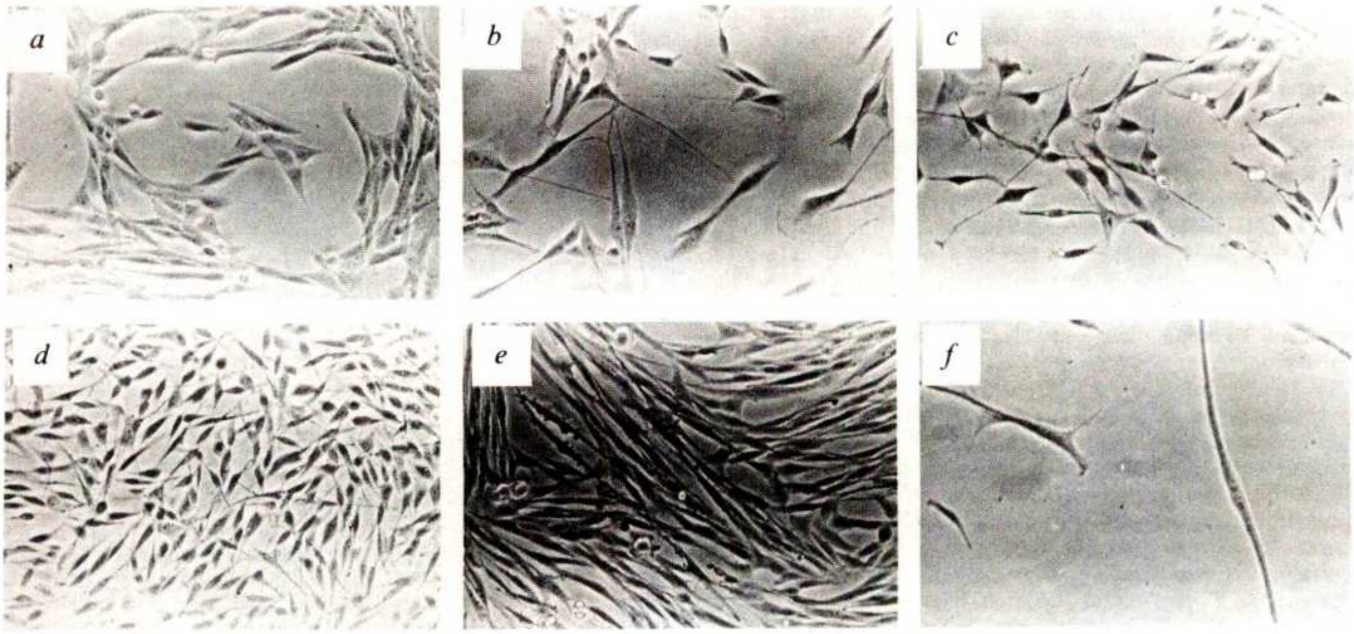

Fig. 2 Morphology and differentiation of EGTA detachment-resistant variant cells. Different cell types were plated into 60-mm tissue culture dishes at various densities and permitted to grow for at least 48 h before photographing the cultures under phase contrast optics (×90). For serumless cultures, the cell layer was rinsed twice with PBS and refed with serumless DMEM for 24 h before photography. The following are displayed: *a*, sparse B104 cells; *b*, neurite-containing B104 cells in serumless medium; *c*, sparse E_RB9 cells in serum-containing medium (note extensive neurite formation); *d*, density-inhibited E_RB9 cells in serum-containing medium (note the extensive array of criss-crossed neurites and the absence of alignment of cell bodies); *e*, E_RA12 cells as they approach confluence in serum-containing medium; and *f*, E_RA12 cells in serumless medium.

Table 2 Tumour formation in nude mice

Cell line	Tumour incidence		
	10^4 cells	10^6 cells	10^7 cells
B104	4/4 (3)	4/4 (1.5)	4/4 (1.5)
C_R4	4/4 (3.5)	4/4 (2)	4/4 (1.5)
E_RB9	0/4 (–)	4/4 (4)	4/4 (3)
E_RA12	0/4 (–)	0/4 (–)	0/4 (–)

Confluent cultures were rinsed twice with PBS and treated with 0.5 mM EGTA in PBS to detach cells. The cells were pelleted by centrifugation and washed once with serumless DMEM. The cells were suspended in serumless DMEM. 10^4, 10^6, or 10^7 cells were inoculated subcutaneously into each athymic nude mouse in 0.1 ml aliquots. Animals were palpitated twice a week to detect tumour formation. Tumour incidence is given as the number of tumour-bearing animals (always resulting in animal death)/number of animals inoculated. The numbers in parentheses indicate the number of weeks required to grow a 1 cm-diameter tumour.

on two different substrata generated variants strikingly different in their ability to generate neurites; both types of variant were distinct from respective parent cells.

The variant cells were also tested for their ability to form tumours in athymic nude mice (Table 2). Three different inocula of EGTA-detached cells were used, and mice were examined for tumour formation over a 3-month period. At all three inocula sizes, 'wild-type' B104 and C_R4 cells formed tumours in all mice with comparable speed. In these experiments, tumour formation always led to death of the animal. Even though E_RB9 cells are density-inhibited in culture, they formed tumours in these animals, although more slowly than B104 cells. E_RA12 cells, on the other hand, did not form tumours in any of the animals even at the highest inoculum size (10^7 cells); these cells are not density-inhibited in culture.

Thus the two EGTA selection protocols generated variants differing widely in tumorigenic potential and neurite differentiation. There is clearly no correlation between tumorigenesis and density sensitivity during *in vitro* growth. Regrowth of EGTA-treated cells on SAM-coated substrata selects for E_RB neurite-constitutive cells which apparently have lost the serum sensitivity for neurite formation as expressed in the parental cells; neurite extension and cell division are clearly not mutually exclusive events in these cells. The E_RA selection generates variants with an altered surface membrane that permits efficient cell fusion but not growth cone formation; the extensive elongation of these cells may also reflect some perturbation of cytoskeletal organization. Further study of these three variant classes should assist in establishing what cell surface properties are important in differentiation of these neural cells and in tumour formation in an appropriate host.

Many of these experiments were performed during a sabbatical leave in the laboratory of Dr Gordon Sato at the University of California, San Diego. Thanks are extended to Ms Bonnie Wolf for assistance in the tumorigenesis studies. L.A.C. was a Career Development Awardee of the NCI (1-K04-CA70709).

Ammonia inhibits phagosome–lysosome fusion in macrophages

A. H. Gordon*, P. D'Arcy Hart† & M. R. Young†

* Biophysics Division and †Laboratory for Leprosy & Mycobacterial Research, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

When foreign bodies, including many microorganisms, are ingested by cultured macrophages, they become enclosed in phagosomes, with which lysosomes usually fuse and then discharge their enzymes and other contents into the resulting phagolysosomes. Such fusion is, however, diminished or absent after the phagocytosis of some pathogens, notably *Mycobacterium tuberculosis*[1] and *Toxoplasma gondii*[2]. Assuming that the nonfusion is due to active inhibition by the intraphagosomal microbe, identification of an inhibitor should clarify the lysosomal control mechanism. It has been suggested that strongly acidic sulphatides present in virulent *tuberculosis*, which, like other substances with polyanionic structural features, can themselves block phagosome–lysosome fusion (P-LF)[3–5], may contribute to the negative lysosome response to ingested tubercle bacilli[4]. We report here another possibility, based on inhibition of fusion of yeast-containing phagosomes by filtrates from cultures of tubercle bacilli on traditional-type defined media; we show that the ammonia content of such filtrates is sufficient to account for their effect. This inhibition of fusion seems to be an hitherto unrecognized intracellular consequence of added ammonia, in striking contrast to the enhancement produced by some lipophilic amines[3].

Filtrates were obtained from surface-pellicle cultures of either *M. tuberculosis* virulent human strain H37Rv after 2–4 months on Ratledge–Hall 'normal' liquid medium[6], containing asparagine as sole nitrogen source, or *M. tuberculosis bovis* strain AN5 after 10 weeks on a modified Dorset–Henly liquid medium of similar composition. Lysosomes of mouse peritoneal macrophages in monolayer culture were prelabelled with acridine orange (AO) for darkfield vital fluorescence microscopy (VFM), or with ferritin for electron microscopy (EM)[3]. The cells were allowed to ingest fresh or 150-krad γ-ray-irradiated *Saccharomyces cerevisiae*, an organism which induces P-LF. Fusion was assessed by transfer of label into the yeast-containing phagosomes. With this test system (see ref. 3 for details), substantial inhibition of P-LF was obtained when the monolayers were exposed to either type of culture filtrate (diluted 1:5 or 1:10 in balanced salt solution (BSS)[7]) at 37 °C for 60 min immediately before the yeasts were offered for ingestion and then continuously until examination 45–60 min later (exposure to culture filtrate not being interrupted at any stage).

Experiments involving distillation, trapping in H_2SO_4 and gas chromatography suggested activity by a volatile base. Therefore, ammonia, a known constituent of *M. tuberculosis* cultures[8], was estimated in the culture filtrates, using glutamic transaminase and NADH (Sigma kit 170-UV), and was found to be as high as 20 mM. Replacement of culture filtrate by ammonia was tried and found to be effective in inhibiting P-LF, both by overall assessment using VFM and by quantitative assessment (based on screening surveys[1]) using EM (Table 1*a*, *b*). (Quantitative differences in estimating fusion between these two methods, and between fresh and irradiated yeasts, have been discussed elsewhere[3].) Corresponding to the formation of phagolysosomes by P-LF, degranulation (loss of lysosomes) takes place. Assessed by labelling the surviving lysosomes with AO, degranulation was much reduced by ammonia treatment of macrophages (Table 1*c*).

Ammonia rapidly enters lysosomes of macrophages and leaves rapidly after removal from the medium[9]. In the present

© 1980 Macmillan Nature Ltd

Table 1 Effect of ammonia on phagosome–lysosome fusion and degranulation in macrophages after ingestion of yeasts

Protocol	Optical system	Observation	Fusion or degranulation (%)	
			Untreated	Ammonia-treated
a	Fluorescence microscopy (AO label)	Phagosome–lysosome fusion	70	10
b	Electron microscopy (ferritin label)	Phagosome–lysosome fusion	92*(350)†	55*(390)†
c	Fluorescence microscopy (AO label)	Degranulation	90	25

a, Macrophage monolayers, after prelabelling with AO, were treated for 45 min with NH_4Cl (10 mM) in BSS at 37 °C and then exposed for a further 50 min to fresh yeasts at 10^6 cells per ml, the NH_4Cl still being present. (The results given are representative of 20 experiments, in 4 of which inhibition was evident using 1–2 mM NH_4Cl.) *b*, Macrophage monolayers, after prelabelling with ferritin, were treated for 45 min with NH_4Cl (5 mM) in BSS, then exposed for 30 min to irradiated yeasts (10^7 cells per ml). After washing to remove excess yeasts, incubation was continued for 45 min and the macrophages were then fixed. NH_4Cl (5 mM) was present throughout (including the yeast pulse and the washing). *c*, Similar to *a* but the yeasts, at 5×10^7 cells per ml, were applied for 30 min only, after which incubation was continued for 150 min, NH_4Cl (10 mM) being present throughout all stages; AO labelling was at the end of this period, immediately before examination. Figures denote percentage loss of AO-labelled lysosomes (results are representative of six experiments).

*Difference between results is significant ($P < 0.01$).

†Number of individual phagosome profiles counted.

work the lysosomes were seen to swell to a degree dependent on dose (evident by VFM and EM). At concentrations up to 10 mM for 2–3 h at 37 °C, the cells remained apparently healthy by light microscopy, with normal uptake of yeasts; by EM, autophagic vacuoles were few and mitochondria seemed normal in appearance. Moreover, when ammonia-treated macrophages that showed inhibition of P-LF were washed well with BSS and incubated for several hours, the lysosomal swelling declined and normal fusion pattern was restored.

Ethylamine and methylamine hydrochlorides were tested in the yeast system and showed some inhibitory activity. In view of this, and the behaviour of other amines tested by us previously, an interesting series with respect to effect on P-LF emerges. Lipophilic secondary or tertiary amines (for example, di- and tri-*n*-butylamine, dihexylamine, dibenzylamine, chloroquine and tetracaine) accelerated P-LF; lower tertiary and secondary amines (such as diethylamine and triethylamine) enhanced slightly; most primary amines tested (for example, *n*-butylamine and ethanolamine) also enhanced slightly[3]. Now we have the opposite effect, that is, some inhibition by the lower primary amines, ethylamine and methylamine, and much stronger inhibition by ammonia. The negative or weakly positive results of testing individual amines other than ammonia for inhibitory activity are in accord with further experiments with culture filtrate which indicate that the latter's ammonia content is sufficient to account for most, if not all, of its fusion-inhibitory activity in the yeast system. These experiments comprised comparison of activities of NH_4Cl and culture filtrate at equivalent ammonia concentrations, and repetition of the trapping experiment mentioned above, but after preliminary removal of the ammonia by treatment with glutamic dehydrogenase, NADH and α-ketoglutarate.

Ammonia raises intralysosomal *p*H (ref. 9) and inhibits degradation of lysosomal proteins[10–12]; so also do some other bases, including methylamine, tributylamine and chloroquine[9–11,13,14]. The present observation that ammonia has the opposite effect on P-LF to that of chloroquine and tributylamine makes it unlikely that its inhibitory activity operates through interference with *p*H and protein metabolism.

Thus, judged by fluorescence and electron microscopy, and by lysosomal degranulation, ammonia can inhibit P-LF in macrophages when *S. cerevisiae* is the target. Moreover, *M. tuberculosis* produces sufficient ammonia when grown *in vitro* to account for most or all of the fusion-inhibitory effect of its culture fluid in this yeast system. The possibility that *M. tuberculosis* achieves its fusion-inhibitory effect by the production of ammonia or relevant amines within phagosomes of macrophages is now being studied.

We thank Mr D. Andrews for a sample of culture filtrate, Mrs S. N. Payne and Mr N. L. Hemmings for analyses, and Miss K. H. Sullivan, Mr J. B. Gawor and Mr I. D. Parker for technical help.

Does the variability of the cell cycle result from one or many chance events?

Arthur L. Koch

Department of Biology, Indiana University,
Bloomington, Indiana 47405

Smith and Martin[1,2] proposed the transition probability (TP) model to explain the significance of the variability of the cell cycle length of individual cells within a clone or culture. This postulates that the cell cycle length consists of a fixed period of time, which is the same for all members of the population, plus a variable period which is distributed according to a negative exponential function among the individual cell cycles. This variable part is contained entirely within G1, may be controlled hormonally by the organism, and is assumed to result from a single first order random process that terminates the variable part of the cell cycle with constant probability. As originally proposed, the model failed to account for timing of the fastest third of the population[3]. Minor and Smith[4] assumed that there is biological variability in the previously presumed constant part of the cycle and that this variability accounts for the failure to see an abrupt discontinuity. They proposed that most of this kind of variation can be cancelled out by comparing sister cells. Thus, they proposed a second plot to test their model, the β-plot. This is a two-cycle semi-logarithmic plot of the percentage of sister-sister cells having a smaller difference in age at division than the time value corresponding to the abscissa of the graph. Their model predicts a straight line starting at 100% at time zero. Any model would require this value at time zero, but theirs requires that the plot be straight and parallel to the terminal slope of the α-plot. Shields and Smith[5] and Shields[6] have convincingly shown that for tissue culture cells of both mouse cell lines and *Staphylococcus albus*, the β-plots are linear for 97–98% of the cell populations and parallel to the α-plots. This has been taken as strong support for the TP model. Recently, in

developing computer simulation of a growth controlled (GC) model[7], I found that certain properties, such as the linearity of β-plots, are very sensitive to the presence of subpopulations of cells with longer doubling times. My major purpose here is to point out three statistical aspects of the cell cycle that are strongly influenced by growth rate heterogeneity for any model of the cell cycle.

The GC model as used here assumes that the sizes at successive divisions are uncorrelated and that the cell division produces daughter cells of equal size. I have assumed both a gaussian normal distribution and a negative exponential distribution and that growth of individual cells may follow exponential, linear or bi-linear growth laws. The negative exponential distribution was chosen because it is non-normal, moderately skewed in the positive direction and is the form assumed by the TP model. In addition, such a distribution would apply if the actual separation of the completed daughter cells proceeds by a process whereby the splitting into two separate cells has a constant probability with time[8] after the cells had physiologically divided.

Figure 1 shows computer-generated α- and β-plots for various combinations of distributions and growth laws. Calculation has been made for the case in which the coefficient of variation of the sizes of cells in the act of division (cv_d) is 0.1. It can be seen that the negative exponential–linear growth model gives linear β-plots; it is, in fact, equivalent to the TP model. However, the α-plot for this case has a quite different terminal slope. When exponential growth is assumed, both choices for the distributions of sizes at division give parallelism between the β-plot and the terminal part of the α-plot, but both are curved downwards. Table 1 gives the statistical parameters of these distributions and other statistics for these submodels.

For a single case, that of the prokaryote, *Escherichia coli*, there are reasons independent of the statistical data for choosing the GC model corresponding to the first line of Table 1. The distribution of sizes of cells showing constriction in electron micrographs is approximately gaussian and not exponential[9,10]. The coefficient of variation of sizes of cells engaged in cell division is small ($cv_d = 8$–14%)[11–13]; the rate of macromolecular synthesis is exponential[14]. Evidence for equality of cell division in producing equal-sized daughters is presented elsewhere[10,13], as are other types of evidence in favour of the model[12,13,15].

Some, but not all, of the statistical data for *E. coli* concerning cell cycle lengths agree with this GC submodel. The coefficient of variation of the distribution of ages at division ($cv_\tau = 20$–25%) is very nearly twice the coefficient of variation of the sizes of cells at division ($cv_d = 8$–14%)[13]. The model also predicts values of ρ_{ss}, the correlation coefficient of sister:sister ages at division of about 0.5 (see first line of Table 1). Values this high or higher have been observed in all studies except where cell division is very asymmetrical.

Certain experimental findings with *E. coli* and other prokaryotes are not predicted but are generally observed. They are: (1) that the measured correlation of ages at division of mother and daughters, ρ_{md}, is usually observed to be more positive as values near -0.5 predicted by the model (Table 1); (2) that the measured skewness of the distribution of ages at division, γ_1, is generally moderately positive instead of being nearly zero as predicted by the theory (Table 1); (3) that the β-plot is linear instead of exhibiting a downward curvature (see Fig. 1). Other choices of growth laws or distributions of division sizes do not give agreement (see Table 1 and Fig. 1). However, these three discrepancies can be fully resolved in a way which leaves the basic model intact by assuming that a small fraction of the cells in the population grow more slowly than do the majority. From Table 1 it can be seen that admixture with 2–3% more slowly growing cells decreases ρ_{md} and increases γ_1 towards values typically observed in the literature. Figure 2 shows α- and β-plots for the gaussian–exponential GC model with $cv_d = 0.1$ repeated from Fig. 1 together with the plots for hypothetical populations in which

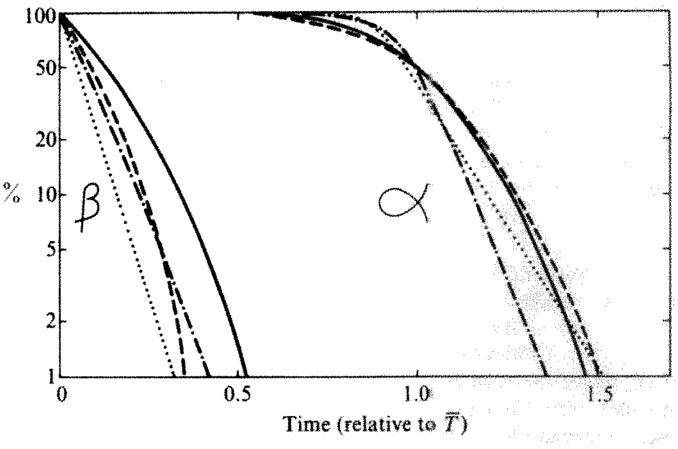

Fig. 1 α- and β-plots for four submodels of the growth controlled model of the cell division cycle. It was assumed that the coefficient of variation of the sizes of cells at division, cv_d, is 0.1 and that cell division partitions cell substances precisely. The submodels differ in the shape of the distribution of sizes at cell division and the mode of growth:

Distribution	*Growth law*	
Gaussian	Exponential	——
Gaussian	Linear	– – – –
Negative exponential	Exponential	– · – · –
Negative exponential	Linear	·····

Table 1 Statistical properties of growth controlled models of the cell cycle

Division distribution	Growth law	Coefficient of variation of the age distribution cv_τ	Skewness γ_1	Kurtosis† β_2	Sister : sister correlation ρ_{ss}	Mother : daughter correlation ρ_{md}
Gaussian	Exponential	0.204	-0.001	2.989	0.501	-0.501
Admixed with:						
2% delayed 0.57 Gen.		0.217	$+0.271$	3.758	0.775	-0.226
3% delayed 0.52 Gen.		0.219	$+0.305$	3.697	0.877	-0.125
Gaussian	Linear	0.221	0	2.886	0.200	-0.400
Gaussian	Bi-linear*					
$C = 1.3$		0.215	0	2.916	0.501	-0.501
$C = 1.6$		0.175	0	2.916	0.501	-0.501
Negative exponential	Exponential	0.136	0	4.651	0.502	-0.501
Negative exponential	Linear	0.157	$+1.196$	6.418	0.200	-0.399

All models are calculated for the assumption that the size of cells at division has a coefficient of variation (cv_d) of 0.1.

*C equals the size of the cell at which the rate of growth doubles relative to the mean birth size.

†For a normal distribution $\beta_2 = 3$.

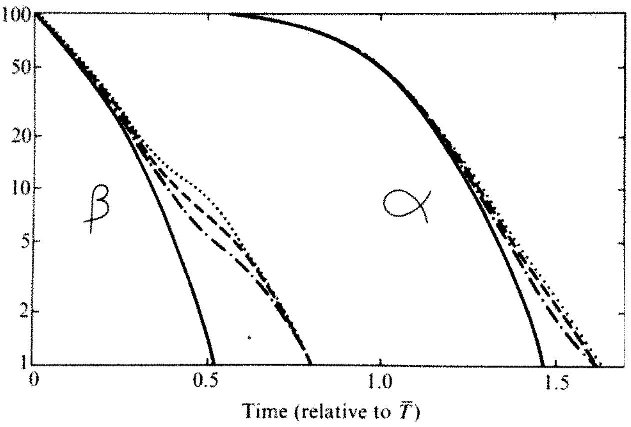

Fig. 2 The effect of straightening the β-plot by the admixture of a few per cent of more slowly growing cells. Calculations are for the gaussian distribution of sizes at division, exponential growth and $cv_d = 0.1$. ———, No admixture; –·–·–, 2% delayed 0.57 of $\bar{T}$; – – – –, 3% delayed 0.52 of $\bar{T}$; …., 4% delayed 0.49 of $\bar{T}$.

2, 3 or 4% are presumed to be delayed in division for about 0.5 of a mean generation compared with the majority population. In each percentage of admixture, I have fitted for the delay that gives the most linear β-plot.

The following conclusions follow from these considerations. (1) A small subfraction of slowly growing cells can greatly affect some but not others of the statistical properties of the life-lengths of cells in a growing culture. The coefficient of variation of the ages at division, and its relationship to the variation in size at division are not as responsive to the presence of a small proportion of more slowly growing cells. (2) The mother-daughter correlation, ρ_{md}, the skewness and kurtosis of the age distribution, γ_1 and β_2, and the curvature of the β-plots are very sensitive to admixture and therefore give little information about the events timing the cell cycle of the bulk of the cells of the population. (3) If there were a very few per cent of a population growing more slowly than the bulk of the cells, the transition probability model would fit the available data for a variety of cell lines very poorly. (4) In one case, that is, for *E. coli*, the gaussian–exponential submodel of the growth controlled model is known to apply because of the results of measurements not involving cell cycle length observations. These measurements involve electron microscopy, molecular biological measurements and autoradiography. In addition, the statistical properties not sensitive to admixture are consistent with the model. Consequently, for this case we believe that admixture of a small amount of a more slowly growing population accounts for the properties mentioned in (2). (5) Because it is virtually impossible to eliminate the possibility of a small, slowly growing subfraction experimentally, the measures mentioned in (2) are less useful and should not be used as a point of argument. (6) It is argued that instead, measurements of the distribution of cell properties at division and at other critical times in the cell cycle, and the growth kinetics of individual cells throughout the cell cycle be used as the basis for cell division models that apply to the majority class of cell populations as other cell types are studied. (7) Although the TP model may function for some cell lines, a single stochastic even cannot be adduced as timing the cell division cycle in any cell line based on the available types of data.

The insulin gene is located on chromosome 11 in humans

David Owerbach*, Graeme I. Bell*, William J. Rutter* & Thomas B. Shows†

*Department of Biochemistry & Biophysics, University of California, San Francisco, California 94143
†Biochemical Genetics Section, Roswell Park Memorial Institute, New York State Department of Health, Buffalo, New York 14263

The polypeptide hormone insulin is required for normal glucose homeostasis. Insulin deprivation results in diabetes, a disease affecting up to 5% of the human population[1,2]. In some animals there are two insulin genes[3]; however, in most others, including humans, a single gene is present. The conclusion that there is a single insulin gene in humans is based on the finding of a single insulin species and on genetic studies involving mutant insulin alleles[4,5]. As the pattern of inheritance of insulin defects is not sex linked, the insulin gene must be located on an autosomal chromosome[5]. Recently, genomic DNA segments containing the human and rat insulin genes have been cloned and the DNA has been sequenced[6–8]. The fact that mouse and rat insulins are identical[3] suggests that the insulin gene sequences and organization are similar. A knowledge of the restriction endonuclease map for the human and mouse insulin genes enables human or mouse insulin DNA sequences to be distinguished in somatic cell hybrids between the two species. In the present study, somatic cell hybrid gene mapping methodologies[9] have been used to determine the chromosome localization[10] of the human insulin gene. Human–mouse cell hybrids with different numbers and combinations of human chromosomes were examined for the presence of specific human chromosomes and the human insulin gene using cloned human and rat cDNA probes. A 14-kilobase DNA fragment containing the human insulin gene was present in some cell hybrids and was easily distinguished from the DNA fragments containing the mouse insulin gene found in all cell hybrids. Co-existence of the 14-kilobase fragment and chromosome 11 indicate that the insulin gene resolves on chromosome 11 in humans.

Human and mouse parental cells were fused with β-propriolactone-inactivated Sendai virus or polyethylene glycol in monolayer culture and hybrid cells were cloned and propagated in hypoxanthine, aminopterin, thymidine (HAT) selection medium (see ref. 9). The cell hybrids were isolated and characterized by isozyme and karyotype analysis (Table 1)[9]. Genomic DNA was prepared from 15 cell hybrids, each containing a full complement of mouse but a reduced number of human chromosomes. This DNA was digested to completion with *Eco*RI restriction endonuclease. The fragments were separated by agarose gel electrophoresis, and then transferred to filters by the method of Southern[11]. Cloned cDNA fragments containing the coding sequences for rat[7] and human[12] preproinsulin mRNA were labelled by nick translation[13] and used as probes for insulin gene sequences in the DNA from human/mouse hybrid cells. Filters were hybridized and washed as described in Fig. 1 legend. Although the human probe cross-hybridizes with mouse DNA sequences, preliminary experiments showed that the best resolution of both human and mouse insulin sequences in cell hybrids was obtained by using a mixed ^{32}P-labelled probe to both rat and

Chromosomally characterized human cell lines were used for parental cells. WIL hybrids (human WI-38 × mouse LM/TK$^-$), RAS hybrids (mouse RAG × human SH 421) and SIR hybrids (human GM 469 × mouse RAG) are derived from chromosomally normal human parental cell lines[22–24]. The remaining hybrid sets were derived using chromosomally characterized human translocation lines for regionally localizing human genes. TSL (GM 2808 × LM/TK$^-$) hybrids involve the [46,XX,t(3;17)(p21;p13)] translocation and segregate the 17qter→17p13::3p21→3pter translocation[25]. XTR (GM 2899 × RAG) hybrids involve the [46,X,t(X:3)(q26;q13)] translocation[26]. DUA (DUV × A9) and DUM (DUV × RAG) hybrids involve the [46,X,t(X;15)(p11;q11)] translocation and segregates the Xqter→Xp11::15q11→15qter and 15pter→15q11::Xp11→Xpter chromosomes[27]. The ALR (AnLY × RAG) hybrids involve the [46,X,t(X;9)(q12;p24)] translocation and segregates the Xqter→Xq12::9p24→9qter chromosome[28]. The JSR (JoSt × RAG) hybrids involve the [46,XX,t(7;9)(q22;p24)] translocation and segregates the 7pter→7q22::9p24→9pter chromosome[29].

*In each hybrid, chromosomes have been determined by Giemsa-trypsin staining[28] and follow the Paris system of human nomenclature[31]. In addition, enzyme markers whose genes have been assigned to each human chromosome, except the Y, have been tested on each hybrid and confirm the chromosome analysis (data not shown)[9,23,32].

†The insulin gene was measured as the 14-kilobase fragment.

‡The LDH A gene has been assigned to chromosome 11 by several laboratories (see ref. 30) and co-segregates with the insulin gene.

human insulin genes and washing the filters at high stringency.

In the control mouse cell line, three DNA fragments of 9, 1.8 and 1.4 kilobases hybridized with ^{32}P-labelled rat–human insulin probe (Fig. 1, channel 1). These results are similar to those obtained with rat DNA[7,8]. As both mouse and rat have two non-allelic insulin genes[3], and as one of the rat insulin genes contains an *Eco*RI site[7,8], the simplest interpretation of the data is that one of the mouse insulin genes also contains an *Eco*RI site. Thus, three DNA fragments containing insulin-specific sequences would be detected.

In the control human cell line (Fig. 1, channel 2), and in all human parental lines used in this study, a single *Eco*RI fragment of 14 kilobases hybridized with the rat–human ^{32}P-insulin probe. This agrees with the findings of Bell *et al.*[6], who showed that the human insulin gene is contained in a 14-kilobase *Eco*RI fragment. The presence of a single-size class of *Eco*RI fragments of human DNA containing insulin gene sequences also provides additional support for the existence of a single insulin gene in humans.

DNA from all 15 cell hybrids contained the mouse *Eco*RI fragments, whereas only some had the 14-kilobase human fragment (see Fig. 1 for representative data). The absence of the 14-kilobase *Eco*RI human fragment indicated the absence of the human chromosome on which the insulin gene is located. As the mouse sequences served as an internal hyridization control, the absence of the human 14-kilobase fragment was not due to other factors such as poor DNA transfer from the agarose gel or loss of DNA from the nitrocellulose filter. The segregation of the human insulin gene, human chromosomes and the chromosome 11 enzyme marker, lactate dehydrogenase A(LDH A) in the 15 human–mouse cell hybrids is shown in Table 1. All 22 autosomes and the X and Y chromosomes were scored both by karyotype and isozyme analysis (Table 1, see also ref. 9). For example, three hybrids (WIL-8Y, TSL-5, DUA-5) contained the human insulin gene but did not retain chromosome 1; it is thus obvious that the insulin gene is not on chromosome 1. The 14-kilobase human insulin fragment was invariably found when human chromosome 11 and LDH A were present in the cell hybrid (Table 1). None of the other chromosomes or enzyme markers co-existed with the 14-kilobase fragment (Table 1). The correlation of human chromosome 11 and the human insulin gene and the lack of correlation with any other human chromosome, conclusively demonstrate the localization of this gene on chromosome 11.

Restriction analysis of somatic cell hybrid DNA is a very useful addition to genome mapping technology. Any gene for which a molecular probe is available can be mapped. Several laboratories have mapped the β-globin genes to the short arm of chromosome 11 (refs 14–17). Our procedure for mapping the human insulin gene includes the use of 10% dextran sulphate in the hybridization mixture, which increases the rate and extent of hybridization with the probe[18]. With 10 µg of cell hybrid DNA and 3×10^4 c.p.m. of probe per cm^2 filter, it is possible to score the insulin-containing DNA fragment in less than 24 h exposure to X-ray film. These conditions permit the use of small numbers of cells (3–6×10^6) which can be obtained either from cell culture or from cells previously frozen for recovery in 10% glycerol, 20% fetal calf serum and tissue culture medium. These frozen cells, previously typed by chromosome and enzyme analyses, can be thawed, washed and used as a source of DNA without growing additional cells and rechecking the chromosome and enzyme complements. Finally, the use of probes and hybridization conditions that detect both mouse and human genes permit the use of mouse genes as an internal standard, thus eliminating external artefacts.

The causes of idiopathic diabetes mellitus are largely unknown. Some forms of the disease can be the consequence of the destruction of insulin-producing β cells of the pancreas after viral infection or by chemicals[1,2]. One example of diabetes, resulting from the production of a mutant insulin with altered biological properties, has also been reported[19]. In juvenile-onset or insulin-dependent diabetes a gene on chromosome 6 near the human lymphocyte antigen D locus (HLA-D) may influence the susceptibility of this form of the disease[2]. The present work demonstrates this locus is not in the vicinity of the insulin gene. There is also a hereditary disposition to the most common form of the disease, maturity-onset or insulin-independent diabetes[1,2]. If maturity-onset diabetes is a consequence of an altered insulin gene, the chromosome localization predicts that there should be a correlation among related diabetic individuals between diabetes and alleles of closely linked genes present on chromosome 11. Several genes have already been localized to specific regions of chromosome 11. The insulin gene may be precisely localized on chromosome 11 by examining hybrids

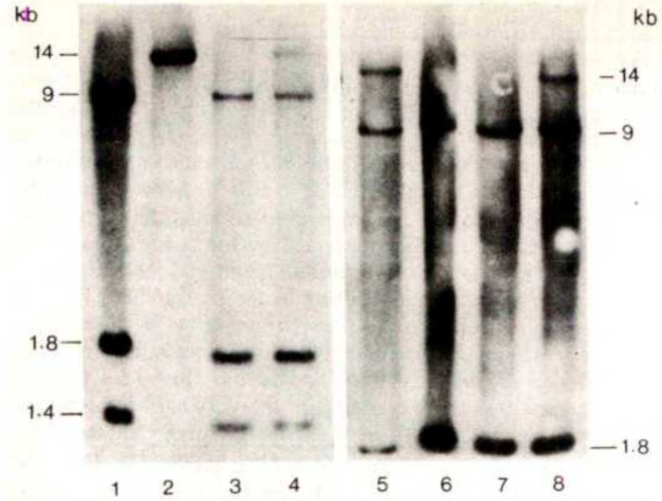

Fig. 1 Analysis of human and mouse insulin related DNA fragments present in restriction endonuclease digests of mouse, human and human–mouse cell hybrid DNA. DNA was prepared from a human T-cell lymphoblastoid cell line, RAG mouse cells and the 15 cell hybrids listed in Table 1. Approximately 4×10^6 cells of each hybrid clone were obtained from cells previously stored frozen in 10% glycerol, 20% fetal calf serum and tissue culture medium and were thawed, washed three times with Hank's balanced salt solution and DNA prepared as previously described[20]. Hybrid cells collected from monolayer culture were also used and prepared in the same way. 20–40 μg of high molecular weight DNA was obtained from 4×10^6 cells. The DNA was digested to completion with endonuclease *Eco*RI. Digested DNA (10–20 μg) was separated by electrophoresis through a 1% agarose slab gel and transferred by the method of Southern[15] to a nitrocellulose filter. pcRI-354 and pcHI-1 were labelled with ^{32}P *in vitro* by nick translation[17] with [α-^{32}P]dCTP and [α-^{32}P]dATP (NEN) to specific activities of $1\text{–}3\times10^8$ c.p.m. per μg. Before hybridization, nitrocellulose filters were treated for 2 days at 42 °C in 10 ml of a mixture of 50% deionized formamide, 5 × SSC (0.75 M NaCl, 75 mM trisodium citrate), 5 × Denhardt's reagent[21], 50 mM sodium phosphate buffer (*p*H 6.5) and 500 μg ml^{-1} sonicated denatured salmon sperm DNA (Sigma). Filters were then hybridized overnight at 42 °C in a 10 ml solution consisting of 50% deionized formamide, 5 × SSC, 1 × Denhardt's reagent, 20 mM sodium phosphate buffer (*p*H 6.5), 200 μg ml^{-1} sonicated denatured salmon sperm DNA, 10% sodium dextran sulphate 500 (Pharmacia)[18] and 2.5 ng ml^{-1} each of heat-denatured ^{32}P-labelled rat and human insulin cDNAs. Filters were then washed three times at room temperature with 2 × SSC, 0.1% SDS for 10 min each followed by three additional washes with 0.1 × SSC, 0.1% SDS at 50 °C for 15 min each. Labelled DNA bands were detected by exposing the filters to X-ray film for 1–5 days in the presence of an intensifying screen (Dupont). The insulin DNA patterns are shown for: (1), mouse RAG cells; 2, human T-cell lymphoblasts; 3, hybrid TSL-2; 4, hybrid SIR-8; 5, hybrid DUA-5; 6, hybrid JSR-6C; 7, hybrid TSL-8; 8, hybrid TSL-5. Fragments of *Hin*dIII-digested λ DNA were used as molecular weight markers. Channels 5–8 were run on a different slab gel and the 1.4-kilobase (kb) mouse insulin DNA fragment migrated off the gel. On long exposures, the autoradiographs of several hybrids (for example, channels 6, 7) showed high backgrounds. On shorter exposures, using the 9.0-kilobase mouse insulin fragment as a reference point, the 14-kilobase region could be accurately scored.

bearing translocations of this chromosome. Extensive information on the genetic loci of chromosome 11 may eventually allow the use of chromosome 11 markers to predict the probability of diabetes in individuals. Eventually, all or parts of chromosome 11 may be used in genetic engineering experiments for correcting diabetes in affected individuals.

We thank Dr R. Pictet for helpful discussions, L. Haley, M. Byers and R. Eddy for technical assistance, and L. Spector and C. Young for assistance in preparing the manuscript. This work was supported by NIH grant AM 21344 to W.J.R. and NIH grants GM 20454 and HD 05196 to T.B.S.

Electrophoresis of proteins in intercellular bridges

Richard I. Woodruff & William H. Telfer

Department of Biology, University of Pennsylvania, Philadelphia, Pennsylvania 19104

Cytoplasmic polarity giving rise at mitosis to daughter cells with distinct but complementary morphogenetic functions has been proposed by Jaffe and co-workers to have transcellular ion currents as one of its essential physiological steps[1]. The clearest evidence is from fucoid eggs in which such currents have been shown to parallel the prospective axis of germination[2,3]. The currents are caused by stabilized accumulations of cation pumps on one side of the cell, and of permeability channels on the opposite side[4]; they are strong enough to suggest that the accompanying gradient in electrical potential could have an electrophoretic effect on the distribution of cytoplasmic constituents, including those that serve as morphogenetic determinants. Although ion currents correlated with axes of morphogenesis have thus been clearly established, their effects on intracellular localizations and morphogenetic activity have remained speculative[5]. We report here evidence that an endogenously generated gradient in electrical potential in the oocyte–nurse cell syncytium of *Hyalophora cecropia* can, in fact, influence the distribution of soluble proteins in a cytoplasmic continuum.

The system consists of seven nurse cells linked to each other and to a single oocyte by seven cytoplasmic bridges, which are clustered in a complex at the centre of the group (Fig. 1). The mitotic divisions giving rise to the eight cells entail incomplete cytokinesis, and the cells subsequently remain in cytoplasmic continuity throughout their 9-month life span[6]. By the time vitellogenesis begins in the oocyte, the bridges are 30-μm wide channels containing no membrane barriers to intercellular diffusion, and little evidence of orientated cytoskeletal elements in their core of cytoplasm[7]. Despite this structural simplicity, nurse cell products migrate into the oocyte in an apparently polarized fashion[8,9]. The bridges provided an opportunity to test for intracytoplasmic electrophoresis because, as we showed previously[7], the equilibrium potential of the nurse cells is several millivolts more negative than that of the ococyte. Furthermore, a negatively charged, fluorescein-labelled, rabbit serum globulin (FSG), when micro-injected into the oocyte, was unable to cross

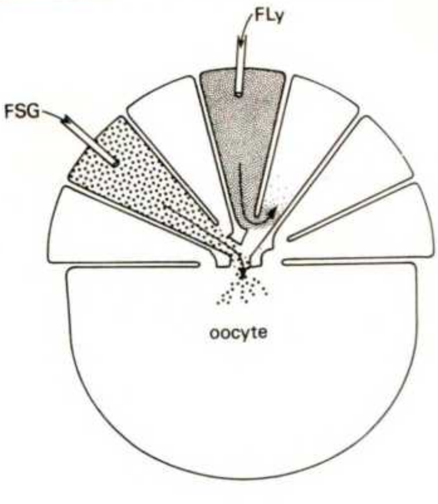

Fig. 1 Diagram of the oocyte and seven nurse cells and the distribution of the seven intercellular bridges that connect them. Also shown are examples of the behaviour of fluorescent serum globulin (FSG) and lysozyme (FLy) after injection into nurse cells.

the bridges into the nurse cells, although it readily moved in the opposite direction when injected into a nurse cell (Fig. 1).

These results showed definitively that the bridges are polarized both electrically and in their ability to transmit protein. Although they were thus consistent with the potential gradient being the polarizing force, satisfactory proof of this proposal needs evidence that basic proteins move through the bridges in the opposite direction from that of the acidic FSG. Our first efforts to test this possibility used fluorescein-conjugated histones, but were thwarted by the tendency of these proteins to adsorb onto cytoplasmic particles at the site of injection before they could diffuse to the intercellular bridges. We have now repeated the experiments with fluorescein-labelled lysozyme (FLy), a basic protein with an isoelectric point of 11.5, and obtained much clearer results. In 40 follicles the oocytes were injected with FLy and in every case fluorescence spread throughout the ooplasm, across the intercellular bridges and into the nurse cells (Fig. 2*a*, *c*). Fixation ranged from 1 to 2 h after micro-injection. In 25 additional follicles a nurse cell was injected and in no case did fluorescence spread to the oocyte (Fig. 2*b*, *d*), even after 2 h of incubation. FLy therefore crossed the bridges only in a direction opposite to that shown earlier for FSG.

An additional difference between FSG and FLy was seen in their capacities to move from nurse cell to nurse cell. In the earlier work FSG micro-injected into nurse cells moved directly to the oocyte, but was never seen to enter the other nurse cells,

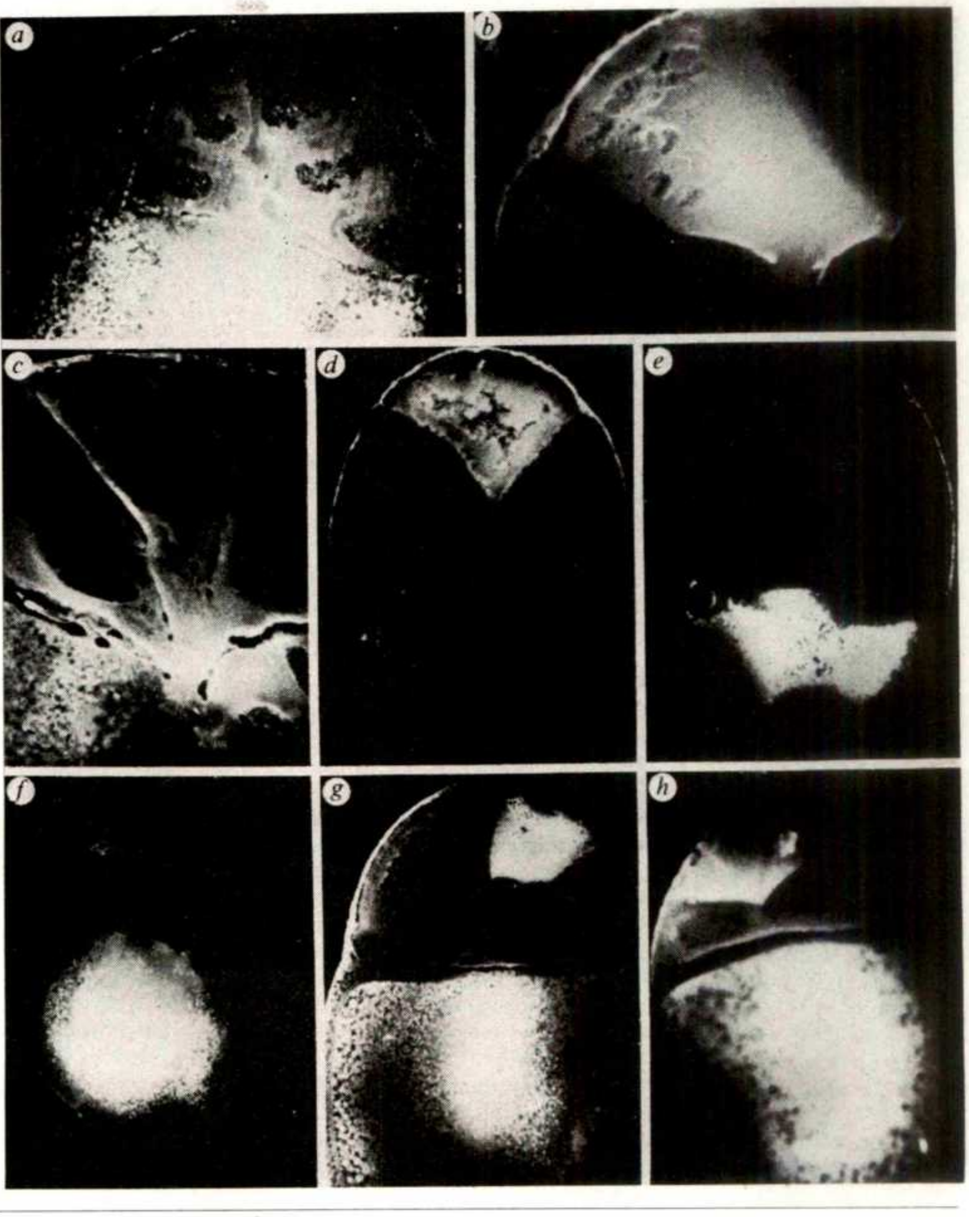

Fig. 2 Fluorescence photomicrographs of follicles injected with proteins labelled with fluorescein isothiocyanate FITC by the method of Nairn[15]. Micro-injection was carried out hydrostatically as described earlier[7]. The follicles were incubated in blood from the animal diluted 1:2 with dissecting solution[16]. In dilutions as great as 1:10, blood protein concentration is still sufficient to maintain membrane permeability and steady-state potentials identical to those which occur in whole blood. Following injection and 1–2 h incubation, follicles were fixed either by freeze substitution (*a*, *c*) or in Carnoy's acid-alcohol (*b*, *d*–*h*), embedded in paraffin, sectioned and examined with a fluorescence microscope. Photographs were taken with Kodak Tri-X pan film (ASA 400). *a*, *c* Fluorescent lysozyme (FLy) micro-injected into oocytes; *b*, *d*, FLy micro-injected into nurse cells. Note in *b* that protein has entered a co-bridged nurse cell (see Fig. 1), but failed to cross into the oocyte. *e*, *f*, Methylcarboxylated FLy (MCFLy) micro-injected into oocytes gave no detectable fluorescence in the nurse cells. *g*, *h*, MCFLy micro-injected into nurse cells. Magnification: in all cases shown, here and in Fig. 3, the width of the nurse cell cap adjacent to the oocyte was about 450 μm.

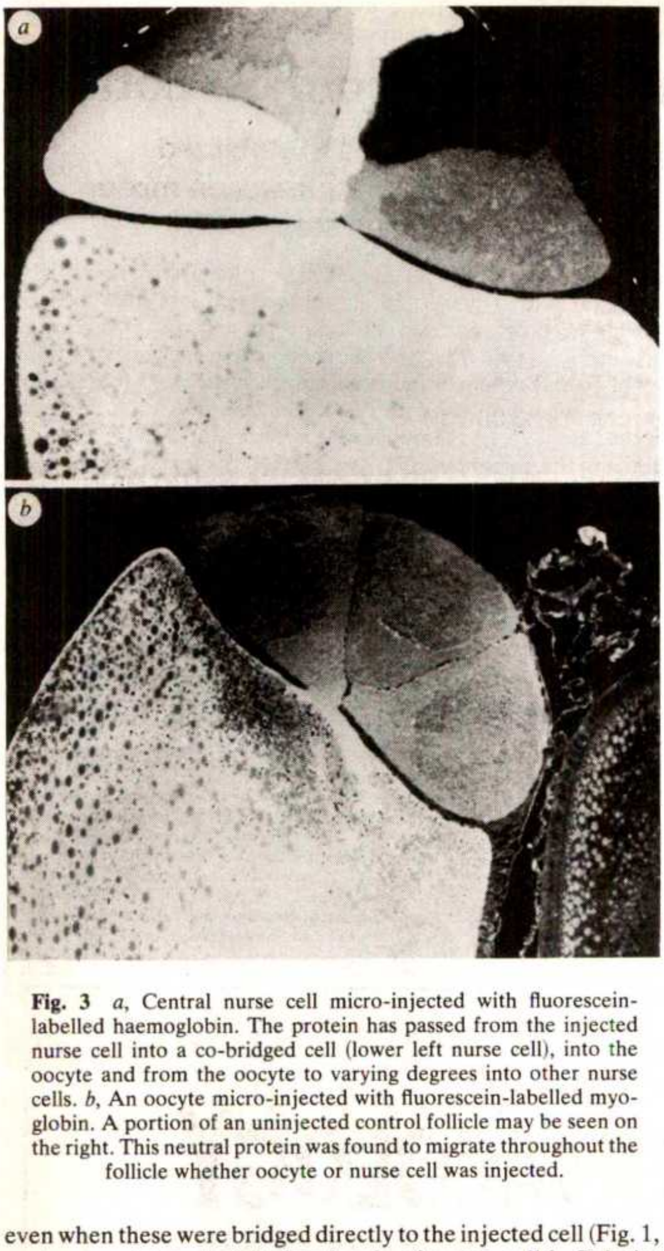

Fig. 3 *a*, Central nurse cell micro-injected with fluorescein-labelled haemoglobin. The protein has passed from the injected nurse cell into a co-bridged cell (lower left nurse cell), into the oocyte and from the oocyte to varying degrees into other nurse cells. *b*, An oocyte micro-injected with fluorescein-labelled myoglobin. A portion of an uninjected control follicle may be seen on the right. This neutral protein was found to migrate throughout the follicle whether oocyte or nurse cell was injected.

even when these were bridged directly to the injected cell (Fig. 1, centre quartet and right hand pair of nurse cells). Polarity apparently extends throughout the bridge complex, and whenever the negatively charged FSG entered this zone, it was unable to move in a direction away from the oocyte. By contrast, when nurse cells were injected with FLy, label entering the zone containing the bridge complex, although unable to proceed into the oocyte, was able to enter the nurse cells directly bridged to the injected cell (Fig. 2*b*). FLy thus seems to diffuse against the electrical potential gradient more readily than FSG.

To confirm that the differences in behaviour resulted entirely from the positive charge of lysozyme and not in part from its small size (molecular weight 14,600), the electrical properties of this protein were altered by methylcarboxylation of its ε-amino groups[10]. The polarity of lysozyme movement in the bridges was now completely reversed—it behaved exactly as FSG had behaved in the earlier work (Fig. 2*e*–*h*), passing from nurse cell to oocyte (48 injections), but not from nurse cell to nurse cell or from oocyte to nurse cell (40 injections). To extend the correlation between charge and mobility through the bridges, we also injected fluorescein-conjugated haemoglobin (21 injections) and myoglobin (28 injections), both of which have isoelectric points close to neutrality, and found that they were able to move in both directions across the bridges (Fig. 3*a*, *b*). When the fluorescein-labelled proteins were compared by electrophoresis in agarose plates at *p*H 7.0, they were found to exhibit the following sequence of mobilities towards the cathode: lysozyme > haemoglobin = myoglobin > methylcarboxylysozyme ⩾ serum globulin. The charge dependence of the mobility of these proteins decisively supports the idea that the potential gradient across the bridges is steep enough to polarize the movement of soluble proteins.

Is the intracytoplasmic electrophoresis observed here a unique adaptation to the transport requirements of the oocyte–nurse cell syncytium or an exceptionally clear example of a more ubiquitous mechanism of polarity? The widespread occurrence of transcellular ion fluxes in developing cells[1,11] suggests that intracytoplasmic potential differences are not unusual. The intercellular bridges, which are a special feature of our system, focus the potential gradient at the equator of the complex, and allow a qualitatively clear result in which fluorescent proteins either do or do not pass through to the uninjected cell. Although the diffusion of our fluorescent probes may prove not to be so dramatically restricted in polarized cells that lack an equatorial constriction, intercellular bridges occur more commonly than might be supposed. Many dividing cells generate transitory bridges of cytoplasm late in cytokinesis[12,13], and ionic communication through these channels attenuates gradually until division is complete[14]. Any dividing cell that is electrically polarized, therefore, should generate a transiently focused gradient in potential steep enough to restrict diffusion to the degree seen here for the oocyte–nurse cell syncytium.

Corrigendum

In the *News and Views* item on 'Dendochronology' by Sara Champion, *Nature* **284,** 663 (1980), reference should have been included in paragraph four to the work of Hubert Polge and in particular to his paper, *Br. Arch. Rep.* S51, 77 (1978).

Erratum

In the letter 'Inhibin is absent from azoospermic semen of infertile men' by R. S. Scott and H. G. Burger, *Nature* **285,** 246–247 (1980), the following was omitted from line 13 on page 247 'relationship of inhibin concentrations to those of serum FSH in spontaneous disorders of the seminiferous epithelium has not been studied. It has been previously shown that a reciprocal'.

BOOK REVIEWS

What price conservation?

Kenneth Mellanby

The Common Ground: A Place for Nature in Britain's Future? By Richard Mabey. Pp.280. (Hutchinson: London, 1980.) £8.95.

WILDLIFE conservation is an important interest of a section of the British public — voluntary conservation organizations such as the Royal Society for the Protection of Birds, the Society for the Promotion of Nature Conservation and the many County Naturalists Trusts have several hundred thousand members. But the majority of the people of Britain are uninformed and indifferent. Is it therefore reasonable to expect wider support — and more money — from central government?

The British Nature Conservancy Council (NCC) is the official organization set up by Parliament "for the purpose of nature conservation and fostering the understanding thereof" and has the task of "maintaining the heritage of wildlife and natural features". Lack of funds and of popular support have always restricted the NCC in its work. During the financial year 1978–79 it received a grant from public funds of £9,535,000 of which £1,725,000 was earmarked for the purchase of the Ribble marshes, a wetland area of international importance for birdlife which would otherwise have been drained and used for intensive arable farming. Unfortunately this grant is unlikely to be increased or even maintained in value, particularly in the face of economic cutback. As one way of gaining support, and in an attempt "to widen the public debate in nature conservation", the NCC asked Richard Mabey to make a special study of the place of nature in Britain. He was helped by the NCC, but was given a free hand to write his own book.

For some centuries Britain has been fortunate in producing gifted amateur naturalists who have often done more than the professional scientists to observe and record our wildlife and the changes in the countryside. Richard Mabey is already well known as a worthy recruit to this body of men and women, and for his books which include *Food for Free* (Collins: London, 1975) which describes the fruits, fungi and other delicacies which the observant may gather in our fields, woods and hedges, and *The Unofficial Countryside* (Collins: London, 1973) which deals with the city and suburbia, and shows how nature adapts to human interference, which may stimulate the spread of many species of wild plants and animals. In *The Common Ground* he deals with human effects on what most people consider to be the natural countryside of Britain.

Of course Richard Mabey is well aware that almost all the landscape in Britain today has been affected by human activity, and that this situation, though changing year by year, has obtained for hundreds of years. Nevertheless, until recently, wild plants and animals were allowed to exist, often in greater numbers than were found in the dull and uniform forest which covered most of the country before agriculture changed the face of the land.

Here Richard Mabey deals at some length with old deciduous woods. Though they now only cover a fraction of the countryside, until relatively recently they continued, as a result of traditional management practice, to be beautiful, diverse and fascinating to the naturalist. They provided recreation for many and biological interest to the observant. Many such woods have now been felled and the land farmed, others have been transformed into uniform stands of exotic conifers.

In the same way farmland, with its hedges and shelterbelts, with old unimproved grassland and a multitude of ponds, allowed native species to flourish. In the past 30 years, farming has become much more productive, but the interest of the countryside and the abundance of wildlife in intensively farmed areas has greatly decreased. Hedges have been grubbed up, ponds filled and old grass with its wealth of wild flowers has been replaced with short-term leys of rye grass and clover.

The description of rural Britain in this book, based on its author's first-hand experience and his careful observation, is depressing to anyone with the slightest interest in natural history. Although only a few species of animals and plants have actually been exterminated, the numbers of many others have been drastically reduced. The whole pattern and diversity of the landscape has been altered and impoverished. However, Richard Mabey is no elitist. He has no time for those who think that conservationists should concentrate their efforts on safeguarding a few reserves rich in rare species, where the public is excluded, while the whole of the rest of the countryside is sterilized. He clearly loves wildlife, and wants to share it with as many people as possible. To him the common species may be as valuable as the scarce, and he wants wildlife to be readily visible in all parts of rural Britain.

Though the NCC has a statutory duty to set up and maintain nature reserves, it fully agrees with Mabey that these are only a part of its responsibilities. Experience has shown that isolated reserves may be of decreasing importance, for they may lose the very species that they were set up to preserve. Thus Monks Wood National Nature Reserve, one of the few areas of old woodland in eastern England, has been known as a site supporting rare and local butterflies for over 150 years. These butterflies appeared to flourish in the nineteenth century when the wood was used for coppice and timber, and in the first part of the twentieth century when its main importance was as a pheasant shoot. Clear felling of much of the wood did not harm the Lepidoptera. Since 1953, when it became an official reserve, and has been managed primarily for wildlife, no fewer than 10 of the 14 species of butterfly most sought by entomologists have disappeared. This may partly be because of inefficient management; as I had this responsibility for part of the time I know that we still do much in ignorance of the results. But I think that the main reason is that a woodland reserve of 150 hectares (and, by our standards, this is a large lowland wood) is too small to support many insect populations if it is an island in an area from which exchange and reinforcement does not take place.

How then can we encourage the return of our wildlife, and how can we convince the public that this is something they should support? Richard Mabey is too honest to pretend that he has any easy answers. He sees the point of view of the farmer, and does not pretend that conservation, or a return to the methods of previous centuries, will increase his income or his productivity. He makes a number of useful points about the way public and voluntary bodies can make minor contributions. His main suggestion is that "we need an imaginative land-use policy — a 'land ethic' — which recognizes that the fate of wildlife is inextricably connected with our own, and that nature conservation touches on the quality (and perhaps the continuance) of all our lives".

I agree strongly with his views on a land-use policy. Earlier this year, as the then chairman of the Environmental Division of the Institute of Biology, I organized a conference on this very subject. In it we discussed the various sectional demands for land — agriculture, forestry, water collection, recreation, waste disposal, nature conservation. Conservationists were agreed that we need to find some way of giving priority to wildlife even when economic forces work in the opposite direction. The difficulty is to find a reason for wildlife conservation which is convincing to those not already committed.

While I fully agree with Richard Mabey that wildlife may contribute greatly to the quality of life — at least of my own life, as one much involved in this field — I am doubtful whether I can support the idea that human continuance on the globe is in any way involved. I was equally worried by the recent *World Conservation Strategy*, produced by the International Union for Conservation of Nature and Natural Resources (see *Nature* **284**, 113; 1980), which relates wildlife conservation to sustainable development. I fear that conservationists may sometimes claim too much. On a world scale it may be wise to try to preserve all species, particularly plants which may have an unexpected potential or contain genetic material which may contribute to better cultivars of food species. I personally would be very upset if the large wild mammals of Africa and Asia were exterminated, but were I a peasant farmer whose crops were consumed by elephants and whose stock was killed by lions I would welcome the elimination of animals which, to me, were pests. British farmers have only gained from the extinction of the wolf, the bear and the beaver, however much some conservationists would welcome the reintroduction of these species.

The modern arable farm in Britain, which has done so much to harm wildlife, has not suffered in the process. The land is producing higher yields, and by any reasonable measure the fertility of the soil is being steadily improved. The disasters arising from monoculture, reduced rotations and increased fertilizer use which some ecologists foretold have not been apparent, though wildlife (including weeds and pests) has been devastated. I am unable to advance any purely economic reason when I try to persuade a farmer to take active steps to encourage wildlife. I have to rely on aesthetic, scientific or even spiritual values — in fact on the 'quality of life'.

Fortunately many farmers are willing to set aside small patches of land where cover may develop and wildlife survive. This is good conservation, but it makes no contribution to agricultural efficiency, in fact it probably reduces productivity slightly. This is the sort of compromise which the late Ivor Brown described as the British genius for making the second best of both worlds.

For, from the point of view of wildlife, it is only a second-best solution. If we are really serious, we must be prepared to establish far more and far larger nature reserves, even sacrificing good agricultural land for this purpose. We must also persuade farmers and foresters to make real sacrifices in productivity. Perhaps *The Common Ground* will help to produce a climate of opinion where such developments are possible. In any event it is an excellent book which will make its readers, even those within the conservation movement, better informed. By showing them how serious have been our losses, it should encourage them to redouble their efforts to protect our wildlife. Whether it will appeal to the non-caring majority is another question. ☐

World of the stellar life-cycle

J. D. Barrow

White Dwarfs, Black Holes: An Introduction to Relativistic Astrophysics. By R. Sexl and H. Sexl. Pp. 198. (Academic: New York and London, 1979.) \$13.50, £7.60.

STARS often die very violent deaths and their mortal nature has caused modern astronomers to focus more and more attention upon the circumstances and consequences of their demise. In so doing, astronomers have become astrophysicists. Supernovae, pulsars, quasars, black holes and the entire body of high-energy cosmic phenomena require for their elucidation a delicate amalgam of knowledge concerning nuclear and quantum physics tempered by an understanding of the all-encompassing effects of gravity.

The more massive a star, the higher the temperature and rate of nuclear ignition in its central regions, the faster it evolves and the more dramatic its death throes. After their nuclear fuel is exhausted the most massive stars collapse; at first slowly but then catastrophically. A huge explosion can transform this unstable stellar state into a supernova explosion, expelling the outer layers of the star and scattering heavy elements and high-energy particles out into space in dramatically visible fashion.

Our Sun is not in the heavyweight stellar league. A member of the stellar bourgeois, it awaits a slower and quieter death. Although at present it burns only about 10^{16} of its 10^{30} kg of fuel every day, eventually, like all stars, it will suffer an irresolvable energy crisis. When the internal supply of fusible hydrogen is exhausted, exothermic fusion of other heavier elements must be employed to stave off the pressures of gravitational collapse. Gravitational potential energy can be tapped by adjusting to a more stable configuration with a contracted core and extended outer regions. The star inflates and appears superficially cooler and redder; it has become a 'red giant'. In such a bloated state our Sun would have expanded to encompass the orbit of Mars.

As the central temperature rises inexorably, heavier and heavier elements undergo exothermic nucleosynthesis until a turning point is reached: even if the temperature is high enough for the fusion of elements heavier than iron, these fusion processes are endothermic. The star has now lost its conventional means of pressure support.

The smallest stars, with mass less than ~ 1.5 that of the Sun, can form a stable, compact state termed a 'white dwarf'. To reach such a configuration the Sun would have to shrink one-million-fold to a size comparable with the Earth and, in so doing, increase its average density to about 10^3 kg per cubic centimetre. It would sit securely locked between the opposing forces of gravity and electron degeneracy pressure. The reason gravity can be countered is the exclusive nature of subatomic society. No two particles of a type that includes neutrons, protons and electrons can occupy the same energy state. In cool 'laboratory' gases pressure is determined by the kinetic energy of the constituent molecules and energy can be extracted by dropping an atomic electron into a lower energy orbit. In degenerate material the energy niches fill from the bottom upwards and no low-energy slots are left vacant. The density, rather than the temperature, determines the kinetic energy of the electrons. Once in the white dwarf state a dying star can only cool to a dark ember. Such are the non-linearities of gravity that, the larger a star in its youth, the smaller the dwarf it becomes in death.

If a star exhausts its nuclear fuel when a little larger than 1.5 Suns, its internal stresses can become so large that electrons are eventually torn from their atomic orbits and crushed into the nuclei. The result is a closely packed lattice of about 10^{57} neutrons, squashed to a nuclear density one-billion times higher than within a white dwarf. A strongly repulsive degeneracy pressure now arises between the neutrons and the squeezing is halted, eventually leaving a 'neutron star' in stable equilibrium, just a few kilometres in diameter. Free neutrons decay into protons and electrons in about ten minutes but the neutrons in a neutron star, like those comprising an atomic nucleus, do not undergo such decay. The resulting proton would have to occupy an extremely unfavourable energy state.

White dwarfs and neutron stars have been observed by radio, X- and gamma-ray astronomers and rapidly rotating neutron stars provide an explanation for the 'pulsar' phenomenon.

The fate of the heaviest stars is well known to the average reader: unstoppable collapse to a 'black hole' state of ever-increasing density. A point of no return, the 'event horizon', is encountered by infalling material and no known forces can support the star once it has been encompassed by this surface. The collapse proceeds inevitably to an unknown singular state.

This is the exotic life-cycle of stellar bodies and its documentation often requires a description of matter in gravitational fields too strong for Newton's classical theory to be accurate. And this is the world that the Sexls equip the student to explore. *White Dwarfs, Black Holes* is a translation of a new edition of their successful German text explaining the nature of general relativity, gravitational waves, relativistic astrophysics and elementary cosmology. It is clear and concise, didactic in style and eminently suitable for final-year undergraduates in physics or astronomy. General relativity is described in qualitative terms (no prior familiarity is assumed and no tensor analysis is developed in the text) with a good description of its experimental status although, unfortunately, the observations of the binary pulsar are not included. The authors maintain a good balance between theory and observation by concentrating upon hard, testable results rather than speculative possibilities. However, it is odd to see some of the theory of primordial nucleosynthesis developed without a glimpse at the observational data on cosmic abundances of very light elements. The authors use physical reasoning wherever possible and avoid the use of inessential mathematics. SI units are used throughout and illustrations are skilfully employed to augment, rather than merely re-state, the textual material. A series of exercises are scattered through the text and many have 'solutions' provided. Some of these questions are a little too open-ended to be useful for private study because specific background references are not provided.

Unfortunately referencing is often scanty and imprecise. There is a considerable amount of name-dropping in the text without reference to sources or follow-up articles, and the bibliography is categorized in a fashion that may be too general for students. A list of specific semi-popular articles would have been useful here. But these are second-order problems in a book that is clearly written, well produced and realistically priced. I recommend it to any student who is contemplating graduate work in astrophysics, to teachers seeking a well-ordered foundation course, or indeed to anyone curious to know what relativistic astrophysics is about. □

J.D. Barrow is a Research Lecturer in the Department of Astrophysics at the University of Oxford, UK.

Experts on vacua

John Yarwood

Methods of Experimental Physics. Volume 14, *Vacuum Physics and Technology.* Edited by G.L. Weissler and R.W. Carlson. Pp. 593. (Academic: New York and London, 1979.) $55, £13.80.

THIS BOOK contains a great deal of useful information, concisely and well-written by a number of American authors, all of whom are widely experienced in vacuum science and technology and have up-to-date knowledge gained in academic or industrial research.

The difficulty in judging the book is to assess at whom it is aimed. Despite the fact that the purpose (according to the title of this series) is experimental, a fairly sophisticated mathematical notation is almost always used by the authors so that a reader of that useful type of person — the technician — is, by and large, ruled out. The style is really more suited to the postgraduate student of science or technology.

Roughly the first half of the text is concerned with the production and measurement of vacuum (mostly high and ultrahigh). Although the authors frequently give ideas and explanations which are novel, the topics concerned have received much attention in textbooks and journals over the past 30 years or so. One wonders, therefore, whether it wouldn't have been preferable to omit most of the well-worn material and concentrate on the more novel second half, beginning with "Metal Vacuum Systems and Components". Here, modern information is provided about components and materials and their most effective use in the design of vacuum systems for specific applications.

The book contains no information about how the undergraduate student should go about undertaking practical work in vacuum science and technology. However, it will be most useful to the member of academic staff who is concerned with the development of such practical experiments and wishes to write them up satisfactorily for undergraduates, students beginning research and for special short courses. □

John Yarwood retired in 1978 as Head of Physics at the Polytechnic of Central London, UK, and is the editor of Vacuum.

First of a series on inflammation

G. P. Lewis

Handbook of Inflammation. Volume 1, *Chemical Messengers of the Inflammatory Process.* Edited by J. C. Houck. Pp.422. (Elsevier/North-Holland: Amsterdam and New York, 1979.) $75, Dfl. 154.

IN THE introduction to this first volume of the *Handbook of Inflammation*, the editor, John C. Houck, gives a splendid though brief account of the various steps in the inflammatory process. The book has then been arranged so that the mediators connected with each stage have been discussed.

Our old friend histamine comes first, but brought up to date in a very interesting way. In addition to the work of recent years on H_2 receptor-mediated actions, the author reviews current ideas on the possible regulatory function of histamine on activities of inflammatory cells. This theme of cell–cell interactions mediated by soluble mediators is taken up again later in the book in several chapters. Lymphokines, which were originally thought only to be the soluble products of activated T-lymphocytes, have now been shown to be not strictly restricted to immune activation pathways. The author of this particular chapter points out that release of soluble intracellular mediators might be a basic method of biological communication and describes lymphokines and cytokines as a plethora of inflammatory mediators which even includes viral and immune interferon.

The kinin system is described in some detail with the emphasis on biochemical aspects; only two of the 46 pages cover the role of kinins in inflammation. The review very adequately covers the relationships between the kinin and fibrinolytic systems and Hagemann factor, and the repetition of much of this in a later chapter on Hagemann factor seems to be unnecessary.

There have been so many reviews on prostaglandins in the past year or so that I was pleased to see only one modest chapter on this subject. But with the increasing knowledge of the importance of products of arachidonic acid metabolism other than prostaglandins, it seems unfortunate that this chapter did not include more information about thromboxane and the lipoxygenase products including SRS-A.

The book includes a very comprehensive chapter on complement and chemotaxis in which old and new methodologies in this complicated field are explained and compared.

In addition to discussions on mediators which might affect intracellular activities, there are two accounts of some cellular components which might be affected and which might play a role in the tissue damage which accompanies chronic inflammatory conditions. These are the lysosomal enzymes of which we are told there are more than 40 which are mostly hydrolytic and the acid cathepsins. They might well play a role not only in causing tissue damage but also in the formation of biologically active degradation products. But in spite of an enormous amount of research in this field, the extent of the involvement of these enzymes is not known. However, the discussions include an interesting description of the control mechanisms involved which might give a pointer to the direction that future work should take.

Volume 1 concludes with three fascinating chapters about factors controlling the growth of cells. Many of us who have become familiar with the mediators of the vascular changes and cell migration and activation in inflammation are not so familiar with growth factors and their inhibitors. The significance of macrophage growth factor in biology, for example, is just beginning to emerge. The future will reveal how important are the factors controlling differentiated cell populations at sites of inflammation and their role in inflammation and tissue repair.

Not only is the proliferation of inflammatory cells a significant aspect of inflammation but the proliferation of endothelial cells in growing blood vessels is also important, particularly in tissue repair. The editors decided to cover this aspect with a review on tumour angiogenesis which I personally found exciting and stimulating.

Finally we are treated to another fascinating account, this time about chalones, the tissue-specific inhibitors of cell proliferation. The chapter starts with the story of the early theoretical considerations and the early experimental evidence for the existence of chalones, and goes on to describe the arguments of mitotic stimulators versus mitotic inhibitors. A final glimpse into the future suggests the possibility of inhibiting the mast cell proliferation in *Urticaria pigmentosa* with a mast cell chalone.

There is no doubt that this first volume of the *Handbook* is a valuable addition to the literature on inflammation. It is a pity that the book, superficially well produced, has suffered from deplorable copy-editing and proof-reading — over 200 typographical and grammatical errors, and discrepancies in the references, have been noted in just two chapters. A list of these has been sent to the publishers, who will hopefully take greater care over subsequent volumes. □

Science from the Serengeti

Hans Kruuk

Serengeti: Dynamics of an Ecosystem. Edited by A.R.E. Sinclair and M. Norton-Griffiths. Pp.389. (University of Chicago Press: Chicago and London, 1980.) $28.50, £17.10.

THE STREAM of papers emanating from the once so active Serengeti Research Institute has dwindled over the past decade, and the Institute is now only a shadow of its former self. The large concerted effort by scientists from many disciplines to provide an ecological basis to the management of this huge ecosystem in Tanzania has virtually stopped. What is the result of all this effort? *Serengeti* is a sample of the diversity of output of the Serengeti Research Institute, with contributions from a dozen of its former scientists; the book is an attempt to take stock, and to evaluate some of the research in terms of conservation and management. It is clearly focused on the phenomenon for which the Serengeti is justly famous, the vast population of migratory ungulates.

Of the 13 chapters, three by A.R.E. Sinclair describe the Serengeti background, the history and the migrations of its animal populations; the interactions between the most important migratory and resident ungulates and the vegetation are studied in detail in a further four chapters by S.J. MacNaughton, P.J. Jarman and Sinclair, L. Maddock, and M. Norton-Griffiths. C.J. Pennycuick analyses the cost of locomotion to the migrants, R. Hilborn and Sinclair describe simulation studies of the Serengeti populations, and P.J. and M.V. Jarman compare ungulate social organizations. Three chapters, one by B.C.R. Bertram, one by J.P. Hanby and J.D. Bygott, and one by D.C. Houston look at the large predators and scavengers, their social systems, population changes and adaptations to the herbivore migrations.

The book is more a collection of distinct individual contributions than a united evaluation. However some of these contributions are outstanding; I was particularly struck by MacNaughton's beautiful experimental approach to the grazing relationships. Norton-Griffiths' clear analysis of the relation between animal populations and movements, climate, fire and other factors in this huge ecosystem should be an example to many other studies in this field. The predator chapters give a summary of much of the work that has been done on the Serengeti carnivores, and they indicate once again the complicated consequences for the carnivores' social organization of a rapidly increasing prey population. At the end of the book there is a useful list of over 300 references to the scientific publications of the Research Institute.

In general, the quality of all the chapters is good, and the book is full of fascinating observations which more than overshadow its shortcomings. One feels the absence of a chapter on the botanical and soil studies carried out in the Serengeti — everything is seen through zoologists' eyes. The two introductory chapters with their categoric statements fall somewhere between reviews and new contributions, without doing full justice to either of these functions. Scientific modesty would be served if it were pointed out that present population levels of ungulates are well above anything that was predicted as 'equilibrium' only a few years ago, thus indicating some of the limitations of the work of ecologists in such an ecosystem, even when the most elegant predictive models are used. And clearly it is prudent not to attempt to explain these population increases only in terms of the eradication of rinderpest in the early 1960s, since non-vulnerable species also increased — a fact conveniently forgotten in some of the chapters.

These are relatively minor grumbles, however, as are the irritation of the printing errors and the unaccredited photographs in one batch in the middle of the book which are not related to the text. What I missed most of all was a final chapter by the editors in which they could have pulled the strings together instead of leaving the papers as separate entities.

Despite all this, the book stands as an important monument to the efforts of the Serengeti Research Institute, and I have no doubt that it will be a work of reference for many studies elsewhere. I hope that before long the Institute itself will again be in a position to make full use of it. □

Hans Kruuk is a Principal Scientific Officer at the Institute of Terrestrial Ecology, Banchory, UK.

Microwave spectroscopy

H.W. Kroto

Modern Aspects of Microwave Spectroscopy. Edited by G.W. Chantry. Pp. 513. (Academic: London and New York, 1979.) £38.80, $89.50.

YET another expensive volume containing articles by several authors! I have never been totally convinced that this is a satisfactory way to publish reviews. Such books often suffer from one or more of three main defects: the material tends to be three or four years out of date on publication, the various chapters may be uneven in quality and balance, and finally, more often than not, many chapters are intrinsically re-hashes of previously published reviews, often by the same authors. On the whole this book is better than average on these three scores and, indeed, microwave spectroscopy is one of the few areas for which there does not exist a surfeit of such books.

The first chapter, "Microwave Spectrometers" (G.W. Chantry and G. Roussy), gives rather brief general descriptions of various experimental techniques which are used to carry out microwave spectroscopy. Although it gives a useful overview I felt the chapter was too short to cover microwave hardware in sufficient depth. The technical aspects are important as microwave spectrometers are no longer commercially available. The chapter has a comprehensive compilation of references.

The second and third chapters are entitled "Microwave–Microwave Double Resonance" (J.G. Baker) and "Infra Red–Microwave Double Resonance Techniques" (H. Jones), respectively. Both are very useful, detailed reviews of the double-resonance method. They complement each other well and are presented at about the right level. The latter includes a section on optical-microwave experiments and so the two chapters, taken together, give a quite comprehensive survey of a technique which has revolutionized high-resolution molecular spectroscopy.

The fourth chapter on modern submillimetre microwave scanning spectroscopy, by A.F. Krupnov, highlights recent advances in the automation of the beautiful wide-band millimetre wave scanning spectroscopy technique pioneered by this author. The techniques described here would be useful were they available to the scientific community. However, the direct experimental value of this chapter is limited because the necessary high-power microwave sources appear only to be available in the military installation at Gorki in the USSR.

Chapter 5, by J.W. Fleming, deals with interferometric spectroscopy at millimetre and submillimetre wavelengths. Although this is a useful review of the technique, I find it a curious choice for this collection, though it does give a welcome change of pace. I suspect that the audience for the other articles is biased towards higher resolution techniques and that this review may not be readily found by those to whom it would be most valuable.

The last contribution is yet another review on interstellar molecules, entitled "Astrophysics of Interstellar Molecules" (G. Winnewisser, E. Churchwell and C.M. Walmsley), and it is valid to ask whether another review is justified. This one is. It presents a different perspective as it is more strongly biased than previous reviews towards spectroscopy — as is appropriate for this volume. It is well balanced and covers the appropriate material comprehensively from a microwave spectroscopists point of view. In addition it is up to date with numerous useful tables.

In all, this is a timely volume for the practising microwave spectroscopist. □

H.W. Kroto is a Reader in Chemistry in the School of Molecular Sciences, University of Sussex, Brighton, UK.

A weather controversy

M.W. Moncrieff

Weather Modification. By G. Breuer. Pp. 178. (Cambridge University Press: Cambridge, UK, and New York, 1980.) Hardback £10.50; paperback £3.75.

WEATHER modification is an emotive subject among meteorologists, and over the past few decades there has been a great deal of controversy. The physics and dynamics of atmospheric phenomena are more complex than most physical systems and, more often than not, incompletely understood. However, the potentially significant social, agricultural and economic rewards of successful weather modification have ensured that a considerable amount of financial backing has been available for experiments, often in the absence of sufficient scientific knowledge. The 'seeding' of clouds by silver iodide crystals to enhance rainfall is one example of how a laboratory technique was applied to real atmospheric clouds before a quantitative knowledge of the physics and dynamics of these systems was available. This book illustrates the basic gulf between the practical application of simple techniques to control complex dynamical systems, with a considerable number of commercial, political and economic consequences, and the background of insufficient theoretical understanding. It is no surprise that debate exists with such contrasting motivations surrounding the subject.

The book, in three chapters, is generally well written and is informative to the non-specialist, and the above-mentioned gulf between theory and application is well documented. It is not intended for the specialist, who might be irritated by the large amount of speculative science and continual reference to political and military application; this is especially true of the last chapter. However, the extensive bibliography is useful to both specialist and non-specialist. In general, a balanced viewpoint on a highly controversial topic is retained, and the layman should obtain much useful information.

The first chapter provides a background largely dealing with the philosophy and history of the topic, and brings out the controversies of the subject, particularly that related to cloud seeding. The introduction to the basic physics is unfortunately rudimentary and out of date. The reader may be left with the mistaken impression of cloud physics and dynamics being a very inexact science; recent advances in computational and mathematical techniques are not considered and the cloud models are typical of those seen in school textbooks. An important aspect stressed is the inadequate statistical significance tests in most cloud-seeding experiments, recognized as a major criticism of the subject in general.

The second chapter is undoubtedly the most quantitative and scientific; subjects such as fog dispersal, seeding of convective and orographic clouds, hail and lightning suppression, and the modification of hurricanes are discussed. The author covers experiments in many countries, mainly the USA, USSR and Australia. An interesting historical review of the basis of cloud-seeding, beginning with Langmuir's first laboratory experiments and the initial euphoric and extravagant claims made about weather control, is included. The seeding of cumulus clouds is reviewed in some detail, but the seeding of orographic clouds has probably been the most successful and has the best history of controlled scientific experiment, especially in the USA. It is no surprise that the modification of hurricanes has achieved little success since the basic dynamics, particularly in the growing stages, are not well understood. The most speculative discussion is centred on the modification of large-scale weather systems and climatic change. This has not yet been deliberately attempted, although man-made effects, such as carbon dioxide production due to industrialization, affect climate although their importance is debatable. The possible causes of climatic change are not reviewed in any detail, but these are also beyond the scope of the book. The economic and political interests in weather modification, particularly in cloud seeding, are described. The importance of the financial support by these interests is probably considerable; scientific support in the subject is, by contrast, largely a by-product of more fundamental research.

The last chapter is mainly speculative and qualitatively deals with social, economic and legal aspects; this chapter is more suitable for the non-scientist. I feel that it is somewhat laboured, could have been condensed considerably and is something of an anticlimax. The importance of military and political interests in research and experiment are again brought out, and perhaps this, above all, emphasizes the lack of proportion in the weather-modification picture. Indeed, it is not clear from this book that the present approach to weather modification is any more scientific than the original experiments in cloud seeding. □

M. W. Moncrieff is a Lecturer in Atmospheric Physics at Imperial College, University of London, UK.

Rats in the lab

Maurice Smith

The Laboratory Rat. Volume I, *Biology and Diseases.* Edited by H.J. Baker, J. Russell Lindsay and S.H. Weisbroth. Pp. 448. (Academic: New York and London, 1979.) $52.50, £29.40.

THIS IS the first of two volumes on the laboratory rat, following earlier publications on the laboratory rabbit and guinea pig which were also sponsored by the American College of Laboratory Animal Medicine.

Contributions from 24 authors have been brought together in 15 chapters and two appendices, forming a most comprehensive reference work. The success of the editors in consolidating the technical material available has been balanced by their equivalent success in producing a readable and yet authoritative work which should be available for reference by almost any worker using laboratory bred rats. This is best illustrated by the first chapter which describes in great detail and clarity the origin of the major outbred strains and the early development of inbred strains.

That this is a mainly American story is some reflection of the earlier recognition by the American research world of the need for defined laboratory animals. However it is significant that despite the understandable selection of authors mainly from the USA, those asked to write the chapters on taxonomy, genetics and inbred strains were British, which is due recognition for the work done in Britain on this aspect of laboratory animal science.

The biological chapters in the first half of the book cover genetics, anatomy, physiology, haematology, clinical biochemistry, nutrition, feeding and housing. They show a refreshing recognition of the relationship between biological and experimental variables, which is sometimes not adequately recognized by those using animals as experimental tools.

One of the best examples of this approach is Chapter 8, "Housing to Control Research Variables", which replaces what could have been a standard chapter on housing with a consideration of the effects of physical, chemical and microbial factors on biological responses.

The chapters on disease are without exception well done and each may be considered a definitive text in its own right, especially when supported by the very comprehensive references which are a characteristic of the book as a whole.

There are, however, occasional anomalies which could cause misunderstanding among British readers. Examples of this are the description of *Corynebacterium kutscheri* as the causative agent of pseudotuberculosis, which in the UK is usually attributed to *Yersinia pseudotuberculosis*. Also, at no point is the term chronic respiratory disease (which is generally recognized in the UK) used in reference to respiratory infection. There is a tendency to deal with respiratory infections as quite separate conditions, and the mixed nature of the outbreaks of respiratory disease so commonly found in conventional rat colonies is not sufficiently emphasized.

It is particularly gratifying that chapters on neoplasia and lesions associated with ageing have been included, while the chapter on human health hazards will prove very useful to those involved with safety problems in animal units.

The appendices on drug dosage and selected normative data are welcome and useful additions. It is to be hoped that some consideration may be given to the enlargement of these sections in future editions.

The book is profusely illustrated throughout with black and white photographs of excellent quality together with more-than-adequate tables, diagrams and figures. Understandably, colour has not been used, but despite this the quality of the publication with its strong hard-backed binding is of the high standard one has come to expect from ACLAM.

Volume I of *The Laboratory Rat* is without doubt a timely and very welcome addition to the literature. I await Volume II, *Research Applications*, with considerable interest and with the certain knowledge that *The Laboratory Rat* will become the standard work of reference on this subject. □

Maurice Smith is Director of Central Animal Services at the University of Cambridge, UK, and Laboratory Animal Consultant to the Open University, Milton Keynes, UK.

Reproduction in perspective

Barry Cross

Oxford Reviews of Reproductive Biology. Volume 1, 1979. Edited by C.A. Finn. Pp. 485. (Clarendon/Oxford University Press: Oxford and New York, 1979.) £30.

UNLIKE several biological disciplines of recent origin, the biology of reproduction has cast its spell on enquiring man for centuries, if not millenia. Even so the acceleration of activity in the last three decades has been remarkable, with research proliferating in the new universities and colleges as well as in long-established academic institutions. Whereas 40 years ago reproductive research was almost exclusively a male preserve, the recession of sex discrimination has brought a tide of female workers to reproduction laboratories, much to the advantage of the subject. Dr Anne McLaren FRS is the chairman of the editorial board of this annual review series and two of the chapters in the first volume are written by talented women scientists.

The book contains seven reviews of uniformly high quality, clearly written and appropriately comprehensive. The authors, who are all at the height of their investigative careers, do not skimp, plagiarize or patronize the reader. They dig deep into the foundation of their respective subjects often referring to much earlier work, and critically examine much present-day dogma.The mix is certainly not what one would expect to find in a textbook on the subject or in an introduction for the educated layman. It perhaps most obviously reflects the impact of refinements in chemical techniques on physiological problems. We have authoritative discussions on the current status of relaxin (D. G. Porter), uterine proteins (R. J. Aitken), molecular biology of spermatogenesis (A.R. Bellvé) and preservation of semen (P. F. Watson), as well as on the established favourites — sexual differentiation of the brain (J. E. Booth), control of gonadotrophins (C. A. Wilson) and milk secretion (R. C. Richards). All are treated in a refreshing way and make stimulating as well as informative reading.

The text is efficiently edited by Professor C.A. Finn and contains very few misprints. Some readers may feel that the scarcity of figures is a disadvantage and that the quality of some of the micrographs in the plates at the end of the book is not very impressive.

But these are small defects, and annual reviews in the series will be eagerly awaited.

Barry Cross is Director of the ARC Institute of Animal Physiology, Babraham, Cambridge, UK, and Head of its Neuroendocrine Group.

ANNOUNCEMENTS

Awards

The Harvey Prize in Science and Technology for 1980 has been awarded to **Professor Michael O. Rabin** (Hebrew University); the Harvey Prize in Human Health for 1979 is awarded to **Professor Ephraim Racker**, (Cornell University).

The Hamburg Foundation Jung-Stiftung für Wissenschaft und Forschung has awarded the Ernst-Jung-Prize for medicine 1980 to **Sir Alan Parks**, (St Mark's Hospital, London).

The 1st Margaret Grant Memorial Fellowship has been awarded to **E. Shyam Prasad Reddy** (Centre for Cellular and Molecular Biology, Regional Research Laboratory, Hyderabad, India).

The following Junior Beit Fellowships for Medical Research have been awarded: **David John Adams; Ian Brown; Elizabeth Gready Hill; Elinor Nancy Lupton; Alexandra Marie Thomson**.

The Geological Society of London has made the following awards for 1980: The Wollaston Medal to **Professor Augusto Gansser**; The Murchison Medal to **Professor J.V. Smith**; The Lyell Medal; to **Professor J.R.L. Allen**; The William Smith Medal to **Mr G. Armstrong**; The Wollaston Fund, Murchison Fund and equal moieties of the Lyell Fund to **Drs R.H. Sibson, M.P. Coward, G.S. Boulton** and **M.R. Leeder**, respectively; The President's Awards to **Drs A.P. Heward, J.K. Leggett** and **B.W.D. Yardley**.

The Institute of Physics has made the following awards for 1980: Charles Vernon Boys Prize to **Dr A.E. Costley** (National Physical Laboratory, Teddington); DuddellMedal and Prize to **Professor A.V. Crewe** (University of Chicago); Max Born Medal and Prize to **Professor Dr H. Faissner** (Rheinisch-Westfälische Technische Hochschule, Aachen); Glazebrook Medal and Prize to **Mr M.C. Crowley-Milling** (CERN, Geneva); Guthrie Medal and Prize to **Professor M.E. Fisher** (Cornell University); Maxwell Medal and Prize to **Professor D.J. Wallace** (University of Edinburgh); Rutherford Medal and Prize to **Professor P.G. Murphy** (University of Manchester) and **Dr J.J. Thresher** (Rutherford Laboratory, Didcot); Prize for the 1979 Graduateship Examination of the Institute to **Mr D.B.Mackay** (Napier College of Commerce and Technology, Edinburgh); Honorary Fellowship of the Institute to **Professor V.F. Weisskopf** (Massachusetts Institute of Technology).

Person to person

The Bioelectrochemical Society (BES) has been founded with the aim of stimulating cooperation among all scientists interested in the investigation, interpretation and practical utilization of biological phenomena by using electrochemical theories and methods. For information apply to Prof. Dr H.W. Nürnberg, Institute of Chemistry 4 Applied Physical Chemistry, Nuclear Research Center, PO Box 1913, D-5170 Jülich, FRG.

In 1967 a meeting of British research workers in the mucopolysaccharide field resulted in the formation of a Club. One of the first meetings, with the French Connective Tissue Club in Paris lead to the formation of the Federation of European Connective Tissue Societies FECTS which met for the first time in 1968. In September (1980) the Collagen Club and the Mucopolysaccharide Club come together to form the British Connective Tissue Society.

Information on intra-thecal overdoses of penicillin is required by J.L. Kay, 14 Ardayre Rd, Prestwick, Scotland. Any factual documented source would be helpful, perhaps reference to toxic effects, such as to the brain and central nervous system, clincial tests, possibly information on animal experiments in related fields and LD 50 tests.

Harvard professor seeks for January 1981 to June 1981 furnished house or flat, preferably in Central London, suitable for two persons plus guest room and study. No children or pets! If exchange is desired: Our 3-bedroomed house is in Lexington (Boston area), 15 min from Harvard, 20 min from MIT, MGH, on 1 acre among trees. Write to Mrs G. Holton, 14 Trotting Horse Drive, Lexington, Massachusetts 02173.

A scientist would like to exchange — for 1 year beginning September 1980 — 3-bedroomed house in an attractive Jerusalem suburb (4 miles from University campus, convenient to University and Medical centres, fully furnished for similar or smaller house or apartment in London. M. Goldberg, Bet Zeit 63, D.N. Harei Yehuda, Israel.

Appointments

Dr J.E. Eastoe is appointed to the Chair of Oral Physiology in the University of Newcastle upon Tyne from 1 October 1980.

Dr David Phillips has been appointed to the new Wolfson Chair of Natural Philosophy in the Royal Institution which was recently endowed by the Wolfson Foundation.

Professor M.H. Williams, currently Professor of Computer Science at Rhodes University, Grahamstown, South Africa, has been appointed to the Chair of Computer Science at Heriot-Watt University, Edinburgh.

Professor Harold W. Woolhouse has been appointed Director of the John Innes Institute, Norwich, and Professor of Biology in the School of Biological Sciences at the University of East Anglia from 1 October 1980.

Dr Paul Freeman has been appointed Director of the Department of Industry's National Engineering Laboratory at East Kilbride to succeed **Mr Denis Mallinson.**

Meetings

16-18 July, **Tropical Animal Production,** Merida (Centre for Tropical Animal Production, Escuela de Medicina Veterinaria, Universidad de Yucatan, Apartado 116D, Merida, Mexico).

21-15 July, **Soil Conservation,** Bedford (Dr R. Morgan, NCAE, Silsoe, Bedford, UK).

23-25 July, **590th Meeting of the Biochemical Society**, Sheffield (The Biochemical Society, 7 Warwick Court, High Holborn, London WC1, UK).

1-4 September, **Environment and Safety Exhibition and Conference,** London (International Environment and Safety Exhibition and Conference, London (International Environment and Safety, Labmate Ltd, Newgate, Sandpit Lane, St Albans, Herts, UK).

3-5 September, **Polymerization Mechanisms,** Liverpool, (Dr John Gibson, The Royal Society of Chemistry, Burlington House, London W1, UK).

9-11 September, **Industry and Environment,** Loughborough (Administrative Officer, I & E Conference, University of Technology, Loughborough, Leicestershire, UK).

15-18 September, **Oxygen and Life,** Birmingham (Dr J.F. Gibson, The Royal Society of Chemistry, Burlington House, London W1, UK).

15-19 September, **Management Studies for Chemists,** Slough (Miss L. Hart, The Royal Society of Chemistry, 30 Russell Square, London WC1, UK).

nature

10 July 1980

Progress on chemical weapons treaty

The decision of the United States House of Representatives to fall in with the Pentagon's request for funds to manufacture chemical weapons again is a serious, even a sombre, development. For the best part of a decade, both the Administration and Congress have been more concerned with the disposal of chemical weapons than their production. From time to time, the US Army has excited public interest and anger by its often clumsy arrangements for shipping unwanted chemical munitions about the place, with the consequence that the dumping of useless weapons at sea has been superseded by more rational techniques for the chemical decomposition of the active ingredients. Although the munitions disposed of by these means have usually been unserviceable or even unsafe, the mere act of disposal has chimed in well with the widespread belief that preparations for chemical warfare would serve no useful purpose, and might even damage the discussions between the Soviet Union and the United States about the form that might be taken by an international convention to prohibit chemical weapons. To be sure, the Pentagon has made no secret of its ambitions to get back into the production business, but Congress (the paymaster) has been stolidly unwilling to agree. Now, it appears, all this has changed (see page 100). Last week the House of Representatives agreed to provide the US Army with the funds needed to clear a site in Arkansas. In the next few weeks, it is almost certain that the appropriation for a pilot plant to manufacture binary chemical munitions will follow. Why has there been such a turnabout?

The influences on the US Congress are plain enough. Especially in an election year, few congressmen will wish to stand out against the Department of Defense. It would be different if detente had not collapsed, or been eroded, by the events in Asia in the past six months. Reports of the Soviet use of chemical weapons in Afghanistan, however insubstantial they may be, must tend also to undermine the resolve of Congress. Yet there must be a more intricate explanation of the sudden flurry of interest in chemical warfare, which is not confined to the United States. Last week, in Britain, a group of Conservative MPs gave it as their view that British cities are especially vulnerable to attack by chemical weapons. In doing so, they amplified some of the concern that members of the British government have expressed about Soviet intentions and the inconclusiveness of the Soviet-American discussions towards the draft of a treaty. What can be the explanation?

The erosion of detente has understandably set people's nerves on edge, but strategic developments in Europe have no doubt also helped to stimulate the current preoccupation with chemical weapons. The West German Chancellor, Mr Helmut Schmidt, makes no secret of his anxiety about the increasing numbers of medium-range missiles on the territory of the Warsaw Pact, not yet matched by the deployment of American cruise missiles within NATO. Yet there is no chance of an agreement to limit these developments while Salt II remains unratified. Until quite recently, European opinion would not have been excessively alarmed by this imbalance. While it has been customary (as it is prudent) to speculate on the ways in which short and medium-range weapons might be used in anger within the confines of Europe, people have usually been willing to accept that the strategic forces of NATO would be used if there were more than token trouble. The novel development is that this confidence has also been eroded, largely as a result of the hesitancy of American foreign policy in recent months. Are these also the circumstances which have led to the speculations that gas might be used in Europe without provoking a strategic response?

If so, it would be helpful that the strategic limitations of chemical weapons should be kept clearly in mind. Whatever the technical sophistication of modern chemical weapons, their strategic limitations remain what they have always been. It is unthinkable that the use or the threatened use of chemical weapons could be used to win a decisive advantage in some major conflict — or that an attempt to use them in this way by any state would fail to excite a nuclear response. The technical utility of chemical weapons, such as it may be, lies in the battlefield — and the Second World War shows that the fear of retaliation may be enough to engender restraint. The possibility that chemical weapons might be used in a nuclear war to win some larger advantage, perhaps that of making it safe to occupy some large tract of ground without first blowing it to pieces, is more real, yet still remote. It is hard to see even the most determined combatants trading the occupation of some other state's territory for the destruction of their own. In short, chemical weapons cannot by themselves substantially shift the balance of strategic strength in any major conflict, which is not to say that the military may not regard them as potentially useful in other kinds of conflicts.

So why not get rid of them? This question has been in the air for the past decade or so. Since 1974, the Soviet Union and the United States have been trying to work out the bare bones of an agreement on the subject. So far, there have been no fewer than eleven rounds of talks on the subject (and the twelfth is now going on at Geneva). A report on progress was presented to the Committee on Disarmament, and another is promised for later this year. While the past six months have seen a slackening of interest, some progress has been made. Yet the problems recognized as serious at the beginning persist.

Verification, as always, is a stumbling block, especially because plants for manufacturing the components of binary chemical munitions may be indistinguishable from ordinary chemical plants. Last year's report on the negotiations used the term "adequate verification" and suggested an international secretariat to supervise the way in which verification would be carried out. It is, however, hard to see the most significant potential signatories of a treaty to ban chemical weapons accepting the degree of detailed inspection that their potential adversaries could require. Any treaty that comes about will therefore demand of its participants a degree of trust in each other (as well as in their sources of intelligence) that has not been much in evidence in the past few years. Yet the closely analogous convention on biological weapons has survived even last year's outbreak of anthrax in the neighbourhood of Sverdlovsk. A convention on chemical weapons could be drafted along similar lines — for which reason it would be a great benefit if the Soviet Union were to provide a more detailed account of the anthrax outbreak than it has so far provided.

The scope of a treaty banning chemical weapons is another of the issues with which people have been wrestling for the past several years. Here again it is hard to see how a fully watertight treaty could ever be drafted. Some materials used in the manufacture of nerve gases have a legitimate place in the chemical industry (while phosgene is widely used as a chemical intermediate). The expressed intention of the Soviet Union and

0028-0836/80/280095-02$01.00

the United States of using incapacitating gases for domestic riot control is another serious snag. Here again, however, there is no reason why even the major powers should not accept a certain degree of fuzziness in what might be required of fellow signatories. It is not as if a violation of whatever treaty there might be would give the violator a decisive advantage.

So what are the prospects that a treaty will eventually be negotiated? And to what extent will the course of events be influenced by the willingness of the House of Representatives to let the Department of Defense have its pilot plant? Given that the Soviet Union (but also France) has the means of using chemical weapons tactically, and on the assumption that, even if the American pilot plant were followed by a full-scale production plant, the munitions produced would be similarly earmarked, there is no reason why the talks at Geneva should be interrupted. Indeed, the new development may persuade the Soviet Union that it would be prudent to make faster progress.

And there is little doubt that, if they chose to do so, the major powers could agree on the text of a treaty that would satisfy their own interests. They have learned, in the past several years, that it is possible to live with measures of arms control whose terms are not as specific as meticulous lawyers would ask. So the prospects for the treaty must depend on whether (and if so when) the major powers decide that the time has come to edge back towards detente. Many will hope that they take the plunge sooner rather than later. When that time comes, they will encounter one of the other longstanding problems of arms control — the unwillingness of other states to sign on somebody else's dotted line. On chemical weapons, France and China at least are likely to insist on their freedom to do what they do at present. Especially now that France has rejoined the enlarged Committee on Disarmament, has not the time come when the major powers should surrender the initiative to the committee? No harm, but only good, could come of such a step.

Two views on technological change

How will new technology affect the structure of society? Off and on, for the past few decades, people have been brooding on this kind of issue. This week, it became known that the British Labour Party is cautiously on the side of the pessimists. An unpublished report due to be considered by the party's National Executive later in the month correctly concludes that recent development in the technology of microprocessors will mean even more unemployment in the United Kingdom unless economic growth keeps pace with increases of productivity now foreseen; predictably, it goes on to argue that increased state intervention in the management of technical and social change is needed. This view neatly follows the publication by the OECD of a report called "Science and Technology in the new socio-economic context" prepared by what the OECD calls a "Group of Experts" for the longstanding Committee for Scientific and Technological Policy (see page 98). The OECD document comes to the same conclusion as the Labour Party, but if anything its prescription is more a charter for interference by social scientists than by governments.

During the past three years, there has been a more or less constant grumble that the applications of microprocessors now in prospect have serious consequences for people's jobs. Some will change in character. Some will disappear altogether. These calculations are correct, although the timing is as ever unsure. It does not follow, however, that microprocessors mean mass unemployment. With this as with any technological innovation, improved productivity in one important sector of industry will mean increased wealth, increased demand for goods and services and therefore more jobs in other sectors. The steam engine, whatever the Luddites said and did about it, was as dramatic a source of increased productivity as ever microprocessors will be — and the end result, at least in countries where steam engines were allowed to make a mark, was more jobs. The only reason not to welcome the coming of the microprocessors is that in some places the potential benefits of their increased productivity will not materialize, or will not be matched by comparable increases of productivity stemming from other new technologies.

The Labour Party document, to its credit, has the wit to recognize that this must be the case. The issue that will be disputed is whether more government intervention is the best way of safeguarding the future of jobs in Britain. The dispute is partly ideological. The Labour Party believes in government intervention. The present government does not. Since neither has a monopoly of wisdom, the need is to decide what governments can and cannot do. Providing every classroom or at least each school with a microcomputer might provide a sporting chance that people leaving school were familiar with one new technology, but is this the wisest course when the state school system is crying out for funds with which to buy books, mathematics text-books among them? Equally, the Department of Industry's scheme for helping industrialists become familiar with the new technology, useful though it may be to some of the participants, is no substitute for investors' sense that they can profitably invest in the British economy, and industrialists' sense that the taxation system will allow them to keep some of the profits. In short, what governments can do is to manage the climate for innovation. Governments themselves are less good at innovation. (This is no excuse for the continued delay in deciding whether in Britain the Department of Industry is to let the microprocessor company INMOS have its second £25 million; the government has a moral obligation that will not go away with the passage of time.)

Broadly speaking, these are the conclusions of the OECD report. The committee marshals impressive evidence which gives the lie to the cynical view that research and development is irrelevant to industrial innovation. The correlation between industrial (as distinct from government) spending on research and development and eventual prosperity is strong. But which is the chicken and which the egg? The OECD committee, while recognizing the difficulty, puts the issue beyond doubt. Governments wishing to foster innovation must foster research and development by industry, but without falling back on short-term fiscal incentives. It is a hard and self-denying recipe, that would entail in Britain some attenuation of the government's own research enterprise. Yet the case for doing more, not less, when times are hard is undeniable.

On the reasons for the hiatus in the affairs of the industrialized countries in the past seven years, the OECD is nothing if not robust. When money is being drained out of the economy, largely by OPEC, cannot be the best time for innovation or even mere change. All that is easier when things are going well. Yet this is a turning point in many people's affairs. More productivity is in the long run the only way out of the crisis. Although the report is short on references to the economists' gurus, Keynes and Friedman alike, it leaves the clear impression that the committee that prepared it considered that innovation is not so much a problem as an answer to an unstated problem. The committee's dissident voice, Professor Emma Rothschild, found this escalator uncomfortable because she had no clear idea where it is going. That is too much to ask.

That is the sensible part of the OECD report. It is less sensible that much of the document is taken up with the supposed need of what is fashionably called technological forecasting. This, after all, is a discipline which has yet to demonstrate itself as such. Many will suspect the phrase to be yet another licence for social scientists to make contradictory assertions about the consequences of technological innovations. The trouble, of course, is that the consequences are almost always unpredictable. All that can confidently be said is that some consequences are profound. What societies faced with rapid technological change thus need of their governments is flexibility — a capacity (and a willingness) to meet unforeseen social changes with compassion and imagination.

0028-0836/80/280096-01$01.00

Red faces (and hot tempers) on 2,4,5-T

The controversy over the use of the herbicide 2,4,5-T in the United Kingdom became even more heated last week with the revelation of a difference of opinion between government agencies over how to determine the safety of the herbicide. Thus Mr John Locke, the director-general of the Health and Safety Executive (HSE), pleaded for a more effective relationship between the executive and the Advisory Committee on Pesticides (PAC) of the Ministry of Agriculture, Fisheries and Food (MAFF).

Locke was speaking at the opening of a new HSE centre at the Royal Show (see page 100). His call for more "tying up" between HSE and PAC is, on the surface, a plea for more rationality in the review processes for toxic substances, but it underscores the strain both organizations are suffering in determining the safety or otherwise of 2,4,5-T.

The director-general's comments were voiced two days before a meeting of the HSE's Advisory Committee on Toxic Substances (ACTS), where 2,4,5-T was the main item on the agenda. Like all HSE advisory committees, ACTS has representatives from both the Trades Union Congress (TUC) and the Confederation of British Industries (CBI). With the TUC already on record as calling for a ban on 2,4,5-T, feelings were bound to run high. By all accounts it was a stormy meeting, with the TUC representatives expressing their dissatisfaction with PAC's review processes for herbicides and pesticides.

As a general rule, the TUC's representatives on ACTS believe that, where issues of health and safety are concerned, HSE should be responsible. The unions suspect the impartiality of MAFF in reviewing the toxicity of chemicals which can be of benefit to agriculture. At the meeting last week, they asked why PAC claimed in its eighth review of 2,4,5-T (published in March last year) that only three tonnes of the herbicide were used annually in Britain, when the real figure is now known to be about twenty times as much. They also want to know the names of all UK manufacturers importing, exporting or selling products containing 2,4,5-T.

Recent Customs and Excise figures confirm that some 116 tonnes of 2,4,5-T were imported into the UK in 1979. With the publication of these revised estimates, the unions are all the more sceptical of the review processes.

MAFF is seriously embarrassed by the error about the tonnage of 2,4,5-T used in Britain. PAC had assumed — wrongly — that the Forestry Commission was the largest user of the herbicide in the UK, and the three tonne figure was based on 2,4,5-T use in silviculture. It is now known that far more 2,4,5-T is used on grassland; on the basis of a recent survey, the use of 2,4,5-T in Britain last year is now put at 58 tonnes.

One especially serious aspect of the affair is that the PAC estimates were given to the Royal Commission on Environmental Pollution during its inquiry into agricultural pollution. In the report of this inquiry published last year, the royal commission gave 2,4,5-T a clean bill of health, partly on the grounds that British usage was relatively small. Members of the commission were wondering this week how the record should be set straight.

PAC is now reviewing the herbicide for the ninth time in the light of information about 2,4,5-T and its dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) contaminant published in the past two years.

The subcommittee responsible, on the instructions of Mr Peter Walker, Minister of Agriculture, has now met a delegation from the National Union of Agricultural and Allied Workers (NUAAW) to hear the union's case against 2,4,5-T. In three and a half hours of often heated discussion, the union delegation insisted that 2,4,5-T should be banned. The delegation was told that the dioxin content of 2,4,5-T now set at a maximum of 0.01 parts per million in the UK is so low that it represents no threat. The herbicide itself is a teratogen in some rodent species at concentrations of 35 milligrams per kilogram of body weight, 10,000 times the concentrations at which dioxin is a teratogen. With the new 2,4,5-T formulation, 2,4,5-T will exert a teratogenic effect before dioxin.

The subcommittee also believes that there is a sufficient safety factor in the assessment of the carcinogenic risks from dioxin. The most reliable study suggests that dioxin is a carcinogen at dose levels of 0.1 microgram per kilogram of body weight per day in rodents. With the new formulation, to consume such a quantity of dioxin, rodents would need to take in 2,4,5-T at concentrations about one-tenth to a half of their body weight.

The subcommittee's recommendations on 2,4,5-T will be considered at a PAC meeting on 24 July. The same evidence will also be reviewed at a special meeting of ACTS at the end of August. Whatever the outcome of these meetings, it is clear that the trade union campaign against 2,4,5-T has had a considerable effect on HSE and MAFF.

The unions see the visit of the NUAAW deputation to the PAC scientific subcommittee as a precedent. But it is unlikely that the trades unions will be satisfied with this modest advance. The unions are openly campaigning for a change in the review process, and it was only natural that John Locke should appeal to MAFF for some help in devising a system which will satisfy all parties.

Alastair Hay

Supreme Court reprieves benzene

Washington

Strict regulation of toxic substances must be backed up by adequate scientific data on their potential danger. This was the message delivered by the US Supreme Court last week when it rejected a proposal by the Department of Labor's Occupational Safety and Health Administration (OSHA) to reduce permitted exposure levels to benzene to one part per million.

Following evidence which emerged in the early 1970s of a link between benzene exposure and various blood disorders — in particular, leukaemia — OSHA produced new regulations in 1977 which would have reduced permitted exposure levels from the current 10 parts per million.

The proposed regulation has been attacked by the chemical and petroleum industries, where more than a million workers are exposed to benzene in products from gasoline additives to paint solvents. The industries claimed that the regulations were unnecessarily restrictive; and that the cost of meeting them — measured in hundreds of millions of dollars — was incommensurate with the expected benefits.

Using such arguments, the American Petroleum Institute last year persuaded a judge in New Orleans to rule the proposed regulation invalid. Much attention had been focused on OSHA's decision to appeal to the Supreme Court, largely because the judge critized OSHA for not weighing the expected benefits of the regulations against the costs of meeting them.

In the event, the Supreme Court skirted around the cost-benefit issue. Only one member — Justice Lewis Powell — insisted that a full cost-benefit analysis should have been carried out; and the matter awaits resolution in two further cases which the court has agreed to hear next year.

No less significant, however, is the substance of the court's ruling in a case which Chief Justice Warren Burger described as raising "difficult unanswered questions on the frontiers of science and medicine". The court ruled that OSHA must demonstrate that a toxic chemical poses a "significant" risk before making a regulation.

This judgement directly undermines one of the fundamental principles on which OSHA's regulatory strategy is at present based. So far, the agency has argued that, where a chemical is suspected of having low-level toxic effects but the scientific and epidemiological evidence is insufficient to characterize these precisely, it must be

0028-0836/80/280097-02$01 00

assumed that there is no threshold below which the chemical can be considered "safe" — and industry is required to lower exposure to the limits of technological feasibility.

OSHA acted on benzene even though the evidence of increased leukaemia incidence among workers in Turkey and Ohio involved people who had been exposed to considerably more than 10 ppm over long periods of time.

The agency argued that only a technological feasibility strategy would suffice to guarantee the protection of workers, but the Supreme Court, in a 5-4 vote, agreed with industry critics that a more thorough scientific and technological justification must be produced. Admitting the existence of considerable uncertainties, the court accepted that the agency is not required to prove its point "with anything approaching scientific certainty".

Even so, in writing the majority opinion, Justice John Stevens said that OSHA had failed to produce "substantial evidence" that the new benzene rules were "reasonably necessary and appropriate" to remedy a "significant risk of material health impairment". OSHA, he said, had not produced empirical evidence or scientific opinion to show that exposure to benzene at or below the 10 ppm level had in fact caused cancer.

Predictably, the court's decision has been welcomed by industry, which has long protested at the expense of meeting the "lowest technologically feasible" criterion. Agency officials admitted that they were "disappointed" with the ruling, but vowed to press on with regulating benzene and other toxic substances.

The closeness of the Supreme Court's decision and the fact that different members gave different reasons for concurring are likely to cushion the impact. Indeed, if OSHA can produce more evidence on benzene, then the tough standard could still stand.

In a strongly worded dissenting opinion, four of the nine justices said they felt OSHA had already produced enough evidence to justify the low exposure limit. And a fifth said that, given additional evidence, he might be persuaded by OSHA's case.

David Dickson.

Soviet environment

Spending more

SOVIET capital investment in environmental protection and the conservation of endangered species will be trebled in the next Five Year Plan (1981-1985), according to what TASS has described as "preliminary data". Since the official figures for the present plan include 11,000 million rubles of direct state funding and 50,000 million from the budgets of industrial enterprises and institutions, this suggests an investment of at least 180,000 million rubles (£125,000 million) in the next five years.

The TASS announcement followed the passing of two major environmental bills, on clean air and the protection of fauna, by the Supreme Soviet. Enactment of the laws was preceded by unusually extensive reporting in *Pravda*, perhaps because of the undoubted pride which the members of the Supreme Soviet show in their progress to date. No other country, observed Deputy P.P. Vavilov, president of the All-Union Academy of Agricultural Sciences, has on its statute books laws of comparable scope, which even protect insects and soil fauna with a direct bearing on soil fertility.

Vavilov nevertheless emphasized that, even when the act becomes law in 1981, further research will be needed to ensure that its provisions are implemented in strict accordance with ecological principles.

What nobody mentioned in the debate, but what must surely have been in the minds of many of the deputies — especially those from central Russia, central Asia, Byelorussia and Estonia — was the present threat from wolves and wolf-dog crossbreeds which, according to some estimates, have doubled in numbers over the past ten years, following cutbacks in hunting and the disbanding of skilled hunting teams. The threat is particularly acute in Estonia.

No less complex are the management problems raised by the clean air bill. Air pollution has been a major problem in many Soviet cities for a considerable time, and one of the earliest preparations for the Moscow Olympic Games was the designing of electric runabout cars for the Olympic village, to reduce the effect of petrol fumes on the athletes.

Not only cities are at risk, however. In the Supreme Soviet debate, Deputy V.M. Kanun from Zhitomir spoke of the pollution threat to the Polessian forests — in spite of the expenditure, during the current Five Year Plan, of "tens of millions of rubles" on anti-pollution measures. Deputy Yu. A, Izrael', Chairman of the State Committee on Hydrometeorology and Environmental Monitoring, observed that the Union-wide anti-pollution monitoring service now has air-pollution monitoring projects in 450 cities; nevertheless, as Deputy Kipel' observed, "many plants and factories go on polluting the atmosphere and water in the same old way".

Water, in fact, is not specifically the subject of the new legislation, although, according to Deputy Izrael', progress in this field is one of the "major successes" of the environmental control programme. "Almost all the rivers of the European part of the USSR", he said, "have become cleaner".

Nevertheless, water may well soon be better regulated. A 200-person multidisciplinary research team, led by Vladimir Lazanskii, head of the All-Union Research Institute for Water Conservation, has completed a detailed computer analysis of the ecology of 26 of the largest rivers in the USSR and fifteen seas and lakes. On the basis of this study, the team has put forward several proposals ranging from the automated control of water conservation complexes and the introduction of closed-cycle processes for metallurgical works to the special processing of rain water and snow melt bearing particles of petroleum products.

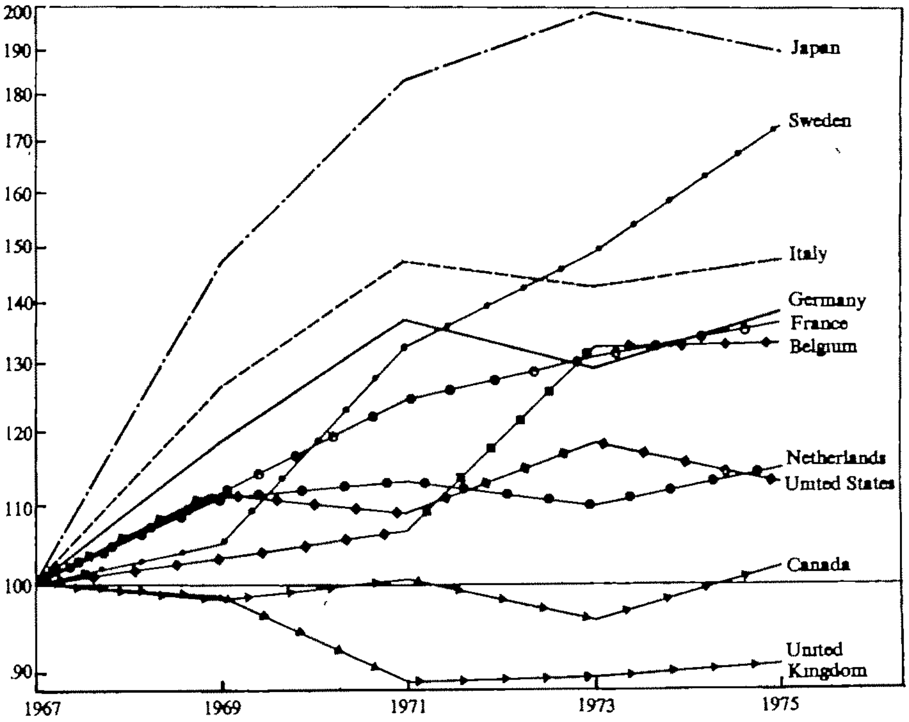
Industrially financed research, OECD countries



0028-0836/80/280098-01$01 00

Biotechnology

France now

A GROUP of French scientists has set up a commercial organization for the exploitation of genetic manipulation. Known as *Transgène*, the company has an initial capital of 40 million French francs. Although the capital has been provided by industrial companies, the sponsors of the new venture include the CNRS (Centre National de la Recherche Scientifique), L'Institut National de la Recherche Agronomique, L'Institut National de la Santé et de la Recherche Medicale and the Pasteur Institute.

The new organization will be based at its own laboratories near Strasbourg and its policy will be determined by a scientific committee including Professor Philippe Kourilsky from the Pasteur Institute and Professor Pierre Chambon from the Louis Pasteur University of Strasbourg. It is intended that the scientific committee will include some scientists from outside France. The scientific director of the enterprise has been recruited but not yet named.

It is understood, however, that the director is at present the head of research at a European pharmaceutical company and is not French.

The formation of *Transgène* has been talked of for several months. The capital for the enterprise has been provided by a consortium of companies organized by the Compagnie Financière de Paris et des Pays Bas (Paribas) and includes the oil company Elf, the French liquid air company Air Liquide and the champagne and brandy firm of Moet-Hennessy. The commercial head of the new enterprise will be the director of research at Parisbas, M. Robert Lattès. It appears that this French initiative has been prompted — some would say provoked — by the publicity given in the past few months to the doings of the Swiss-based company Biogen, but the organizers of *Transgène* also have in mind the steps taken in the United States during the past few years to put genetic manipulation on a commercial footing. Although nothing is known as yet of the work on which *Transgène* will be engaged, it is expected that the company will be recruiting a staff of between 50 and 80 people, most of whom will be based at the laboratories in Strasbourg.

Transgène appears to have hit on a novel way of reconciling the conflict of interest between university researchers and commercial interests that inevitably arises in such circumstances. Fifteen per cent of the shares are to be held by the sponsors of the enterprise, including the Pasteur Institute and the CNRS. A further eight per cent of the shares will be the property of a foundation yet to be established whose function will be to support basic research in the general field of molecular biology — a task that will become feasible if and when Transgène makes money.

The Strasbourg laboratory will not be completed for two years. In the meantime Transgène is hoping to make arrangements for research to begin on a contract basis in some other laboratory, possibly at the Louis Pasteur University. The scientific staff will be recruited in time to begin work at the turn of the year but the initial scientific objectives will not be defined until the scientific board is complete around October.

University industry

Surrey consults

SHORTAGES of funds are increasingly making British universities search for alternative sources of finance. The University of Surrey has in this way branched out beyond the usual pattern of university work. Last week it formally opened a new institute to tackle industrial health and safety problems.

Surrey's Institute of Industrial and Environmental Health and Safety has actually been operating for 18 months. So far, it has earned about £700,000, one-third from grants and donations and the rest from specific contracts. According to its director, Professor James Bridges, the institute is already almost entirely self-financing and hopes eventually to make a profit which can be ploughed back into the university. The members of the institute's staff are either tenured in an academic department, on short-term research council contracts or have been specifically employed by the institute on annual rolling contracts.

The institute is an amalgamation of several different academic units (the Wolfson Bionalytical Unit, the Materials Handling Research Unit, the Industrial Biomedical Unit and the Toxicology Unit). It also includes two new units, the Isolator (Gnotobiotics) Unit and the Occupational Health and Hygiene Service. The last of these is the most unexpected. It carries out no research as such, but aims to provide local industries too small to employ their own specialists with advice on health and safety problems.

The Occupational Health and Hygiene Service appears to be an effective way of making links with local industry. An investigation of sore throats and bronchitis at one local factory led to the Wolfson Bioanalytical Unit being called in to take air samples. It finally identified the source of irritation as chromium carried from one part of the plant to another when the wind was in a particular direction. The Wolfson Unit also solved a problem in the handling of glass fibre resins in a local factory after a similar introduction.

Most of the institute's work so far has been funded by larger organizations. The Materials Handling Unit, for example, has completed an ergonomic study for the EEC of the body stresses caused when men lift heavy objects, and is now doing a similar study of female workers for the UK Health and Safety Executive.

The Isolator Unit was created to build up on a previous collaboration with Vickers Medical Limited to design and make medical isolators out of flexible film. The unit is now designing film units for isolating experimental animals and protecting workers handling drugs and other potentially dangerous materials. The Toxicology Unit is engaged on fundamental work on biochemical pathways in man and animals, but most of its contract work consists of *in vitro* testing for mutagenesis and carcinogenesis.

The institute acts more as a research association than a university research department. According to its staff, the prospects for the next year or two are good, with plenty of work on hand. Thereafter, the institute will have to live on its wits, helped by whatever reputation it acquires in the meantime.

Judy Redfearn

Poles protest at academic censors

SCIENTIFIC publications should be totally exempt from state censorship, according to a report by the Polish "DiP" group *(Doswiadczenie i Przyslosc* — Experience and the Future). This unofficial body, which includes leading figures from the academic and literary professions, Party and church, was originally established in November 1978 as a discussion group to consider the economic crises facing Poland. Unable to hold the open discussions they had planned, the members of DiP have relied on questionnaires. The first such survey, "Report on the state of the country and ways of putting it right", was made in May 1979; the second, "How do we get out of this?" in December 1979 and January 1980. This second report is now in circulation.

Questionnaires were completed by 141 people. (Some of those approached declined to take part saying that they had no faith in the sense of the exercise.) The sample included 65 scientists, of whom 39 were university lecturers and professors — biologists, physicists, mathematicians and agronomists. The result is a penetrating study of the economic and social problems of the Polish People's Republics.

A necessary condition for any reforms to be successful, it says, is that confidence should be restored in the government. To this end, *inter alia*, a free flow of information is essential. A proper definition of material liable to censorship (military and industrial secrets) should be laid down, and academic publications exempted from the censors.

0028-0836/80/280099-01$01.00

Chemical weapons

Congress agrees

Washington

Citing circumstantial evidence of the use of poison gas by Soviet troops in Afghanistan, the US Congress has taken the first step towards ending an eleven-year moratorium on the production of chemical weapons.

By-passing the White House — which has nevertheless so far raised no objection — the House of Representatives last week approved the army's use of funds to renovate facilities at its Pine Bluff Arsenal in Arkansas to house the production of so-called binary chemical weapons.

The amount of money is relatively small — $3.1 million out of a total military construction budget of $4,800 million. A further $19 million will be needed to equip an intended pilot plant for the production of 155 mm binary shells. Given minimal opposition, either from within Congress or from the Administration, legislators pushing for the pilot plant are confident they can persuade the House to provide the extra cash, and that the Senate will go along. If so, the Pine Bluff plant could be in operation by 1983.

The Department of Defense has planned for two further extensions of the plant at a cost of $185 million — production plants for 8-inch artillery shells containing the British nerve agent VX and for so-called "big eye" bombs for the US Navy, like the 155 mm shells containing the nerve gas GB.

Binary weapons, the latest thing in the military gas-man's catalogue, offer safe storage and use; two relatively innocuous chemical components which react to produce a military gas only after the weapon has been primed. The US Army has been working on their developmnt since the mid-1960s.

In 1974, Congress turned down a proposal to manufacture them, on the grounds that the Soviet-American negotiation of a treaty covering chemical weapons, begun that year, would be jeopardized.

Officially, those talks still drag on. In each of the past two years, the Department of Defense has asked Congress for funds for binary weapons production, pleading Soviet superiority in both offence and defence. On each occasion, the request has been blocked by the White House.

Now the political climate has changed. Although Presidents Carter and Brezhnev agreed last year in Moscow to encourage the negotiations, the Soviet presence in Afghanistan has brought progress to a standstill. The future of the treaty, some US officials consider, will now depend on broad political considerations and not on the question whether or not the United States is producing chemical weapons.

Reports of the Soviet use of chemical agents in Afghanistan helped to change the mood of Congress and the Administration, although the details are still far from clear. US officials say there is now "strong" evidence of the use of riot-control agents, "middling" evidence of incapacitating agents, but that evidence of the use of lethal nerve agents is "weak". They support a proposal for an international fact-finding mission to gather more precise details of events in Afghanistan.

These reports, combined with accusations of Soviet development of biological weapons after the anthrax outbreak in Sverdlovsk, have created a climate in which support for a unilateral moratorium is waning. Some critics nevertheless remain vocal. Chemical weapons are of little real tactical value, "contributing nothing to fire power unless the other side chooses to use chemical first" says Professor Matthew Meselson of Harvard University.

In Congress, however, those who have previously resisted the chemical weapons programme have no plans to organize opposition to the new developments. Some argue that, since the army's existing stock of wet-eye nerve bombs is deteriorating and could become a serious health hazard, the production of binary weapons would be the lesser of two evils.

The White House occupies neutral ground. It has not supported the congressional amendments to its defence request, but neither has it opposed them. In the present climate, if Congress does give the green light to the chemical weapons facility, a presidental veto is unlikely.

David Dickson

British farming

Science on show

Agricultural shows still have the same appeal for the British public as they did in Thomas Hardy's day. The Royal Agricultural Society of England's annual show, however, is more than family entertainment. The theme of last week's show, like that of recent years, was the application of science in agriculture. Publicly supported research was much in evidence.

The Ministry of Agriculture, Fisheries and Food (MAFF) has always prided itself on the value of its research and development to the agricultural industry. In the wake of the Rothschild reorganization, almost half of the work done by the institutes of the Agricultural Research Council (ARC) is under contract from government departments. This year, for example, MAFF is spending about £34 million on basic research, matched by a similar contribution from the ARC. About £2 million will come from other sources. The Agricultural Development and Advisory Service (ADAS) will spend £54 million on getting the results of research to the farmer. The work of ADAS and ARC institutes was therefore prominent at the Royal Show. No doubt in an attempt to stave off the criticism that much of this research is too basic to bear on farmer's practical problems, the exhibits included examples of both pure and applied research.

The National Vegetable Research Station (NURS) displayed its basic research on the introduction of resistance to tobacco mosaic virus into tomato plants. It is also seeking to interest British food processors and growers in varieties of small outdoor tomato plants which yield fruit that is superior to (although more expensive than) Italian canned tomatoes.

Import substitution is a recurrent theme. The NVRS, proud of having helped to reduce the level of British onion imports since the early 1970s by the introduction of Japanese varieties which can be planted all the year round, is now working towards the home-grown baked bean.

On animal nutrition, the Rowett Research Institute is improving on the starch equivalent as a means of assessing the metabolic value of feeding stuffs. The Animal Diseases Research Association was last week offering advice on the prevention of hypothermia in lambs and the Meat Research Institute on the measurement of fat deposition in live animals. The long-term objective is to find better ways of controlling the proportion of fat to lean meat.

In these and other wys, the Royal Show has become an annual celebration of the notion that British agriculture is outstandingly efficient. The increase of agricultural productivity in the past 30 years is certainly impressive. The belief that British agriculture is the most efficient in the world has become almost a myth, difficult to challenge.

Such a challenge has come, however, from the Centre for Agricultural Strategy at the University of Reading. In a report published last week, the centre says that British agriculture is by no means streets ahead of European agriculture. Belgium, the Netherlands and Denmark may be doing better. The centre agrues that British farmers have invested too much capital in their businesses, especially in farm machinery. The Royal Show last week would have tempted them further down this primrose path.

Judy Redfearn

Fusion

Studied design

Planning time is running out for the INTOR project, the international design study of a thermonuclear reactor set up last year by the International Atomic Energy Agency. At the ten-day biennial conference on fusion and plasma physics just ended in Brussels, the members of the international design team (Euratom, Japan, the Soviet Union and the United States) confirmed that their final report will be with the IAEA next June. Then, it is acknowledged, will be the time for tackling

0028-0836/80/280100-02$01.00

the political problems.

INTOR stands for International Tokamak Reactor. The objective so far has been to define the design parameters of a 620 MW (thermal) tokamak which would test engineering systems required in a commercial fusion reactor. The objectives of INTOR are to produce a token amount of electricity and to demonstrate tritium breeding and 25-50 per cent availability. Decisions on the future of the project will be taken by members of the design team only when the final report is ready.

For the time being, the team is innocent of politics. The first difficult step will come when the design study is complete and it is necessary to set up a full-time design group.

If ever built, INTOR will be a net consumer of electricity and tritium. The reactor would use a charge of 3 kg of tritium which would have to be replaced every six months. Average electrical power consumption would be 200 MW. Capital costs would be of the order of the cost of the American Engineering Test Facility, about $1,000 million. **Robert Walgate**

US fusion

Middle course?

Washington

Magnetic fusion research in the United States will be further encouraged by a new report prepared for the Department of Energy. The report concludes that research is now sufficiently encouraging to justify a new stage of engineering experimentation.

Even so, the report falls short of endorsing the Engineering Test Facility being promoted by some members of the fusion research community. It says that the proposed high neutron flux and heavy usage, as well as the role of the ETF as a direct stepping-stone to commercial fusion, are "too ambitious" and "inappropriate at this stage".

The report recommends instead that the department should construct, at an estimated cost of less than $1,000 million over ten years, a more modest Fusion Engineering Device (FED) based on the tokamak design. This device, the report says, should be sited at a new Center for Fusion Engineering (CFE).

The proposals come from a subcommittee of the department's Energy Research Advisory Board, chaired by Dr Solomon Buchsbaum of Bell Laboratories. Officially they are still in draft form; but they are likely to form the backbone of the Administration's response to critics who claim it has been dragging its feet on the commercial application of fusion.

The Buchsbaum committee in passing attacks a previous report prepared two years ago by a similar committee chaired by Dr John Foster of TRW Industries. That argued that it would be unwise to pursue an ambitious programme based on the tokamak design, urging that research support should be spread more widely.

The Administration has responded by increasing support for alternative designs, in particular for the Elmo Bumpy Torus being developed at the Oak Ridge National Laboratories (*Nature*, 1 May), to the chagrin of the potential commercial sponsors of fusion techology, who have felt that the Foster committee was too cautious.

Leading the attack has been Mr Mike McCormack, chairman of the energy subcommittee of the House Science and Technology Committee. Mr McCormack has been pushing hard for an accelerated fusion research and development programme. Last year his subcommittee appointed a 12-member Fusion Advisory Panel which recommended that the ETF, being designed at Oak Ridge, should be built in 1987.

The Buchsbaum committee is the response to the McCormack initiative by Dr Edward Frieman, director of the Office of Energy Research. It justifies its shift of view by citing recent "rapid scientific progress" and says that the US is now ready to embark on the exploration of the engineering feasibility of fusion.

Among recent successes are:

- validation of empirical predictions of achievable electron energy confinement times;
- demonstration in experiments with neutral beam currents that the heating of plasma to ignition temperature is feasible;
- the absence of evidence that impurities will tend to accumulate in the centre of high density plasmas; and
- the existence of several promising schemes for steady-state current drive using radio-frequency or particle-injection techniques.

These and other developments, the committee says, make it appropriate to move on to the study of ignited plasmas — where fusion reactions proceed without external energy being supplied. This would be one of the principal goals of the FED, which would also be used to explore reactor technology and to study safety questions. But the new report, like that of the Foster committee, asks that attention should continue to be given to alternative designs in case the tokamak configuration disappoints.

The committee therefore supports the proposal for a large tandem mirror machine, if only to prove the principle that open-confinement systems may be feasible; this may be included in the 1982 budget request. The committee also asks that work on the Elmo Bumpy Torus should be strengthened to clarify some immediate physics issues, but adds that the proposed $75 million investment is "too large, given the existing uncertainties in the physics of the EBT configuration".

The appearance of the committee's draft report aptly coincided with a debate in the House of Representatives on the Department of Energy's proposed 1981 budget. As part of a general attempt to trim long-range energy research, the House Appropriations Committee had proposed that the magnetic fusion budget be reduced by $23 million from the Administration's request for $396 million (an 11.5 per cent increase over this year).

Waving copies of the Buchsbaum report, House members were able to restore the money by an amendment which also reduced some of the proposed cuts in high-energy and nuclear physics research programmes. But Mr McCormack is not satisfied. He is now talking of introducing a supplementary budget request later in the year to bring the fusion budget more into line with the Buchsbaum proposals, which recommend that the total budget be almost doubled over the next five to seven years.

Not unexpectedly, the Buchsbaum report is less bullish than Mr McCormack. It says that heavy spending on the engineering aspects of fusion will not be necessary until 1983-84. By then, results from the Tokamak Fusion Test Reactor at Princeton will be available, and should help to decide the design details of the proposed Fusion Engineering Device.

David Dickson

New NSF director

Dr John B. Slaughter (below) was nominated to take over from Richard C. Atkinson as director of the National Science Foundation last week. Slaughter, an engineer by training, has been persuaded to return to the NSF after leaving only a year ago to become academic vice-president and provost of Washington State University. He had previously been assistant director of NSF for astronomical, atmospheric, earth and ocean sciences. Atkinson, a psychologist, has already taken up an appointment at the University of California.

Albanian science

Isolated still

Albania is embarking on its own characteristically isolated programme of science and technology. At the two-day plenary meeting of the Central Committee of the Albanian Workers' Party last month, the main theme was the need to increase the level of scientific research and to apply research and development more effectively for the development of the country.

The issue is timely. The five-year plan (1981-85) now being prepared includes increases of industrial and agricultural production of 40-42 per cent. But with the departure of the Chinese, "self-reliance" has become the order of the day. Addressing the plenum, Ramiz Alia of the Party's Political Bureau paid a glowing tribute to the Albanian "specialists, technicians and workers" who had had to take over the various technological projects left unfinished when the Chinese quit.

According to Alia, Albania is now able to design and set up "self-reliantly" every object the economy needs, whether "industrial, hydrotechnical, railway or cultural". Self-reliance is also to be the watchword for the future. In the natural sciences, he stressed the need for research in applied nuclear physics and the mastering of neutron and laser technology for both industrial and military use. Research projects in biophysics should also, he said, be started.

On the applied side, Alia emphasized the importance of water management; he said that 52 per cent of the arable land in Albania is now irrigated — the highest proportion in Europe. Alia also called for strains of wheat capable of producing 70 to 80 quintals per hectare, an increase of 10 to 15 per cent compared with existing hybrids. Alia said that fundamental work was needed to reach the target of 95 per cent extraction of useful minerals.

The first Secretary of the Central Committee of Albania, Enver Hoxha, in his closing address to the plenary session, put the Party's demand in more general terms. Albania, he said, has now reached an advanced stage of economic and social development, so that what is now required of science is "a generalization, improvement and an entire positive transformation in practice and theory — a qualitative break, a revolution in production technique, technology or organization". Technological advance, however, must not be accompanied by a drift from agriculture. Development of the agricultural sciences and the intensification of agricultural production is aimed at maintaining the current demographic distribution, in which some two-thirds of the Albanian population live in the countryside. **Vera Rich**

CORRESPONDENCE

Cruel Malthus

SIR, — Peter Laslett[1] does injustice, I believe, to British social science in stating that, except perhaps for John Maynard Keynes, "Thomas Robert Malthus may be quite justifiably called . . . the most important of all English-speaking social scientists". From the "population principle" which Malthus claimed[2] to have "established in the first six pages" of his 1798 *Essay*, Malthus concluded that poverty was caused primarily by the "vices" of the poor themselves.

Accordingly, "to assist the poor in such a manner as to enable them to marry as early as they please and rear up large families is a physical impossibility[3]". Ferociously consistent, this mild-mannered cleric and professor advocated abolition of the poor laws which sheltered, though inadequately, the helpless poor. He opposed repeal of the corn laws, universal suffrage, and a regularly meeting representative parliament.

Malthus's stature as a social scientist may be judged from his pronouncement[4] that "The structure of society in its great features will probably always remain unchanged. We have every reason to believe that it will always consist of a class of proprietors and a class of labourers." Yet his doctrine, which was born during the French Revolution, has surfaced repeatedly in various guises at times of social stress.

This recurrence is not particularly surprising. Malthus himself stated the political utility of his "principle" quite baldly in later editions of the *Essay*[5].

"Among the poor themselves, its effects would be still more important. That the principal and most permanent cause of poverty has little or no *direct* relation to forms of government or the unequal division of property; and that as the rich do not in reality possess the *power* of finding employment and maintenance for the poor, the poor cannot in the nature of things possess the *right* to demand them, are important truths flowing from the principle of population which when properly explained would by no means be above the most ordinary comprehension.

"And it is evident that every man in the lower classes of society who became acquainted with these truths would be disposed to bear the distresses in which he might be involved with more patience; would feel less discontent and irritation at the government and the higher classes of society on account of his poverty; would be on all occasions less disposed to insubordination and turbulence; and if he received assistance either from any public institution or from the hand of private charity, he would receive it with more thankfulness, and more justly appreciate its value.

"If these truths were by degrees more generally known . . . the lower classes of people as a body would become more peaceable and orderly, would be less inclined to tumultuous proceedings in seasons of scarcity, and would at all times be less influenced by inflammatory and seditious publications from knowing how little the price of labour and the means of supporting a family depend upon a revolution.

"The mere knowledge of these truths, even if they did not operate sufficiently to produce any marked change in the prudential habits of the poor with regard to marriage, would still have a most beneficial effect on their conduct in a political light; and undoubtedly one of the most valuable of these effects would be the power that would result to the higher and middle classes of society of gradually improving their governments without the apprehension of those revolutionary excesses, the fear of which at present threatens to deprive Europe even of that degree of liberty which she had before experienced to be practicable, and the salutary effects of which she had long enjoyed."

While Malthus's hopes for pacifying the "poorer classes" have not been conspicuously successful, the doctrine has found a new use in the post-war years, as the poor in the developing countries have raised demands on their erstwhile rulers. The Malthusian resurgence[6] assuages the conscience of the "class of proprietors" in the rich countries and facilitates inaction by their governments.

Nuclear protest

SIR, — Your leading article of 19 June concerning nuclear power exemplified many of the elitist opinions of the scientific "community". It appears you would like the public to reach an understanding of "the niceties of nuclear power" similar to its understanding of the relation between salary rises and inflation. The simplistic view of the economy (salary rises cause inflation) that many people have has been impressed on them by successive governments and the Tory press. Is this how you want the nuclear power debate to proceed?

Your arrogant suggestion that the willingness of people to demonstrate is sustained only by the division of "professional" opinion is insulting to the many demonstrators who have arrived at an anti-nuclear position after careful consideration of available information on all the aspects of nuclear power.

The "key to the future of nuclear power" does not belong with a small and self-interested clique of professionals; it belongs with society as a whole. The real trouble with the nuclear debate is not that it is too polite but that it centres on technical discussion while ignoring the political, for example, the proliferation of nuclear weapons that is already accompanying the proliferation of nuclear power, the setting up of an armed secret police force and the denial of trade union rights (which is one of the main political reasons for developing nuclear power, according to Thatcher). Hopefully, members of the public will continue to see through the "leave it to the experts" myth.

Yours faithfully,

NEWS AND VIEWS

How to use geothermal energy

from S.W. Richardson & A.A.L. White

WITHIN the next decade it will be possible to obtain large quantities of hot water from permeable geological formations buried deep in the sedimentary basins of the UK[1]. The temperature of the water is restricted by the terrestrial heat flow and the occurrence of suitable formations to a maximum of 110°C (ref. 2) but this limit could be extended if the technology is developed to extract heat from impermeable crystalline rocks[3].

There is a multitude of possible uses for this relatively low grade heat but here we consider the relative merits of just two such applications: the generation of electricity and the provision of district heating. These uses are very different in structure. District heating is, at first sight, the obvious application — and has dominated official thinking for several years[4] — but is capital intensive due to the cost of the network of pipes needed for distribution. The plant required to convert the heat into electricity is relatively cheap but provides a much less efficient use of the energy due to the low conversion efficiencies of heat engines operating at these low temperatures. To illustrate the differences between these schemes we investigate the case of two hypothetical entrepreneurs, one considering investing in boreholes and a distribution network hoping to make a profit by selling heat to householders; the other aiming to sell geothermally generated power to the electricity utility.

It is reasonable to assume that the scheme which offers the higher return on capital is more likely to be implemented. Costs and income for converting a small city to district heating are found using figures produced for the Combined Heat and Power reports[5-7]. Electrical generation is provided by 10 MWe plant based on the Rankine cycle with an organic working fluid and costs are taken from American generic studies[8,9]. The geothermal energy is assumed to be provided by pairs of production-reinjection boreholes or 'doublets' sunk into proven aquifers at 3 km depth containing water at 100°C. Aquifer transmissivity is taken to be 3.5×10^{-4} m^2 s^{-1} and flow rates of 50 kg s^{-1} are maintained by pumping. The cost of providing these holes[8] is £1.0M per doublet for a scheme involving a number of doublets.

District heating

Allowing for heat exchanger effectiveness and losses in the distribution system, we assume that each doublet will be able to provide water at 90°C to the householder. With a 60°C (ref. 5) return temperature this represents some 6.3 MWth, sufficient to provide for 1520 households (see p.85 of ref. 5). The cost of the distribution network varies with the housing density[5,7] and the capital costs of this scheme are as follows.

Household density per hectare	12	20	50	150
Heat load, MW km^{-2}	6	10	25	75
Distribution pipework cost per household £ (1980) (ref 5, p 80)	2600	1270	600	520
Total costs per doublet £M (1980)	4.95	2.93	1.91	1.79

It has been assumed that £1 (1976) = £1.6 (1980) and that all the boreholes are drilled within the city (extra significant figures are included allowing the argument to be followed in detail).

The energy papers found that each household will require 39 GJ per year[6] so the installation of the network will allow the entrepreneur to sell 5.9×10^{13} J per year.

The sale price of this heat will be determined by the price of alternative fuels since householders will not choose to convert their existing wet central heating system, or pay to have a number of radiators installed, unless the heat is considerably cheaper: indeed a major obstacle to district heating could be the need to coerce people to join the system[7]. However, in this work we have assumed 100% penetration of the heat market as this was the figure used to derive the costs in the energy papers. The current UK prices for heating alternatives, making due allowance for the inefficiency of domestic boilers, are shown below. Geothermal district heat sold at each of these prices produces the annual income shown.

Fuel	Price, £ per GJ	Income, £ per year
Gas	1.95	116,000
Coal	2.40	142,000
Oil	5.50	325,000

Against income must be set the pumping costs since the 'doublet' operation will require some 250 kWe. At 38% load factor[6] this represents £29,000 per yr. where the electricity is purchased from a utility at 3.5p per kWh. The net incomes are shown as percentages of the capital costs in the Figure and are seen to vary from 2% per yr. if the heat were supplied at gas prices to a sparse area of 12 households per hectare, to 16% if heat were supplied at oil prices to a densely populated area with heat demand from 150 households per hectare.

Obviously a geothermal district heat scheme will be relatively attractive in a fuel economy dominated at the present time by oil. This is the case in France and explains the energetic French exploitation of their geothermal resources in heating schemes. In Britain, where the heating market is dominated by gas, geothermal district heating schemes will be rather less attractive as an investment.

The income from each doublet may be increased if it is possible for the householders to accept a lower return water temperature of 50°C, allowing each borehole to supply 2,025 households. However, the network costs increase in proportion and the returns on capital are not significantly altered.

Similarly the load factor of the geothermal system could be increased by adding fossil fuel fired boilers to the network to provide for peak demands. However, the network extension required to accept the boreholes' output cause the improvements, if any, to be of second order.

Electricity generation

The efficiency of Rankine cycle generation from a hot water geothermal source is[10]

$$\eta = \alpha \left[1 - \frac{T_0}{T_2 - T_1} \ell n \left[\frac{T_2}{T_1} \right] \right]$$

where T_0 is the heat rejection temperature determined by the environment, T_2 is the

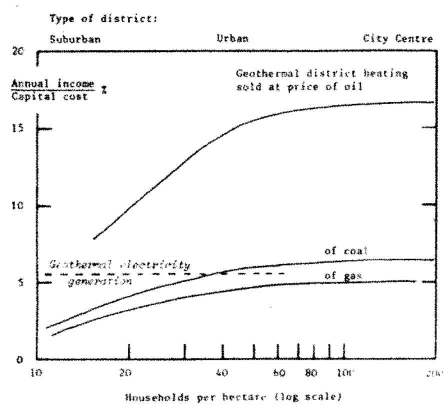
0028-0836/80/280103-02$01.00



How return on capital for a geothermal district heating scheme varies according to the household density and the equivalent fuel price.

geothermal source temperature and T_1 is the temperature at which the geothermal fluid is reinjected into the aquifer. α is an empirical constant which is determined by the losses in the power cycle and we take the value $\alpha = 0.6$[8]. For $T_2 = 373$ K, $T_1 = 308$ K and $T_0 = 298$ K, $\eta = 0.073$ and the gross electrical output is 1 MW per doublet. The capital cost of the plant is £754,000[8] and the cost of the boreholes and connections to the central plant is £1.34M per doublet. Total capital is thus £2.09M for a net electrical output of 750 kWe. Operating at an 80% load factor this entrepreneur is able to sell some 5.3×10^6 kWh each year to the utility worth £116,000 at the current price of 2.2p per kWh paid by the Electricity Council's Area Boards. The return on capital is 5.5% per year.

Relative and absolute merits of the applications

Of the two schemes, electricity generation would have a higher return on capital if the price at which the other sold heat were determined by gas, for all dwelling densities. For a density of 40 households per hectare it would require an increase in the price of gas by 30% with the electricity price unchanged for district heating to hold the advantage. On the other hand, if the price of heat were fixed by oil, district heating would provide the better investment for densities greater than 12 households per hectare. The relative merit of the schemes is not sensitive to the assumed temperature of the aquifer.

It should be noted that we have stacked the odds in favour of district heating, in three respects particularly. First, the boreholes are assumed to be within the district they serve. Heat transmission would materially raise the capital cost of the scheme. Second, we have included no 'overheads' allowance for the district heating scheme. For the electricity scheme most of these costs are included in the difference between the Area Board's buying and selling price for electrical energy. Third, we have assumed (with refs 5 and 7) 100% market penetration. To achieve this, district heating would in fact have to set its price considerably below that of competing fuels.

Neither of the schemes is particularly attractive in absolute terms; but should energy prices as a whole increase relative to other costs this particular conclusion could well be reversed. In a regime under which a large proportion of electricity is generated from fossil fuels, major relative changes in electricity and fossil fuel prices seem unlikely.

We conclude that the generation of electricity from low grade heat is at least as likely to become an attractive proposition as the provision of geothermal district heating in countries which, like Britain, generate a large proportion of their electricity from fossil fuels. Paradoxically, the geothermal electricity option saves money but wastes fossil fuels: we suspect that none but the most high minded will be put off. □

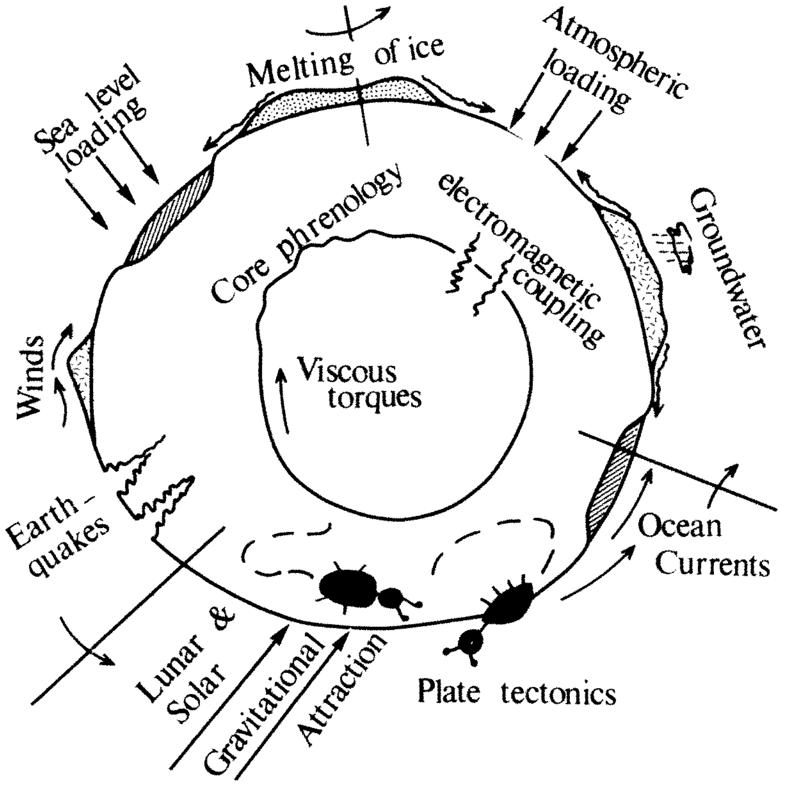
Changes in length-of-day and atmospheric circulation

from Kurt Lambeck

OBSERVATIONS reported in this issue of *Nature* (Hide *et al.* p141) show that zonal components of atmospheric momentum contribute to high frequency changes in the length-of-day.

For many years astronomers have observed fluctuations in the Earth's rate of rotation — or changes in the length-of-day — that are attributable to various forces acting on the Earth's mantle and to a redistribution of mass within the Earth, oceans and atmosphere. Despite the smallness of these departures from uniform rotation — changes in length-of-day of about 10^{-3} s typically occur over time intervals of a few days to several years, and changes of about 10^{-2} s occur over several decades — they have intrigued geophysicists for many years and a complete discussion requires one to delve into atmospheric and oceanic circulation problems, into the Earth's elasticity and anelasticity and into magnetohydrodynamics of the core[1,2] (Fig. 1). Astronomers measure the integrated amount τ by which the Earth is slow or fast

Fig. 1 Schematic illustration of the forces that perturb the Earth's rotation. Topographic coupling of the mantle to the core has been referred to as 'Core Phrenology' by R.R. Hide while the beetles, following T. Gold, represent the effect of continental drift.



0028-0836/80/280104-02$01.00

after a certain time interval by comparison with a uniform time scale and the first derivative of this function gives a measure of the change in the length-of-day. Figure 2 illustrates the spectrum of the proportional changes in the length-of-day. Present techniques give accuracies for τ of about 1.5×10^{-3} s for an integration time of about 5 days[3] but new observational techniques based on laser range measurements to artificial satellites or to the Moon and long-baseline radio-interferometry have been developed. Preliminary results[4,5] indicate that improvements in resolution and precision are imminent.

We can anticipate that a new part of the length-of-day spectrum will rise above the measurement noise level (see Fig. 1). For example, rapid changes in length-of-day may occur in conjunction with very large earthquakes, similar to the Chandler wobble problem[6,7], in which the direction of the rotation axis is displaced relative to the Earth's crust when large earthquakes occur. Such changes will only be evident if there is no 'meteorological noise' in the length-of-day data or if the meteorological contribution to the length-of-day changes can be reliably evaluated from the meteorological data.

The contribution of the atmosphere to the broad spectrum of rotation perturbations has long been recognized as being important. A satisfactory quantitative comparison of the zonal angular momentum computed from wind data with astronomical observations was made only relatively recently[8] but it is now recognized[9] that variations in length-of-day with frequencies between about 0.2 cycles yr^{-1} and 4 cycles yr^{-1} are mainly a consequence of an exchange of angular momentum between the Earth and the atmosphere. This conclusion was substantiated by Lambeck and Hopgood in a recent compilation of ten years of zonal angular momentum[10]. At higher frequencies (i.e. $\gtrsim$ 4 cycles yr^{-1}) the atmosphere may contribute significantly to the length-of-day spectrum[1,9]. A quantitative comparison of the length-of-day observations with the zonal winds in this frequency range has now been attempted by Hide and co-workers, (this issue of *Nature* p141) based on data collected in 1979 during the first CARP Global Experiment.

Hide *et al.* have attempted to evaluate the zonal component of the angular momentum of the atmosphere at 12 hourly intervals using wind and pressure data collected during two 8 week periods in 1979. Where observations were incomplete they were supplemented by values deduced from numerical circulation models. A comparison with the astronomical length-of-day data, particularly for the second period, indicates a generally good agreement and confirms that the atmosphere makes a significant contribution to the high frequency changes in length-of-day. In particular, observed changes in length-of-day over five day periods can be attributed to rapid exchanges of angular momentum between the solid Earth and the atmosphere. From Hide *et al.*'s Fig. 3 it is also clear that shorter period, atmospherically induced, changes in rotation can be anticipated when the new methods of observing the rotation are fully exploited. What Hide *et al.*'s results show is that for precise and high-resolution length-of-day observations to be of geophysical use, the zonal wind field must be globally known with an accuracy and resolution that is at least as good as that collected during the first CARP Global Experiment. Such a major undertaking is justifiable for meteorological reasons. If future work substantiates Hide *et al.*'s conclusion then it may also become possible to use the high frequency and irregular length-of-day fluctuations as global contraints in numerical modelling of the circulation and, in particular, this may lead to a better understanding of how the atmospheric torques are distributed over the Earth's surface.

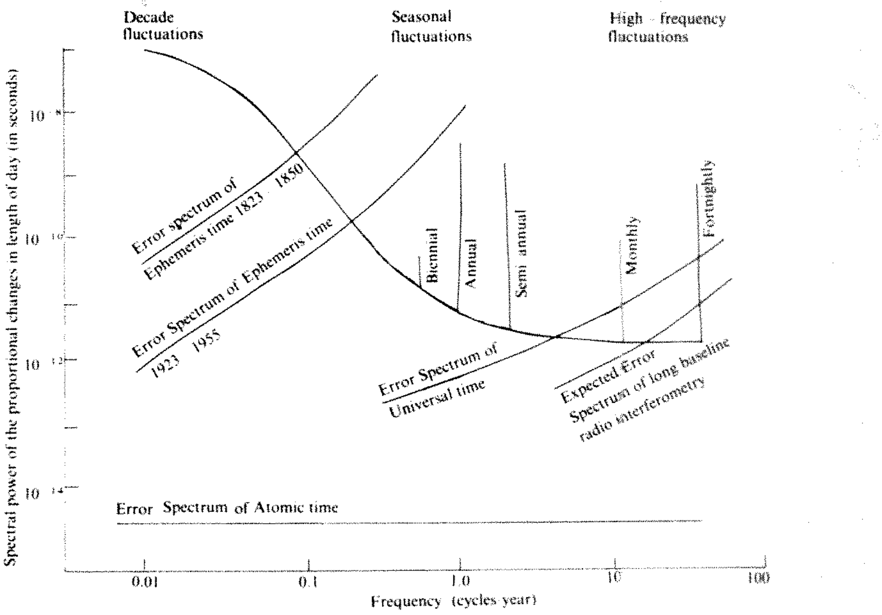


Fig. 2 Schematic spectrum of the proportional changes in length-of-day based on astronomical observations taken since the early nineteenth century. The error spectrum of Universal time is that which can be attained with astronomical observations since the introduction of atomic time. The error spectrum of ephemeris time is appropriate to the older data for the indicated time-intervals.

Towards the other end of the length-of-day spectrum, meteorological influences do not appear to be very important[1,10] although some contribution cannot be excluded. Recently it has been suggested by Currie[12] that there is an 11 year length-of-day fluctuation asociated with the solar cycle. Such a suggestion has been made previously[13] but this conclusion is hard to reconcile with the quality of the earlier astronomical data. For example, prior to 1850 the astronomical data becomes only barely significant when averages are taken over 10 years while from 1923–55 only 5 year averages are significant (Fig. 2). Only since the introduction of atomic time in 1955 can one be certain that fluctuations with about 10 year periods will reflect real changes in rotation. This being said, a relation between solar activity and the Earth's rotation cannot be dismissed if there is a solar influence on the zonal circulation as was suggested most recently by Nastrom and Belmont[14]. Attempts at evaluating the contribution of the atmosphere to long period length-of-day variations have not been wholly successful through lack of complete and reliable meteorological data but they do indicate that the winds can contribute at most about 10–20% to the decade length-of-day fluctuations[1,10].

Partly by an elimination process, core-mantle coupling processes[1,15] remain the most likely contenders for these decade fluctuations but here, as at the higher frequencies, the atmospheric contributions should be eliminated before other geophysical mechanisms can be reliably evaluated. Hide *et al.*'s results shows that this indeed can be done. ☐

The Pneumatic Clock on the Place de la Madeleine.

100 years ago

To distribute the time with accuracy and uniformity in a large city is a problem of great utility and extreme importance. This problem has been all but completely solved by the pneumatic clocks erected since March last in the principal streets of Paris and among a considerable number of subscribers, who, for a halfpenny a day, receive dials with pneumatic receivers established in the public streets and in private buildings.
From *Nature* **22**, 8 July, 126, 1880.

Neurological mutants affecting myelination

from Richard P. Bunge

THEIR names (twitcher, quaking, jimpy, shiverer, trembler and dystrophic) suggest characters from a Dickens novel. They are, in fact, colloquial designations of the neurological abnormalities characterizing 6 strains of mutant mice, each with severe abnormalities of the myelin sheath within some part of their nervous system. These mutants provide important models of human disease and were the subject of a recent international meeting.*

The spiral membrane of the myelin sheath is formed by an intriguing feat of cellular acrobatics. The myelin forming cell extends a cellular process over a length of nerve fiber and deposits an expanding sheet of plasma membrane as a 'jelly roll' around the axon. As this cell process extends, the cytoplasm between the layers of plasmalemma is extruded and the spiralled membrane compacts into a multilayered sleeve; this provides the insulating properties that increases conduction velocity. The myelination process, which occurs during the fetal and neonatal period, requires a large metabolic investment in the synthesis of prodigious amounts of new cell membrane; about 1/3 of the weight of the mature mammalian central nervous system is myelin.

Each of the curiously named myelin deficient mutants appeared on stage at the Seillac meeting but for one it was a debut. Twitcher provides a direct example of the results of a degradative enzyme deficiency in myelin-forming cells. This autosomal recessive mutant, first observed in 1976 at the Jackson Laboratory, has been studied by Duchen and his colleagues at the Institute of Neurology in London. They have observed that both the central nervous system (CNS) and peripheral nervous system (PNS) contain excessive numbers of macrophages laden with peculiar crystalloid inclusions and multiangular bodies. These were found in areas of myelin loss and closely resembled cells that occur in the human degenerative disorder known as human globoid cell leukodystrophy, or Krabbe's disease. When Suzuki and Kobayashi at Albert Einstein in New York measured enzyme activities in this mutant they found a severe shortage of the enzyme that catalyzes the breakdown of one of the most prominent myelin glycolipids, cerebroside, to ceramide and galactose. Whereas myelination begins in a relatively normal manner in these mice, the amount of myelin present progressively declines as cerebroside accumulates. The twitcher mouse thus seems to provide a model of the fatal Krabbe's disease.

Such exact modelling of human disease is uncommon but two of the other mouse mutants present pathological pictures resembling rare hereditary human disease. In the X-linked mutant jimpy (*msd* seems to be an allele) there is little myelin and the few myelin forming cells present in the CNS appear immature. Because there is little evidence of myelin breakdown or lipid storage it is considered a primary failure of CNS myelination, a condition comparable to the Pelizaeus-Merzbacher disease in man. Infants often succumb during the first 3 or 4 years of life. The primary lesion in both the human and mouse disease is not known but work presented by Braun and co-workers of Montreal suggests that a membrane precursor to myelin accumulates in the jimpy mutant but is not converted into myelin.

The mutant trembler presents primarily PNS abnormalities including abnormal and sparse myelination with the concurrent deposition of connective tissue components which in time enlarge the peripheral nerve trunks. Aguayo and colleagures of Montreal (*Soc. Neurosci. Symp.* **4**, 362; 1979) note that conduction velocity is much slowed in these nerves, that axon diameter is reduced and that Schwann cell proliferation continues at abnormally high rates into adulthood. Drawing on their experience with nerve transplantation (including the transplantation of human nerve biopsy specimens into immunosuppressed mice), this group has shown that trembler Schwann cells express their characteristic abnormality with axons in normal mice, and that Schwann cells from patients with Charcot-Marie-Tooth disease (an hereditary human disease with marked peripheral nerve hypertrophy) express a very similar phenotype with normal mouse axons.

The dystrophic mouse was discovered in 1975 (Bradley & Jenkinson *J. Neurol. Sci.* **25**, 249; 1975) and was initially considered a model of muscle disease. It has been found to have a peculiar lesion in the nerve roots of its PNS, involving a more or less total failure of Schwann cell

---

*A meeting on Neurological Mutations affecting Myelination was held at Seillac, France, April 13-17, 1980. The organiser was Nicole Baumann and support provided by the French agency, INSERM. The proceedings will be published by Elsevier — North Holland.

Richard P. Bunge is Professor of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri.

0028-0836/80/280106-02$01.00

performance in these areas. Bunge and colleagues from St. Louis presented arguments at the meeting that this type of lesion could best be explained by an abnormality of extracellular matrix (ECM) within the nerve, i.e. a deficiency in the microenvironment of the Schwann cell. This contention derives from evidence that Schwann cell development is retarded if only axonal contact is available without simultaneous contact with appropriate ECM material (Bunge & Bunge *J. Cell Biol.* **78**, 943; 1978).

Centre stage was reserved for a relatively new mutant, shiverer (the mutant *mld* may be an allele). Interest in this mutant derives from the specific lack of one of the major myelin componets — basic protein (Dupouey *et al. Neurosci. Letters* **12**, 113; 1979). This constituent is of special interest for it causes a severe and sometimes fatal immune response when presented as an antigen with Freunds adjuvant. It previously had been assigned a quite specific role in normal myelin structure — that of stabilizing the compacted membranes of the myelin sheath. It was therefore not unexpected that CNS myelination was found to be severely deficient in this mutant (Privat *et al. Neurosci. Letters* **12**, 107; 1979) but it was surprising that myelin within the PNS, which also lacks basic protein, was quite normal in appearance, even at the level of the electron microscope (Kirschner & Ganser *Nature* **283**, 207; 1980). This mutant was much discussed at the Seillac meeting; several attendees suggested that available data indicate a different role for basic protein in CNS and PNS myelin. □

Timing in embryological development

from Michael H.L. Snow & Patrick P.L. Tam

NORMAL tables of embryonic development give the impression that the developmental processes are neatly co-ordinated, both spatially and temporally. The precision of timing of events is much stressed and frequently quoted in hours and minutes elapsed since the initiation of development. Certainly the synchrony observed between embryos of one species growing in a defined environment seems much more than mere coincidence. Evidence is accumulating that suggests a timing mechanism operates to control the emergence of developmental events. It is envisaged as a clock consisting of five components; the driving force (main-spring), operating an oscillatory mechanism (pendulum, balance wheel), which produces periodicity of emergent events (chimes on the hour), and all depending upon a linkage mechanism between oscillator and event (cog-wheels), and a capacity for adjustment in response to disturbance (correction for fast or slow running), (Brady *Biological Clocks*, Arnold, 1979).

In biological terms little is known about the driving force, the linkages or the homeostatic mechanisms but they can be presumed to exist. Studies have focussed on oscillators and the periodic events. More often than not the oscillatory mechanism has been ascribed to events in the cell cycle, DNA replication, cytokinesis. The premise that these reflect the operation of a clock has arisen from the characteristic regularity of the process in different tissues, and cell types. However the distinction made between proliferative cycles, which merely increase the number of identical cells, and quantal cell cycles, which generate daughters with developmental options different from the mother cell (Holtzer *et al. Q. Rev. Biophys.* **8**, 523; 1975) suggests that differentiative events may be gated by a periodicity not necessarily associated with cell cycles. Recent work throws some light on this subject.

The cell nucleus is generally regarded as the control tower for cellular functions and it has been implicated in the timing of various developmental events. In Ascidian embryos the specific expression of the enzyme acetylcholinesterase in presumptive muscle cells of the neurula (Whittaker *J. Embryol. exp. Morph.* **55**, 43; 1980) has been shown to be under a stringent control apparently directly related to the number of DNA replications undergone in the nucleus. The timing of its appearence is unaffected when cell or nuclear divisions are prevented by metabolic inhibitors (Satoh *J. Embryol. exp. Morph* **54**, 131; 1979). In the mouse embryo, cavitation of the morula to form a blastocyst seems more plausibly related to nuclear events since it is not governed by chronological time, nor interfered with by manipulation of cell number or supression of cytokinesis (Smith & McLaren *J. Embryol. exp. Morph.* **41**, 79; 1977).

Nevertheless, the nucleus can be excluded from other closely timed developmental events. In the mouse the time of compaction of the morula prior to blastocyst formation is not altered by changes in cell number, cell division, nuclear: cytoplasmic ratio or inhibition of DNA replication (Johnson, Pratt & Handyside in *Cellular and Molecular Aspects of Implantation*, Plenum, 1980). Similarly in *Xenopus* eggs periodic changes in contractile activity in the cortex of the cell are observed in perfect phase with cleavage divisions but persist in the absence of actual cell division and also continue when the cell is deprived of its nucleus (Hara, Tydeman & Kirschner *Proc. natn. Acad. Sci. U.S.A.* **77**, 462; 1980). Cytoplasmic or membrane associated mechanisms need to be considered for the control of these events. At the molecular level in the mouse the timing of synthesis of 'tissue-specific' polypeptides is the same in normal or experimentally disturbed embryos (Johnson, Handyside & Braude in *Development in Mammals* **2**, (ed. Von Blerkom & Brockway) North-Holland 1977; *Devel. Biol.* **44**, 148; 1975).

It is an attractive idea that the future development of the embryo is timed by a clock set in motion at the very beginning of development but is this feasible? The control of somitogenesis in Amphibian embryos is a later event that is precisely timed, regular and is currently explained in terms of a clock model (Cooke *3rd. Symp. Brit. Soc. Devl. Biol.* Cambridge University Press, 1977; Pearson & Elsdale *J. Embryol. exp. Morph.* **51**, 27; 1979; Elsdale & Pearson *J. Embryol. exp. Morph* **53**, 245; 1979). In mammals the later molecular events concerning the *in vitro* appearence of amylase activity in pancreatic primordia (Wessels & Cohen *Devel. Biol.* **15**, 237; 1977; Spooner, Cohen & Faubion *Devel. Biol.* **61**, 119; 1977) and the onset of responsiveness to androgen by mouse mammary tissue (Kratochwil *Devl Biol.* **61**, 358; 1977) seem to relate to chronological age rather than cell cycle parameters since the biochemical changes coincide with the timing expected *in vivo* despite the fact that tissue mass and cell number may be quite different from that in the embryo *in utero*.

It is unlikely however that the whole embryo is controlled by a single clock. Recent studies in the mouse in which embryos recover from a severe size reduction show that the neural ectoderm, the somatic tissues of somite and limb-bud, and the germ cell population recover according to different timetables and appear to be under separate intrinsic controls (Snow & Tam *Nature* **279**, 555; 1979). So, either the clocks can be changed independently at tissue or organ level by an exogenous insult or, during development when various cell populations are set aside each one becomes a mosaic of time zones. It is intriguing to speculate whether the obvious co-ordination of tissue interactions in normal embryogenesis arises as the result of the harmonics generated by signals of differing periodicity originating from the different time zones. Such a system is reminiscent of the phase-shift model for spatial and temporal organisation proposed by Goodwin and Cohen (*J. Theoret. Biol.* **25**, 49; 1979). □

Cree-Ojibwa hunting and the hare-lynx cycle

from Robert M May

MANY animal species exhibit well defined cyclic variations in abundance. Of particular fascination to ecologists are the dramatic cycles shown by many mammals in the boreal region of North America; these include the 3–4 year cycles of mice, voles and lemmings and the 10–11 year cycles of the snowshoe hare, lynx and other fur bearers. Indeed the hare-lynx cycle, which shows pronounced and regular oscillations extending back nearly 200 years, is presented in essentially all introductory ecology texts as the classic example of prey-predator oscillations (with discussion centering on whether the driving mechanism is the predation of lynx on hare, or predation of hare on their food supply with the lynx then entrained). A most readable review is by Hutchinson[1].

The cycles in populations of fur bearing animals are, in the main, deduced from records of pelt sales, kept by the Hudson's Bay Trading Company and administrative agencies of the Canadian North. From time to time, people have questioned the assumption that these records accurately reflect the abundance of the harvested species. Thus Elton and Nicholson[2] and Keith[3] have considered — and dismissed — the possibility that fluctuations in prices, caused either by business cycles in nineteenth century Europe or by factors intrinsic to the fur trade, have driven the cycle. Cyclic epidemics of disease affecting the trappers have also been suggested, but seem unlikely[4,5]. A more substantial suggestion, made independently by Gilpin[6] and Weinstein[7], is that pelt records may reflect changes in the foraging strategy of the trappers, rather than changes in the population densities of the fur bearing animals.

Winterhalder[8] has recently combined ecological studies with historical evidence about the foraging practices of Cree and Ojibwa Indians in northern Ontario, in an exploration of the extent to which apparent population cycles are artefacts of fur trapping practices.

Winterhalder first surveys studies showing that hare was a major component in the diets of boreal forest people. Particularly in the nineteenth and early twentieth centuries, when moose were scarce in, or absent from, northern Ontario (and possibly also from parts of Manitoba and Quebec), hare and fish were the main items in native diets. Winterhalder next examines the energy budgets for foraging for hare by Cree. In years of peak abundance there are around 1,200 hare per km^2, and he estimates a net acquisition rate of around 5,200 kcal per hr for time invested in snaring hares. At the trough of the hare cycle, the creatures are patchily distributed, but average around 13 hare per km^2 and their net yield to Cree hunters is about 1,200 kcal per hr. (These figures are based on trapping with stationary wire snares, which were not widely used before 1910; the older balance poles with snare loops made of string were probably not more than 10% less efficient). These figures suggest hare snaring would allow trappers to feed their families with relatively small investments of time and energy, when hare were abundant; the activity consumed significantly more time and energy when hare were relatively scarce. Finally, Winterhalder shows that[8] "until the twentieth century interior fur trappers could not exchange pelts for significant quantities of food. Dry goods, metal implements, tea, tobacco, and in some cases alcohol were available, but it was a recurrent problem for trading companies to transport or obtain sufficient food provisions even to maintain trading post personnel." Thus native trappers seldom had the option of exchanging pelts for food, and in times of shortage the pursuit of species highly ranked as food-producing resources necessarily had priority over those valuable mainly for their pelts.

These facts and inferences can be recast in the language of MacArthur and Pianka's[9] theory of optimal foraging. To this end, Winterhalder separates the species sought mainly for food from those sought mainly for pelts, making allowance for some intermediate types. The food species, ranked roughly in the order of their net value (food value less costs of pursuit and capture), include moose, hare, beaver, fish and muskrat. The fur bearers include lynx, otter, mink, marten, fisher, beaver, muskrat, and hare. When highly ranked food resources (moose and hare) were plentiful they provided ample food that could be easily obtained (often by women and adolescents), allowing male trappers to[8] "concentrate on the second economy represented by the fur trade". But when hare became scarce (and with moose rare or absent throughout much of the nineteenth century), more attention had to be devoted to lower ranking food resources, such as fish and muskrats, thus lowering the overall efficiency of the food quest. This in turn restricted the time available for participating in the fur trade; nor could furs be exchanged for staple foods. As a result, pelt-counts should be expected to cycle in parallel with the population abundance of hare.

Winterhalder also quotes from trader's reports, compiled by Bishop[10] from the Hudson's Bay Trading Company Archives. For instance, "the Indians say that they cannot hunt furs for want of Rabbits for they say that there is a few Martens on thir Lands but they cannot Make Traps for want of Provisions to live on."

Several interesting predictions follow from this analysis.

First, the above mechanism would have the peak abundance of pelts of most fur bearers, such as lynx, fisher and marten, occurring roughly contemporaneously with the peak of hare abundance (and therefore, presumably, the peak of hare pelt-counts). The dynamical properties of prey-predator associations, on the other hand, would have the predator populations lagging those of their hare prey, typically by about one quarter of the period of the cycle. This dichotomy is not discussed by Winterhalder, who observes that either explanation of the cyclic fluctuations in those animals sought mainly for fur (and not for food value) is roughly consistent with the data. Gilpin's[6] analysis, however, suggests the predator cycles do not lag significantly behind the hare cycles; this work could be taken to support the view that cycles in pelt records of fur bearers are artefacts of Cree-Ojibwa foraging strategies, rather than measures of the population dynamics of the animals themselves.

Second, Winterholder observes that pelt-count cycles are more pronounced in the nineteenth than in the eighteenth and twentieth centuries. This was also a time when moose and caribou were relatively absent from the hunting grounds of the Cree and Ojibwa; without this important food source to buffer fluctuations in the hare population[8], "the correlation between hare abundance and native attention to the fur trade should be strongest".

Third, muskrat is an interesting species in that it ranks relatively low both as a food source and in fur value. Winterhalder suggests that in times of hare-feast muskrat would have been spurned, but that in times of hare-famine the native hunters drew heavily on this less desirable food source, and sold the ensuing pelts. The resulting prediction is that peaks in muskrat pelt-counts should come in the troughs of hare abundance, and have nothing to do with the absolute abundance of muskrats as such. A somewhat irregular pattern of this kind is actually observed, particularly in the second half of the nineteenth century (when, as noted above, all patterns were more marked, by virtue of the absence of

moose).

There are, of course, extensive field studies of the population dynamics of snowshoe hare, and, to a somewhat lesser extent, of lynx. These studies show the populations do in fact cycle, with periods of 10–11 years, Indeed, Bryant (of the University of Alaska) has shown that many of the deciduous plants browsed by snowshoe hare in Alaska manifest defensive responses to heavy browsing, by producing resins or other compounds that are repellent or toxic to hares[11]. The time lag in mounting this response is around 2–3 years; such a time lag in the regulatory mechanism will tend to produce population cycles of period $4 \times (2 \text{ to } 3) \simeq 10$ years in the overall prey (food)-predator (hare) system[12]. Species predatory upon the hare will then track this cycle.

In short, there is direct evidence to show that populations of hares and other boreal fur bearers do exhibit oscillations. But the nature of the foraging economy of the Cree-Ojibwa hunters must be kept in mind when we try to draw inferences about populations from records of pelts traded; peltcounts tend to amplify and sharpen the underlying population cycles of fur bearers (such as fisher and marten) and some cases (such as the out-of-phase muskrat cycles) may be pure artefacts. ☐

Primary productivity in the sea

from Richard W. Eppley

PEOPLE have been measuring primary production in the oceans using the ^{14}C method of E. Steemann Nielsen for nearly 30 years, yet they still argue about the accuracy and meaning of the measurements. Some of the debate concerns methodological details of little interest beyond the circle of measurers, but a larger part questions our understanding of photosynthetic mechanisms, the absorption of sunlight by plants in the sea, quantum efficiency of photosynthesis as a function of depth and submarine irradiance, metabolic adaptations of algae and other matters of broader interest. Oceanographers debated these issues 2-5 June at the 31st Brookhaven Symposium on Biology in the presence of experts in the laboratory study of photosynthesis and algal physiology. The productivity of coral reefs and seaweeds was also discussed along with the significance of global oceanic production for human affairs.

Measurement of ocean photosynthesis is no longer the exclusive territory of algal ecologists and physiologists as the experimental seawater samples contain minute animals that graze on the contained phytoplankton and bacteria — a microcosm exists within the productivity bottles. While this has long been known, we now realise that we must assess the flow of photosynthetic products among tiny animals and bacteria — the province of microbiologists and protozoologists — as well as among phytoplankton in order to estimate primary production. There is also concern that many oceanic species may not survive the mechanical and chemical insults of the measurement conditions and thus photosynthetic production may be underestimated by present methods. The size of the underestimate is unknown. There is agreement, however, that the problem is more extreme for the central oceanic gyres, such as the Sargasso Sea and comparable regions in the South Atlantic and North and South Pacific. Guesses of the magnitude of the underestimate seem to range from a factor of two to an order of magnitude for these areas. However most of a day's production in such regions is eaten, digested, defecated, decomposed and the organic-bound nutrients recycled during the day-night cycle of the 24-hour day. Thus, even those measurements suggesting higher values for production, such as daytime increases in oxygen in the water and in the concentration of organic particles, living and dead, involve daytime increases that disappear by the following dawn. Upward revision of the photosynthetic rates would not imply more food for fish although it would require some new thinking about the rates of elemental recycling in the surface waters and the ecological significance of microbial food webs. Our understanding and the validity of 30 years of historical measurements of production in the central oceans are more at stake than practical matters.

Z. Dubinsky (University of Bar Ilan, Israel) confirmed J. E. Tyler's earlier finding that the quantum yield of photosynthesis is very low at the sea surface and increases to near maximum expected values at the bottom of the photic zone. Jack Myers (University of Texas, Austin) explained why the theoretical maximum quantum yield (0.125 from the Z-scheme of photosynthesis with equimolar reaction centres for photosystems I and II) is rarely attained: the photochemical reaction centres are not always open to traffic. A. Ley (Rockefeller University, New York) found the reaction centres of unicellular red algae were not present in equimolar amounts; this would reduce the maximum quantum yield expected in dim light, depending on the proportion of reaction centers I and II. The practical problem of the quantum efficiency of photosynthesis arose in an argument over central ocean productivity. The arguments for order-of-magnitude greater production would require unrealistically high differences in quantum efficiencies between coastal and open-ocean regimes. Production would be 1-2 grams carbon m^{-2} day^{-1} in both yet the fraction of sunlight absorbed by phytoplankton is an order-of-magnitude greater in coastal than oceanic waters.

Many of those present were interested in photosynthesis light curves (T. Platt, Bedford Institute, Dartmouth, Canada) the regulation of chlorophyll, and other photosynthetic pigments in algal cells (P. Falkowski, Brookhaven National Laboratory; J. Marra, Lamont-Doherty Geological Observatory) and the vertical distribution of photosynthetic pigments in the ocean (S. W. Jeffrey, CSIRO, Australia). Falkowski presented the interesting hypothesis that regulation of cellular chlorophyll content by light may involve a competition for ATP between ammonium assimilation leading to protein synthesis on the one hand and the use of glutamate in the biochemical synthesis of chlorophyll on the other. Both Marra and Falkowski suspect that the rapid adjustment of cellular pigment content with changing irradiance and light quality (i.e. with depth) can serve as tools to study rates of vertical water motions in the photic zones. Here biology may provide information on the near surface circulation that is difficult to assess with physical observations.

Developing conceptually adequate mathematical models of ocean phtosynthesis and phytoplankton growth rate (realted to photosynthetic production by the phytoplankton standing stock) has been a difficult task. Nevertheless, T. Bannister (University of Rochester) has achieved a satisfying model which could be fitted to the old data of J. Myers and J. R. Graham on *Chlorella* and the new data of E. Laws (University of Hawaii) for the diatom *Thalassiosira fluviatilis*. The latter data set and modelling includes nitrogen, phosphorus and light-limited growth. Several generalizations from the work will be useful in the field assessments: both the dark respiration rate and the ratio of chlorophyll a to carbon in phytoplankton are linear functions of growth rate, and the photosynthesis light saturation term is not altered when growth rate is reduced by nutrient limitation.

Titbits of information were offered in profusion in the lecture hall and in the corridors. For example, R. Rivkin (Johns Hopkins University) has succeeded in measuring with ^{14}C the photosynthesis of individual cells of some large dinoflagellates. Cell division in diatoms seems to be less under the control of a biological clock than in dinoflagellates (S. W. Chisholm, MIT). It is still not clear whether photo-

Interferon nomenclature

AT a recent, specially-convened meeting an international group of scientists attempted to devise a system to define and classify the interferons*. The following is the unanimous report from the group.

The committee accepted the definition for interferon: "To qualify as an interferon a factor must be a protein which exerts virus non-specific, antiviral activity at least in homologous cells through cellular metabolic processes involving synthesis of both RNA and protein."

The preferred abbreviation for interferon is IFN, each interferon to be identified according to animal of origin: e.g. human (Hu IFN); murine (Mu IFN); bovine (Bov IFN); rat (Rat IFN); chicken, porcine, feline, equine interferon, etc. However, it may be necessary in some cases to apply generic nomenclature: e.g. monkey = *Rhesus* interferon, etc.; fish = *Salmo* interferon, etc.; bat = *Taderida* interferon etc.

Interferons will be classified into types on the basis of antigenic specificities, type designations to be alpha (α), beta (β) and gamma (γ), corresponding to previous designations of leukocyte (Le), fibroblast (F), and type II (immune) interferons, respectively. The old terminology of 'leukocyte', 'fibroblast' and 'immune' interferons were, by committee consensus, abolished, as they clearly were misnomers: both leukocyte and fibroblasts can produce each of these two types of interferon, and 'immune' interferons are often induced by mitogens rather than by immune recognition reactions. Also, the abbreviation 'F' has often been used to designate either fibroblast or fast migrating interferons. Alpha and beta interferons are usually acid-stable and correspond to what have been called type I IFNs; gamma interferons are usually acid-labile and correspond to what has been called type II IFNs. If there are discovered to be classes of IFN which are not presently recognized, they could be designated sequentially IFN-delta, epsilon, etc. The Table lists the new nomenclature for human and murine interferons and the corresponding designations which have been or are being employed. Interferon preparations may contain more than one type: for example, interferons derived from human lymphoblastoid cells and interferons from murine fibroblasts contain both IFN-α and IFN-β. These can be designated as to predominant type. Thus, the interferons presently employed in clinical trials are either HuIFN-α or HuIFN-β, or admixtures thereof.

The committee's recommendations apply at present only to human and murine IFNs, since there is insufficient information about IFNs from other animal species to allow differentiation into types. Workers using IFNs from other species are encouraged either to attempt preliminary classification based on antigenic homology with existing antisera specific for human or mouse alpha, beta or gamma IFNs, or to establish sequence homology with the known types of human and mouse interferons.

It is recognized that there may be size, charge, sequence and other heterogeneities within the designated IFN types. Currently, there is insufficient information available about the nature of these differences to allow designation of specific subtypes. Properly documented differences in molecular size appear to be useful parameters for differentiation until more stringent criteria (amino acid sequence, monoclonal antibodies) become available. Molecular weight designations may be indicated in parentheses, e.g. Hu IFN-α (18K) or Mu IFN-β (38K), or subtypes of IFNs based on specific amino acid sequence differences can be classified as Hu IFN-α_1, HuIFN-β_2, etc.

Indication of interferon origin for those that behave antigenically similarly may also be helpful. Thus, interferon from human lymphoblastoid cells and interferon from human leukocytes are both classified antigenically as HuIFN-α, yet these interferons differ in certain amino acids. Therefore, the nomenclature HuIFN-α (Ly) or HuIFN-α (Le) may be used until such time as specific differences in amino acid loci have been established and subtype designations can be assigned. Also, it is now recognized that there are a number of forms of HuIFN-α that differ in certain amino acids; eventually these may be designated according to specific amino acids and their locations. Schemes for such designation of subtypes of each of the major IFN types will be developed at subsequent meetings of the Nomenclature Committee. The next meeting of the committee will be held in April 1981. Suggestions and comments for consideration by the committee should be forwarded to the committee's Chairman.

The committee hopes that scientists and scientific journal editors will adopt the proposed nomenclature to avoid the proliferation of terms for the same substances and the indiscriminate naming of newly discovered factors. □

Old and new nomenclature for human and mouse interferons

New Nomenclature	**Old Nomenclature**	
	Human	**Mouse**
IFN-α	Le (leukocyte), type I, pH 2 stable, foreign cell-induced	F (fast), C, type I, pH 2 stable
IFN-β	F (fibroblast), Fi, type I, pH 2 stable	S (slow), A,B, type I, pH 2 stable
IFN-γ	IIF (immune), type II, T, pH 2 labile, antigen-induced, mitogen-induced	immune (IIF), type II, pH2 labile, T, antigen-induced, mitogen-induced

---

The meeting was sponsored by the National Institute of Allergy and Infectious Diseases and the World Health Organization — US National Centre on Interferon and was held at the National Institute of Health in Bethesda, Maryland on March 7, 1980. Those attending were: William E. Stewart II (Chairman; Interferon Laboratories, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, New York 10021, US), J. Edwin Blalock (Galveston, TX), Derek C. Burke (Coventry), Charles Chany (Paris), June K. Dunnick (Bethesda), Ernesto Falcoff (Paris), Robert M. Friedman (Bethesda), George J. Galasso (Bethesda), Wolfgang K. Joklik (Durham, N.C.), Jan T. Vilcek (New York), Julius S. Youngner (Pittsburgh) and Kathryn C. Zoon (Bethesda).

---

respiration is significant for marine phytoplankton (J. Burris, Pennsylvania State University). On a global average the fate of about 80% of the primary production is to be recycled within the photic zone. The relative importance in nutrient recycling of bacteria, microzooplankton, larger zooplankton and nekton in the photic zone appears to vary between the continental shelf, the slope water and the open ocean (W. G. Harrison, Bedford Institute, Dartmouth, Canada).

Harrison's paper is indicative of the expanding interest of biological oceanographers in the fate of primary production. Globally, about 20% of it appears to sink out of the photic zone. J. Walsh (Brookhaven National Laboratory) postulated that a large fraction of this sinking flux on the continental shelf off New York is buried in the sediments of the upper continental slope, as shown by the relatively high sediment organic carbon content and a low (~ 6) ratio of carbon to nitrogen in the organic matter. Models of carbon flows in the circulation of the deep ocean (M. Fiadeiro, Yale University, New Haven) suggest what the magnitude of the sinking flux of organic carbon may be. Unhappily, the experimental measurements of the flux in the North Pacific using particle interceptor traps are inconsistent with the models. Further collaboration among the several oceanographic disciplines seems required to clarify such problems and especially to define the significance of sinking organic particles as sinks and transporters of atmospheric carbon dioxide from fossil fuel burning. □

Zeolitic structures as revealed by high-resolution electron microscopy

L. A. Bursill*, Eliz. A. Lodge & J. M. Thomas†

Department of Physical Chemistry, Cambridge University, Lensfield Road, Cambridge CB2 1EP, UK

Interpretable images at 3–5 Å resolution of synthetic A-type zeolite suggest possible mechanisms of vitrification and introduction of dislocations into zeolitic structures. Techniques may be developed to extend the lifetime of these, and possibly other, beam-sensitive cage or tunnel structures. Evidence also exists for Si^{4+}/Al^{3+} ordering in the aluminosilicate framework.

ZEOLITE silicates are of considerable practical and academic interest in view of their role as catalysts, ion-exchangers, gas-purifiers, environmental cleaning agents and, following vitrification, as potentially useful matrices for the burial of radioactive waste[1]. For both channel and cage varieties synthetic adaptation has given rise, *inter alia*, to ultrastable zeolites possessing specific catalytic activity for either the cracking of petroleum or the production of gasoline from methanol, using highly silaceous hydrophobic molecular sieve solids such as ZSM-5 (ref. 1). The general chemical formula of a zeolite is $M_xD_y.Al_{x+2y}Si_{n-(x+2y)}O_{2n}.mH_2O$ where M and D may be mono- and divalent cations respectively, usually alkalis and alkaline earths in nature, but other ions in synthetic varieties. Dehydration of zeolites is usually complete at 350 °C (refs 1, 2) and is often reversible: dehydrated zeolites are strong desiccants, however, and molecules other than water may rapidly fill the channels[1].

Crystallographic studies and their implications for practical applications have been reviewed elsewhere[1,2] and an atlas of known zeolite structures is available[3], although most structural work has relied on X-ray methods[2]. Gard[4], however, used electron diffraction to obtain evidence for a pseudosymmetric cell doubling of a 'Union Carbide' zeolite A. Although his data led to a refinement of the structure when the weak reflections were measured by X-ray goniometry[5], the wide range of zeolitic structural variations remains to be fully appreciated[1]. Thus there may be marked differences between hydrated and dehydrated forms[2] and it is not always practicable to locate all of the M, D and H_2O sites or the sites of other ion-exchanged entities. Often crystals are too small (~0.1 μm) for X-ray studies. Moreover, there are apparently many possibilities for the occurrence of short-range order, antiphase domain structures, topological transformations, coherent intergrowth, polytypism and stacking disorder. These are particularly relevant in considering the synthesis of new phases having desirable catalytic, sieve, or other properties. In several areas of solid state chemistry, such as transition metal oxides and chalcogenides, alloys and silicates high resolution electron microscopy has proved invaluable in elucidating the local atomic arrangement which may, in many cases, be lost or not readily detected using X-ray diffraction alone[6,7].

There have been very few reports of high-resolution studies of zeolites. Although Menter[8] first observed images showing $d_{111} = 14.7$ Å spacings in a synthetic faujasite in 1958 it was not until 1978 that Sanders[9] obtained the first high-resolution (~3 Å) two-dimensional image of a (Linde L) zeolite. Sanders, however, used a zeolite as a resolution test object for a 1-MeV electron microscope and no new information about the structure was obtained. This sparsity of electron microscopic data stems principally from the electron beam sensitivity of zeolites, which vitrify within seconds, or at most minutes on examination in normal electron microscope illumination conditions. This beam sensitivity is probably linked with the water present in zeolites.

We report here the observation at high resolution (3–5 Å) of two-dimensional structure images of a synthetic Na-A zeolite. Interesting changes associated with the crystalline/glass transformation and the first observation of dislocations in zeolites are also described.

Stabilization of zeolites for electron microscopy

We hypothesize that the primary source of the crystalline/glass transformation induced by the electron beam is the production of ionized species, in particular hydroxyl ions, which lead to bond softening and bending in the aluminosilicate framework. This, when accompanied by elastic stresses associated with dehydration, will strongly favour collapse of the structure and consequent transformation to a grossly disordered (glassy) state. We, therefore, set out to dehydrate some well crystallized zeolites by heating in air, or *in vacuo*, before examination in the electron microscope, by ion-exchanging H_2O by inorganic salts, either during or after synthesis, and began a systematic study of a wide range of zeolites to discover which of these are least beam sensitive. However, in the case reported here, we were able to increase the longevity of the crystalline state significantly by simply pumping the specimens overnight *in situ* in the electron microscope (at $\sim 10^{-7}$ torr).

Experimental

The NaA zeolite samples used here were prepared by the Charnell method[10]. Their nominal stoichiometry is $Na_{12}(AlO_2)_{12}(SiO_2)_{12}.27H_2O$ when fully hydrated. Fine crystals, ~10–50 μm diameter, of this zeolite were placed in an agate mortar and crushed using a hard vertical thrust of the pestle, whereby a remarkably high incidence of ⟨100⟩ zone axis diffraction patterns were obtained. Such specimens were rapidly tilted into the symmetrical orientation using a JEOL-200 CX side-entry goniometer. Many such crystals showed good lattice images on the viewing screen and some of these persisted for a sufficiently long time (1–3 min) to enable objective lens astigmatism to be corrected and the optimum defocus established before photography. Exposure times were typically 4–11 s, using Kodak 4463 electron image film developed in D19 for 8 min.

Two sets of objective lens pole pieces were used having spherical aberration coefficients $C_s = 2.5$ mm and 10 mm respectively. Calculations of the corresponding lens transfer functions at 200 kV showed that at the Scherzer defocus[11] the 'interpretable image' resolution limits were ~3 and 4.1 Å respectively. Previously it had been shown that 3 Å limit could be achieved, for example with parawollastonite and cordierite, only if a suitably reduced gun bias setting was used, along with low beam divergence (semi-cone angle $\alpha \lesssim 1$ mrad) and if all sources of acoustical vibrations were eliminated.

Experimental results

Figure 1*a* shows a high-resolution image for the [001] orientation. Note the large white blobs and also much smaller white blobs linking the former along ⟨100⟩. The dark intensity surrounding the small tunnels can be just resolved into four dark blobs. Figure 2*a* shows a wider view of the crystal. A strip of essentially structureless contrast may be seen along the thin edge. This is presumably amorphous as it shows a characteristic lack of fringe contrast which extends progressively into the crystal with increasing exposure to the electron beam. At the same time the electron diffraction spots gradually fade giving way to a diffuse halo pattern. In many cases it was possible to record only two images before all structural detail was lost. The interface between glass and crystal is surprisingly sharp in Fig. 2*a*, showing unit cell steps (~12 Å high) along ⟨100⟩ directions. Note changes in contrast giving a patchy appearance. Some patches (~150–200 Å diameter) show a loss of fringe detail in one of the ⟨100⟩ directions (A), others show generally reduced (B) or virtually no (C) visible structure. Note especially that small islands of fringes (D) may be found, apparently completely surrounded by glass. These remnants of structure show fringes only along ⟨110⟩. Further inspection of Fig. 2*a*, by sighting along [100], reveals what seems to be an extended dislocation (circled). Further dislocations are more obvious in Fig. 2*b*, which shows nearly the same area, but was recorded using larger objective lens defocus. Patches are now more clearly outlined, by dark lines resembling Fresnel fringes, and terminating half-planes (dislocations) are seen to be associated with the interface between patches of fringes misoriented by ~5–10° with respect to the bulk.

Figure 3 shows a pincer-shaped intrusion of glassy material into a Na A crystal. The latter introduces a dislocation and extensive (~100–200 Å) strained regions around the intrusion tip.

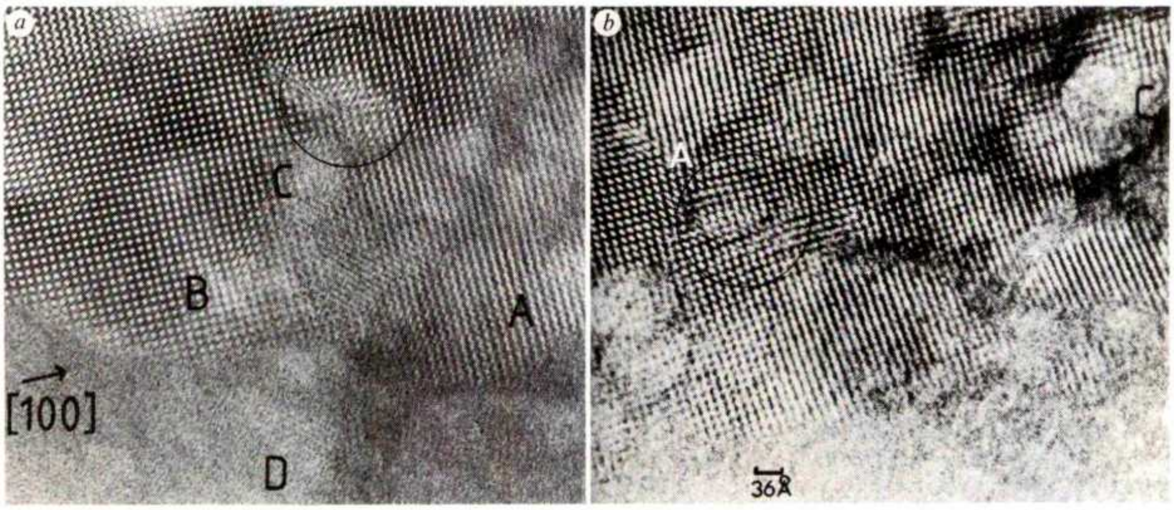

Fig. 2 *a*, *b*, Wider view of zeolite A crystal for two defects of focus showing development of glassy strip along thin edge of crystal and the appearance of patches ~150 Å diameter showing preferential loss of one set of {100} fringes (A), weak (B) or absent structural detail (C) and islands of weak {110} fringes (D) completely surrounded by glassy material. Note occurrence of extended dislocations (circled), sight along ⟨100⟩.

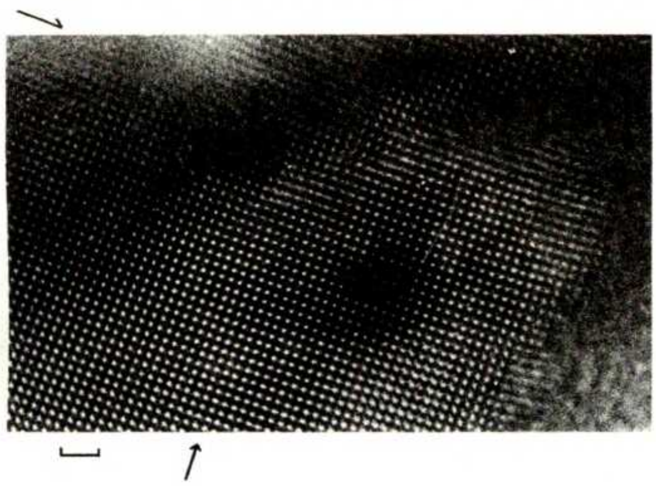

Fig. 3 Area of Na A showing pincer-shaped intrusion resembling a glass-filled Griffith crack. A dislocation may be seen by sighting along the rows of tunnels (indicated by arrows).

Discussion

The ideal chemical formula is $Na_{12}(AlO_2)_{12}(SiO_2)_{12}$. $27H_2O$ when fully hydrated, with cubic unit cell $a = 24.6$ Å, containing eight formula units[5]. The aluminosilicate framework contains two types of polyhedra: one a simple cubic arrangement of eight tetrahedra and the other a truncated octahedron of 24 tetrahedra (β cage). Their combination (Fig. 1*c*) produces a large cavity (α cage) with tetrahedral centres occupying the apices of a truncated cuboctahedron, free diameter 11 Å. We have used the 12.3 Å psudo-cell[12], space group Pm3m, for convenience here, as there are not observable effects in the [001] projection due to Si/Al ordering. However, we have obtained evidence, from electron diffraction patterns of [110], $[11\bar{2}]$ and $[21\bar{3}]$ zones that Si/Al ordering does take place in our zeolite preparation. Thus *hkl* (all odd) reflections satisfying $h + l = 2n$ were observed[13]. This confirms the recent criticism of space group Fm3c for Na A on the basis of high-resolution magic-angle spinning ^{29}Si NMR studies[13,14]. The proposed Si/Al ordering scheme contradicts Loewenstein's rule[15]. Zeolite A is thought to retain its structure on dehydration, which is reversible, after which the cell parameter decreases by only 0.02 Å (ref. 2).

Computer simulated images were obtained using multislice techniques[16] and programs previously developed by Jefferson *et al.*[17]. Computed images of zeolite Na A showed a faint grey blob in the centre of the α cage (large tunnels) if atomic coordinates for the Na atoms were included (Fig. 1*b*). These did not occur on the experimental images, suggesting that some Na atoms were either absent or had moved away from the centres of the tunnels on dehydration. In fact, the image match was improved by leaving out those Na^+ atoms having low partial site occupancy (indicated by open circles in Fig. 1*c*). Otherwise the image match was achieved assuming effective resolution of 3.1 Å. Further improvements in resolution (to 2.4 Å) are expected when ultra-high-resolution pole pieces ($C_s = 1.2$ mm) become available. However, we have clearly demonstrated that high-resolution images of zeolitic silicates may be obtained and that details of the contrast may be matched by computer simulation. Both large and small channels have been located. Further calculations and even higher resolution experimental images are necessary to determine whether specific cation-exchange sites may be located, but we expect that certain heavy ions may be found. We have already shown that the images are sensitive, in optimum defocus conditions and for sufficiently thin crystals, to the cation content of the larger tunnels.

Na A zeolite shows interesting contrast effects associated with transformation to the vitreous state. At least three processes seem to be operating. Thus, for Fig. 2*a* there is an extremely sharp interface, containing unit steps of 12 Å, which seems to advance into the crystal one unit cell at a time, starting at the thin edge. Second, there are patches or islands of structure, B and C in Fig. 2*a*, which are misoriented by several degrees with respect to the bulk of the crystal. These sometimes show a deterioration in image visibility suggesting loss of crystallinity (A, B) whereas other patches appear completely vitreous. Patches of types A and B imply a preferential breakdown of the structure on {100} planes whereas remnants of {110} planes may continue to exist even in areas completely surrounded by glass (D). Apparently, vitreous regions ~150-Å diameter form inside the bulk crystal, although we cannot rule out the possibility that regions having roughly circular cross-section are propagating into the crystal from upper or lower surfaces. Lattice rotation and the consequent production of dislocations may arise from the changes in cell parameter associated with the breakdown of {100} planes or with elastic strain due to changes in density of partially or completely transformed material. However, inspection of the structural drawing (Fig. 1*c*) immediately suggests that the origin of preferential breakdown on {100} planes is due to shear across the relatively weakly bonded structural units linking β-cages. This may be associated with the loss of Na and consequent rearrangement of the aluminosilicate framework, possibly by face-sharing of β-cages forming sodalite type structure units[2,3]. (Note that sodalite may be obtained from zeolite A by a three-dimensional crystallographic shear operation $\{100\}\langle\frac{1}{2}00\rangle$). The circled extended dislocations in Fig. 2*b*, *c* may well represent the initial stages of this process. More detailed analysis of the defects shown in Fig. 2, may lead to structural models for the dislocations and for transition structures.

A third transformation mechanism is suggested by the dislocation and strained region, surrounding the pincer-shaped glassy intrustion in Fig. 3. This resembles a glass-filled Griffith crack. Thus eventually relatively large areas (0.1–0.5 µm) will be split off from the bulk crystal. This mechanism also leads to islands of crystalline or paracrystalline regions surrounded by glass. (Similar intrusions were observed in a [011] zone axis image of zeolite A.)

This work was supported by the SRC, the University of Melbourne, and Unilever Limited. We thank Dr C. J. Adams for Na A specimen, and Drs D. A. Jefferson and G. R. Millward for their cooperation.

Atmospheric angular momentum fluctuations and changes in the length of the day

Fluctuations in the angular momentum of the Earth's atmosphere correspond fairly well with equal and opposite fluctuations in the angular momentum of the Earth's 'solid' mantle. A decrease of 20% of the relative angular momentum of the atmosphere during the second half of May 1979 was accompanied by a speeding up of the rotation of the mantle causing the length of the day (l.o.d.) to decrease by 0.6×10^{-3} s. Although motions in the Earth's liquid core produce the more pronounced 'decade' variations in the l.o.d. there is no evidence that core motions produce l.o.d. variations on much shorter time-scales.

FLUCTUATIONS in the angular momentum $\mathbf{M}_a$ of the Earth's atmosphere are of considerable interest to geophysicists and astronomers concerned with the dynamics of the 'solid' Earth as well as to meteorologists concerned with the general circulation of the atmosphere and numerical models[1-6]. All components of $\mathbf{M}_a$ exhibit fluctuations due to changes in the distribution of mass in the atmosphere and in the pattern of winds, and these will be associated with changes in the rate of rotation of the underlying planet and with movements of the poles. We are investigating these fluctuations as new wind and pressure observations become available from FGGE (First GARP global experiment where 'GARP' is Global Atmospheric Research Programme), which started at the beginning of December 1978 and lasted for 1 year. A detailed study of fluctuations in all components of angular momentum in the Earth–atmosphere system based on these new data will be reported elsewhere. Here we outline our determinations of the main contribution to fluctuations in the axial component of $\mathbf{M}_a$, namely that due to changes in the distribution and strength of zonal winds. (The main direct effect of redistribution of mass in the atmosphere is the alteration of the direction of $\mathbf{M}_a$ which is shown largely as the slight compensating movements of the pole of rotation of the solid Earth[1,2].) The results are a valuable check on established methods for measuring variations of the Earth's rotation on a time scale of several weeks, and should prove particularly useful in testing new methods for monitoring more rapid fluctuations of the Earth's rotation. These new methods[4], notably very long base-line interferometry and laser ranging to artificial satellites and the Moon will eventually provide useful data on the general atmospheric circulation.

The density of the atmosphere decreases rapidly with height and more than 95% of the mass of the atmosphere is contained within the troposphere, which extends from the ground to an altitude of ~10 km, and the lower stratosphere. These regions of the atmosphere rotate faster on average than the underlying solid Earth with a typical relative speed of about 10 m s^{-1}. Exactly how this super-rotation (a term used for the generally more rapid relative motions found in the very tenuous regions at heights around 300 km) is produced and maintained against the tendency for friction to oppose differential motions between the atmosphere and the underlying planet is a central problem in dynamical meteorology.

In the absence of energy sources such as solar heating, internal radioactivity, and tidal forces due to the Moon, Sun and planets, the solid parts of the Earth (crust, mantle and inner core) and fluid parts (atmosphere, oceans, liquid outer core) would rotate together as a rigid body with angular velocity $\mathbf{\Omega}$ equal to the angular momentum $\mathbf{M}+\mathbf{M}_a$ of the whole system (magnitude $5.85 \times 10^{33}\,\mathrm{kg\,m^2\,s^{-1}}$) divided by its principal moment of inertia $I + I_a = 8.04 \times 10^{37}\,\mathrm{kg\,m^2}$ where I_a is the principal moment of inertia of the atmosphere. During the development of the three-dimensional and non-axisymmetric global atmospheric circulation following the imaginary switching-on of the main source of energy for atmospheric motions, solar heating, $\mathbf{M}_a$ would increase by an amount $\delta\mathbf{M}_a$ (magnitude $\doteqdot 1.5 \times 10^{26}\,\mathrm{kg\,m^2\,s^{-1}}$), associated mainly with the average super-rotation of the troposphere and lower stratosphere at average angular speed $|\delta\mathbf{M}_a|/I_a$ relative to the underlying plant, about the main rotation axis. As $I_a = 1.42 \times 10^{32}\,\mathrm{kg\,m^2}$ then $|\delta\mathbf{M}_a|/I_a \doteqdot 10^{-6}\,\mathrm{rad\,s^{-1}} \doteqdot 1.5 \times 10^{-2}|\mathbf{\Omega}|$. To conserve the angular momentum of the whole system a change $\delta\mathbf{M} = -\delta\mathbf{M}_a$ in $\mathbf{M}$ would occur, largely manifested as a reduction in the magnitude of the angular velocity of the solid Earth by an amount $|\delta\mathbf{\Omega}| \doteqdot |\delta\mathbf{M}_a|/I \doteqdot 2 \times 10^{-12}\,\mathrm{rad\,s^{-1}} \doteqdot 3 \times 10^{-8}|\mathbf{\Omega}|$. Thus the l.o.d. $= 2\pi/|\mathbf{\Omega}|$ would increase by about 3×10^{-3} s which is small in absolute terms but comparable in magnitude with the largest changes in the l.o.d. revealed by astronomical transit observations. Fluctuations in the relative angular momentum $(\mathbf{M}_a - I_a\mathbf{\Omega})$ of the atmosphere of 20% in magnitude could therefore produce changes in the length of the day of 6×10^{-4} s and as there are observed changes of this magnitude on meteorological time scales of weeks and months it is reasonable to suppose that these changes might be produced by the fluctuations in the net couple $\mathbf{C}$ applied by the atmosphere to the underlying planet[1-3].

The couple $\mathbf{C}$ is a result of the instantaneous imbalance between the positive couple exerted by the atmosphere on the Earth in mid-latitudes, where the zonal component of surface winds is generally eastward (westerly) and the negative couple in tropical regions, where the surface (Trade) winds have a westward (easterly) zonal component, and to a much lesser extent in polar regions, where westward surface flow is found. Although comparatively large (and negative) during the setting-up process, this imbalance usually amounts to no more than a few per cent and fluctuates in sign, exhibiting persistent quasi-biennial, seasonal and irregular variations. Direct determinations of $\mathbf{C}$ cannot yet be made: even with a complete set of surface wind and pressure observations, an understanding of boundary layer processes and airflow over

0028-0836/80/280114-04$01.00

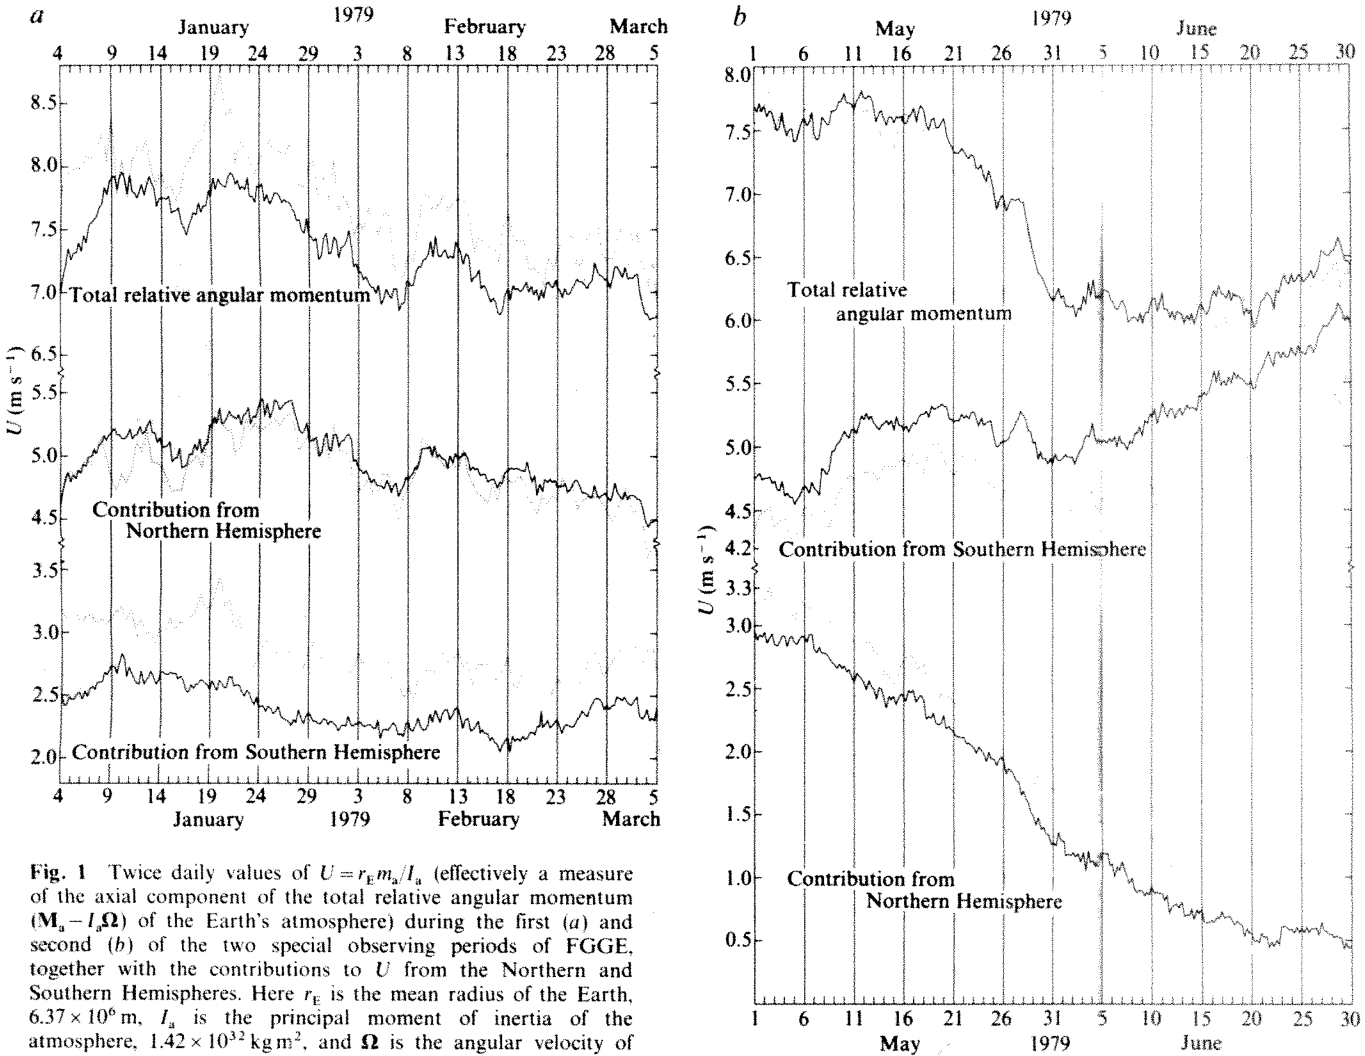

Fig. 1 Twice daily values of $U = r_E m_a / I_a$ (effectively a measure of the axial component of the total relative angular momentum $(\mathbf{M}_a - I_a\mathbf{\Omega})$ of the Earth's atmosphere) during the first (*a*) and second (*b*) of the two special observing periods of FGGE, together with the contributions to U from the Northern and Southern Hemispheres. Here r_E is the mean radius of the Earth, 6.37×10^6 m, I_a is the principal moment of inertia of the atmosphere, 1.42×10^{32} kg m^2, and $\mathbf{\Omega}$ is the angular velocity of the solid Earth relative to an inertial frame. Solid lines are based on the analysis scheme used by the British Meteorological Office and the broken lines on the US National Meteorological Center analysis scheme.

and around mountain ranges well beyond the present knowledge would be required. But values of **C** can be inferred indirectly from variations in the distribution and magnitude of zonal winds or from determinations of associated variations in the l.o.d.

Angular momentum budget

In examining the angular momentum budget of the solid and fluid parts of the Earth allowance should be made for the contributions from the oceans and fluid core as well as from the atmosphere. The relative angular momentum associated with ocean currents is very much less than $(\mathbf{M}_a - I_a\mathbf{\Omega})$ so that direct angular momentum transfer between the oceans and the solid Earth should produce negligibly small effects. On the other hand the relative angular momentum associated with motion in the liquid metallic outer core might be as much as $10 \times (\mathbf{M}_a - I_a\mathbf{\Omega})$ in magnitude, and indeed it is generally considered that angular momentum transfer between the core and solid mantle is responsible for the biggest fluctuations ($\doteqdot 5 \times 10^{-3}$ s) observed in the l.o.d., the so-called 'decade variations'[1,2,5,6]. It is unlikely (as the present study implies) but not yet certain that the core can produce significant l.o.d. changes on time scales less than a few years; this is a matter for more extensive future investigations of residual effects based on accurate determinations of l.o.d. changes and of the atmospheric contribution[5]. Conversely, the expected relationship between short-period l.o.d. fluctuations and changes in $\mathbf{M}_a$ is likely to involve the moment of inertia I_m ($= 7.1 \times 10^{37}$ kg m^2) of the crust and mantle, not the moment of inertia I of the whole Earth, which is $\sim 10\%$ greater than I_m.

The quantity

$$m_a \equiv \int_{-\frac{1}{2}\pi}^{\frac{1}{2}\pi} \int_0^{2\pi} \int_{r_s}^{\infty} \rho(r,\theta,\lambda,t)\, u(r,\theta,\lambda,t)\, r^3 \cos^2\theta \, dr\, d\lambda\, d\theta \tag{1}$$

is the axial (parallel to $\mathbf{\Omega}$) component of the relative angular momentum $(\mathbf{M}_a - I_a\mathbf{\Omega})$ of the whole atmosphere. Here ρ and u are the density and zonal (west–east) component of wind velocity at a time t at a point with spherical polar coordinates θ (latitude), λ (longitude) and r (distance from the centre of the Earth), the volume integration being taken over the whole atmosphere, from the surface $r = r_s$ of the Earth upwards. The density and pressure in the atmosphere satisfy the hydrostatic relationship $\partial p/\partial r = -\rho g$ where g is the acceleration due to gravity. Because the effective thickness of the atmosphere is very small compared with the mean radius r_E ($= 6.37 \times 10^6$ m) of the underlying planet, within the atmosphere g does not depart significantly from its mean surface value of 9.81 m s^{-2} and so both r and g can be treated as constants in equation (1). Thus, we have

$$m_a \doteqdot \frac{r_E^3}{g} \int_{-\frac{1}{2}\pi}^{\frac{1}{2}\pi} \int_0^{2\pi} \int_0^{p_s} u(p,\theta,\lambda,t) \cos^2\theta \, dp\, d\lambda\, d\theta \tag{2}$$

where p_s is the surface pressure.

It is convenient to introduce as a measure of m_a a quantity U with dimensions of speed (m s^{-1}):

$$U = r_E m_a / I_a \qquad (= 4.48 \times 10^{-26} m_a) \qquad (3)$$

U is thus equal to the relative zonal velocity at the equator of a solid body having the same mass distribution and total angular momentum as the atmosphere.

Relative zonal velocity

Determinations of U have been made from data obtained at 12-h intervals during the two periods 4 January (0GMT)–5 March (0GMT) and 1 May (0GMT)–30 June (0GMT) 1979. The procedure adopted is to evaluate U from finite interval approximations to the continuous integral (2) using values of the zonal wind defined at grid points on a global three-dimensional mesh. These grid-point values are obtained from the raw observations (which are, in general, not made at the grid-points) by an elaborate analysis method involving temporal as well as spatial interpolation and weighting based on forecast fields generated by a numerical circulation model[7]. These results are referred to as the Meteorological Office (MO) results. To give a preliminary estimate of the errors involved, the MO results were compared with what we call the NMC results. The latter were obtained by recalculating U from an analysed data set from the US National Meteorological Center: this data set had been produced using the analysis scheme in operation at the NMC[8]. Any discrepancies between the MO results and the NMC results can be mainly attributed to differences in analysis schemes, but also to the fact that the basic data sets were not quite identical. Figure 1*a* shows the variation of U for the first special observing period as well as the separate contributions from the Northern Hemisphere (NH) and Southern Hemisphere (SH). The difference between the two global variations is largely accounted for by the discrepancy in the SH values, the NH values being in much better agreement. Even in the SH the discrepancy seems to be more systematic than random, so that changes with time are quite well correlated between both records; however, this is not definite in view of the absence of marked trends in both SH records. The global angular momentum is dominated by the NH contribution. This is expected because of the large pole–Equator temperature gradient in the NH winter, which produces a large vertical variation of zonal winds, and the comparative weakness of mean surface winds. The NH makes a comparatively large contribution to changes in the global angular momentum. This is consistent with the hypothesis that interaction of the energetic winter hemisphere circulation with orography is the main mechanism responsible for fluctuations in U.

Figure 1*b* shows the variations of U and the contributions from the NH and SH during the second period. Fluctuations in the NH and SH contributions to U in the MO and NMC results are similar, but there are quasi-systematic differences. Thus the NMC results are systematically lower than the MO results for the SH contribution, whereas the reverse is the case for the NH contribution: nevertheless, the two global results are in good agreement. The SH contribution to U dominates during the second period, and the time variation reflects mainly the seasonal decline of the NH contribution. This is associated, of course, with the weakening of the NH zonal circulation as the temperature difference between low and high NH latitudes decreases. Changes on time scales of 1–2 weeks are generally less marked than in the first period, possibly because of the comparative scarcity of land masses and mountain ranges in the SH and the weakness of the NH circulation in summer. However, the most marked change of U found in these results did take place during the second period.

Discussion

A comprehensive error analysis is not yet available; this will form part of future studies. However, the appearance of the same major changes in U in both MO and NMC results presented here suggests that these features are real. A decline in U of ~1 m s^{-1} between 21 January and 7 February is conspicuous in both MO and NMC results (Fig. 1*a*) and an even more spectacular decline, ~1.5 m s^{-1}, appears between 18 May and 2 June in both records also (Fig. 1*b*).

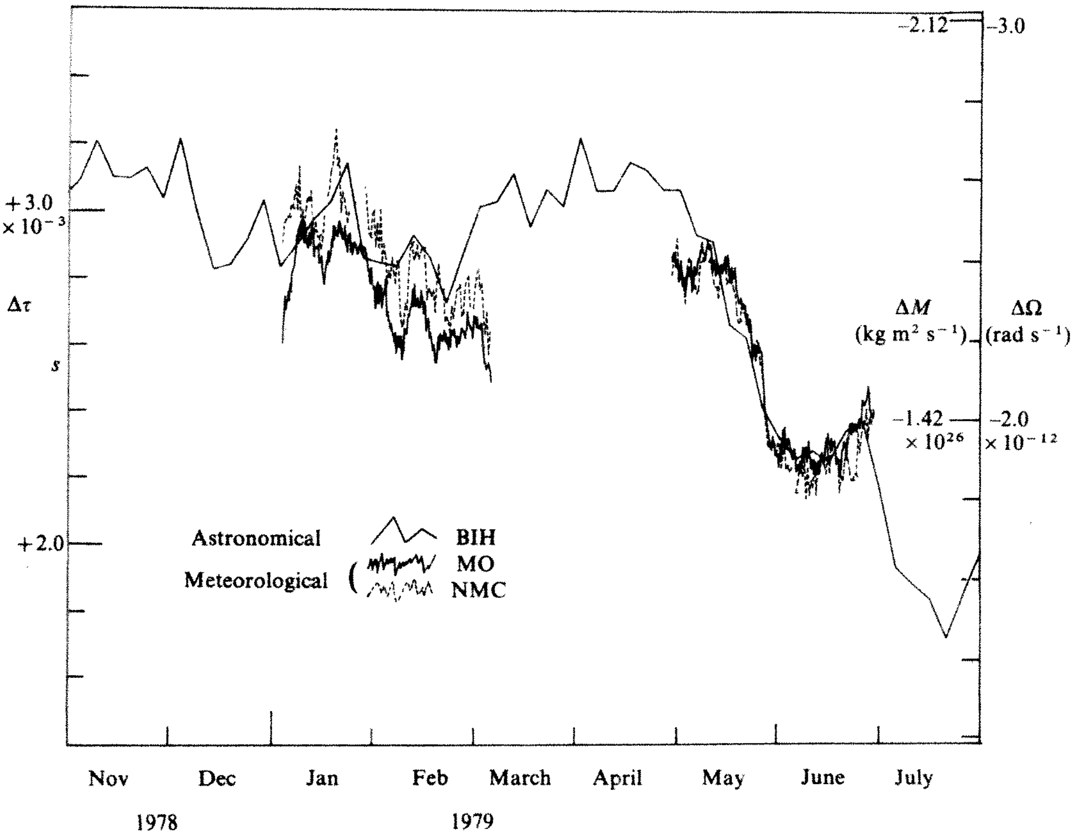

Fig. 2 Comparison of the expected changes in the length of the day (Δτ) derived from the meteorological results displayed in Fig. 1 alongside observed changes from astronomical measurements (see text).

We now compare the meteorological results with estimates of l.o.d. variations, as revealed by astronomical observations. These estimates can be made by comparing universal time (UT), defined by the Earth's rotation, with atomic time (TA). UT1 is based on the rate of rotation of the Earth as determined astronomically from transits of stars and Doppler tracking of artificial satellites; TAI is the international atomic time scale based on a certain resonance of the caesium atom and can be regarded as perfectly uniform for the present discussion. It is necessary to allow for all significant tidal effects[1,2,10]. This was achieved by taking values of the difference between TAI and UT1 at intervals of 5 days as published by the Bureau International de l'Heure (BIH) in Paris, which have already been corrected for annual and semi-annual tides and diurnal nutation, and removing effects due to fortnightly and monthly lunar tides (M_f and M_m (ref. 1)), thus obtaining a quantity $f(n)$, where n is an integer specifying the pentad to which f refers. (The amplitudes of these tides were taken from Table 14.3 of ref. 10.) The values of $f(n)$ were then smoothed to eliminate high-frequency scatter and the first derivative $\Delta\tau(n)$ at each pentad was calculated. This was done using the following 11-point convolute (which exploits the fact that the data were equally spaced in time):

$$\begin{aligned}\Delta\tau(n) \equiv (429\times 5)^{-1}\{89f(n)&+84(f(n-1)+f(n+1))\\ &+69(f(n-2)+f(n+2))\\ &+44(f(n-3)+f(n+3))\\ &+9(f(n-4)+f(n+4))\\ &-36(f(n-5)+f(n+5))\} \qquad (4)\end{aligned}$$

If TAI–UT1 is in seconds, $\Delta\tau(n)$ measures the change in the length of the day relative to the reference day of 86400 SI seconds, which by convection is the average length of the mean solar day during the nineteenth century and corresponds to an angular speed $\Omega_0 = 7.29211515\times 10^{-5}\,\mathrm{rad\,s^{-1}}$ (see ref. 6). The results are joined by a light continuous line in Fig. 2. The right ordinate gives the corresponding values of $\Delta\Omega(n)$ and $\Delta M(n)$ where

$$\Delta\Omega = (\Omega - \Omega_0) \equiv -\Omega_0^2\Delta\tau/2\pi \qquad (5)$$

and

$$\Delta M \equiv -\Omega_0^2 I_m \Delta\tau/2\pi \qquad (6)$$

which is the concomitant change $I_m\Delta\Omega$ in the angular momentum of the Earth's mantle.

If the fluctuations δm_a (as measured by δU, see equation (3) and Fig. 1) in the axial component of relative angular momentum $(\mathbf{M}_a - I_a\mathbf{\Omega})$ of the atmosphere manifest themselves largely as equal and opposite variations in the axial component of the angular momentum of the mantle of the Earth $I_m\Omega = I_m(\Omega_0 + \Delta\Omega)$ then the corresponding fluctuations $\delta\Omega$ in Ω (and in $\Delta\Omega$ since Ω_0 is constant by definition, see equation (5)) are such that $\delta\Omega$ satisfies

$$\delta\Omega \doteqdot -\delta m_a/I_m \qquad (7)$$

The corresponding fluctuations in the length of the day are given by

$$\delta(2\pi/\Omega) \doteqdot \delta m_a(2\pi/\Omega_0^2 I_m) \doteqdot \delta U(2\pi I_a/\Omega_0^2 r_E I_m) \qquad (8)$$

Values of the quantity

$$U(2\pi I_a/\Omega_0^2 r_E I_m) \qquad (9)$$

are plotted in Fig. 2, based on the MO and NMC results presented in Fig. 1. If the hypothesis expressed by equation (8) is correct and the values of $\Delta\tau$ evaluated by the 11-point smoothing procedure (see equation (4)) are dependable, then the curves representing the meteorological data in Fig. 2 should resemble the shape of the curve representing the astronomical data but be separated by a constant vertical distance $\Delta\tau_*$, to be determined from the data. Thus

$$\Delta\tau \doteqdot \Delta\tau_* + U(2\pi I_a/\Omega_0^2 r_E I_m) \qquad (10)$$

Comparison of these results shows that this is so, especially during the second special observing period. Indeed the curves are nearly coincident; that is to say $\Delta\tau_* \ll \Delta\tau$. This unexpected result implies that the net reduction of the angular momentum of the mantle due to the combined effects of tidal friction and other agencies (including any couples acting on the base of the mantle as a result of motions the liquid core of the Earth) since the nineteenth century is close in magnitude to the mean relative angular momentum of the atmosphere in 1979.

The likely connection between fluctuations in the zonal winds and in the l.o.d. has long been appreciated[1–3] but the earliest studies were handicapped by the incomplete wind data. Now, as a result of FGGE, it has become possible to make a close comparison between the changes in the angular momentum of the atmosphere and the mantle. The agreement overall shown in Fig. 2 between the expected changes in the l.o.d. according to the meteorological results and the changes observed astronomically is good, particularly during the second special observing period. The 11-point smoothing was chosen because it reduced the considerable scatter in the 'raw' astronomical results and yet preserved apparently real fluctuations greater than about 10^{-4} s. The agreement shown in Fig. 2 indicates that the meteorological results provide some control on the degree of smoothing that might safely be applied to the astronomical data. Previously this has only been possible from a consideration of the internal errors, which is an unreliable procedure.

Conclusions

By continuing the surveillance of the atmosphere it should be possible to subtract the changes in the angular momentum of the atmosphere from the astronomically determined changes in the angular momentum of the mantle and thus find the residual changes due to interaction between the mantle and the core. The magnitude and temporal behaviour of this interaction will be of particular interest. When the new methods for monitoring the Earth's rotation based on very long base-line interferometry and laser ranging to artificial satellites and the Moon are fully operational, it should also prove possible to carry out a more detailed comparison with the meteorological data. The results of such an investigation will be reported elsewhere.

It is impossible to acknowledge by name all the individuals to whom we are indebted for data, useful discussions and other help, but we should particularly like to mention Dr P. Bender, Mr P. Hart, Professor K. Lambeck, Dr A. Oort, Mr N. Saker, Dr D. Smith and Dr G. Wilkins. R.H. is grateful to Dr C. Leith and other members of the Atmospheric Analysis and Prediction Division for facilities generously made available during a visit to the National Center for Atmospheric Research, Boulder, Colorado.

Evidence for live ^{247}Cm in the early Solar System

Variations of the ^{238}U/^{235}U ratio in the Allende meteorite, ranging from −35‰ to +19‰, are interpreted as evidence of live ^{247}Cm in the early Solar System. The amounts of these and other r-products in the Solar System indicate values of (9,000 ± 3,000) Myr for the age of the Galaxy and ~8 Myr for the time between the end of nucleosynthesis and the formation of meteoritic grains. Three possible explanations are presented for the different values of the latter time period which are indicated by the decay products of ^{247}Cm, ^{26}Al, ^{244}Pu and ^{129}I.

THE nuclide ^{247}Cm decays to ^{235}U with a half life ($t_{1/2}$) of 15.6 Myr. As both parent and daughter are actinides, the existence of live ^{247}Cm at the time when solids formed in the primitive nebula would only cause variations in the present ^{238}U/^{235}U ratio if chemical fractionation separated Cm from U. Thus, uranium isotopes in primitive solids may provide important information on the time scale (T) for galactic nucleosynthesis and the time interval (Δ) between the termination of nucleosynthesis and the formation of solids in the early Solar System[1].

Earlier age estimates, based on the normal ^{238}U/^{235}U ratio, 137.88 (ref. 2), the ^{238}U/^{232}Th ratio, and/or these ratios in combination with the ^{187}Re/^{187}Os, ^{244}Pu/^{238}U and ^{129}I/^{127}I ratios[3-11], indicate that galactic nucleosynthesis occurred on a time scale T of $\sim 10^4$ Myr and that solids formed after an interval Δ of $\sim 10^2$ Myr. However, recent discoveries of the decay product of ^{26}Al ($t_{1/2} = 0.73$ Myr) in Allende[12,13] and the decay product of ^{107}Pd ($t_{1/2} = 6.5$ Myr) in the Santa Clara iron meteorite[14] imply that the interval Δ may instead be ~ 1 Myr.

In addition to isotopic anomalies from *in situ* decay of short-lived radionuclides which existed in the early Solar System, the discovery of isotopically anomalous oxygen in Allende was interpreted as evidence that meteorites trapped ^{16}O-enriched interstellar dust grains[15]. It has also been suggested that the oxygen anomaly indicates incomplete mixing of material injected from a nearby supernova (SN) which triggered the collapse of the presolar nebula[16], or isotopic differences between the various chemical components of the interstellar medium which were taken up differentially as solids formed[17]. The discovery of nucleogenetic anomalies, in addition to radiogenic ones, has overthrown the dogma of isotopic homogeneity in the pre-solar nebula, and raised doubts about the validity of classical nucleocosmochronology.

Recently, Arden[18] reported that the ^{238}U/^{235}U ratio is as low as 46 in an acid-etched residue of Allende, and additional analyses seemed appropriate to verify these findings. We report here the results of precise measurements of uranium isotopes in various phases of the Allende, C3V carbonaceous chondrite. Variations in the isotopic composition of uranium are attributed to the existence of ^{247}Cm and to chemical fractionation of ^{247}Cm/U in the early Solar System. The levels of ^{247}Cm indicated by our results are then used in the Cm–U–Th cosmochronometer to consider the SN trigger[16] and the presolar grain[15,17] hypotheses.

Experimental techniques and standards

The isotopic composition of uranium and concentrations of U and Th in inclusions and acid resistant residues of Allende were precisely determined by using a spike enriched in ^{233}U, ^{236}U and ^{230}Th and by pulse-counting on a two-stage, NBS-type mass spectrometer[19]. Details of the present study will be published elsewhere[20]. The ^{233}U–^{236}U double-spike was used to monitor mass fractionation of uranium isotopes.

By this technique, the ^{238}U/^{235}U ratio can be reproducibly determined in 1 ng of standard uranium, NBS-U-500, to within ±0.01% of the certified value. However, in 0.1–1.0 ng of a standard of natural uranium, NBS-950a, this ratio can be determined only to within ±0.5‰ (2σ). The reproducibility of ^{238}U/^{235}U ratio measurements on a standard solution of NBS-950a and on terrestrial basalts is shown in Fig. 1. The accuracy of the ratio measurement on small amounts of uranium depends solely on the count rate of ^{235}U, and 0.1 ng of natural uranium always provided a signal of more than 100 counts per second (c.p.s.). When the count rate of ^{235}U is less than 50 c.p.s., the apparent value of the ^{238}U/^{235}U ratio tends to become smaller because of background contribution to the ^{235}U signal.

Uranium anomalies in chondrules and inclusions

Inclusions of Allende were separated from a specimen coated with fusion crust using stainless steel tools under a laminar flow bench in an ultra-clean laboratory. Inclusions supplied from the National Museum of Natural History and several inclusions left from the previous U–Pb chronology study[21] were also analysed. Some of the inclusions were analysed by electron microprobe for mineralogy. The isotopic compositions which we measured for U in these inclusions are shown in Fig. 2.

Our results demonstrate that: (1) inclusions of Allende indeed display variations in the ^{238}U/^{235}U ratio, ranging from −4 to +3.5% of the terrestrial value, 137.88, whereas Arden[18] reports normal to lower values in all samples except one; (2) spinel-bearing pink aggregates show definite negative isotopic anomalies in the ^{238}U/^{235}U ratio ranging from −4 to −0.5%, but all white to grey aggregates show positive anomalies ranging from +0.5 to +3.5%; and (3) the Mg-rich chondrules show no definite anomaly pattern, with variations of +3 to −3% in the ^{238}U/^{235}U ratio, whereas this ratio ranges from normal to +2% in the Ca–Al-rich chondrules.

Such large variations in the ^{238}U/^{235}U ratio (up to 7%) cannot be the result of isotopic fractionation alone and will

therefore be taken to indicate Cm/U fractionation. In view of the fact that ^{244}Pu ($t_{1/2} = 81$ Myr) and ^{129}I ($t_{1/2} = 16$ Myr) survived the interval Δ, it would be reasonable to assume that ^{247}Cm ($t_{1/2} = 16$ Myr) was also present in early Solar System condensates. If chemical fractionation of Cm/U occurred, then the grey to white aggregates trapped actinides with a lower Cm/U ratio than did the pink aggregates. Although the mineral components responsible for these fractionations are not known to us, it seems plausible that the orange-red V-rich spinel or Ti-bearing fassaite[22] may have lower $^{238}U/^{235}U$ ratios because $^{247}Cm^{3+}$ may have entered V^{3+} or Ti^{3+} crystal sites in preference to UO_2^{2+}.

Alternative explanations for the variations observed in the $^{238}U/^{235}U$ ratio include: (1) differences in recoil effects when the U isotopes were produced by α-decay; (2) contributions to the presolar nebula of transbismuth elements from two or more r-processes of nucleosynthesis with different $^{238}U/^{235}U$ production ratios; (3) contributions from two or more nucleosynthesis events which occurred at different times; (4) an 'early' cosmic-ray irradiation which preferentially destroyed ^{235}U (ref. 23); or (5) the presence of live ^{242}Pu ($t_{1/2} = 0.38$ Myr), the precursor of ^{238}U, in the early Solar System. The latter possibility is indicated if Lee *et al.*[24] are correct in concluding that ^{26}Al levels in Ca–Al-rich inclusions of Allende require a very short formation interval after nucelosynthesis, Δ <3 Myr. In any case, the early Solar System contained other r-products, ^{244}Pu and ^{129}I, with half lives comparable with that of ^{247}Cm. Thus, Cm/U fractionation is the most probable cause for the ^{235}U excess.

Uranium anomalies in acid etched residues

Because the mineral phases responsible for the negative and positive anomalies were not clearly identified in this early phase of our study, we prepared HCl–HF insoluble residues of Allende matrix to see if the anomalous uranium might reside in the minerals (carbon, chromite and spinel) which contain isotopically anomalous noble gases and tellurium[25–29]. The presence of anomalous noble gases and tellurium in such residues implies a signature of presolar grains which might be the source of isotopically anomalous uranium.

Our procedure for preparing these residues is that of Anders' group[25–27]. After removal of most visible inclusions, an insoluble residue of 154 mg was prepared from 31 g of the Allende matrix by treatment with HCl–HF at room temperature. The residue was then etched repeatedly, for periods of 24 h, in 6 M HCl. Etching was conducted in a Teflon container at 150 °C, with the dissolution of chromite, and probably spinel. After five HCl etchings, the solution was essentially colourless, indicating that the chromite ($FeCr_2O_4$), and probably the spinel ($MgAl_2O_4$), were dissolved. We denote this fraction as 'spinels'. The black residue which remained was then etched for 24 hours in concentrated HNO_3 (16 M) at 200 °C. In these conditions, the 'carbon' was dissolved leaving a yellowish-white residue. This residue was further treated with concentrated $HClO_4$ for one day at 150 °C.

The dissolution of 'spinels' in HCl at elevated temperatures was verified by a mock experiment on terrestrial chromite and spinel. The HCl dissolution was used instead of the H_3PO_4–H_2SO_4 mixture[27,29] to minimize analytical blanks. The dissolution of 'carbon' may be accompanied by the dissolution of an ill-defined mineral 'Q' (refs 25–27). We denote this fraction as 'carbon' because it was obviously the dominant phase which dissolved when the residue was treated with concentrated HNO_3 at 200 °C.

Measured concentrations of U and Th in each fraction and the isotopic compositions of U are presented in Table 1. Due to the low ^{235}U count-rate in fraction 2 the data for 'spinels' have large experimental uncertainties. In spite of this, the high $^{238}U/^{235}U$ ratio in 'spinels' is quite significant because, as noted above, measured $^{238}U/^{235}U$ ratios tend to become small when the ^{235}U signal is less than 50 c.p.s. The amounts of U in fractions 3, 4, 5 and 7 were too low for reliable isotopic analysis.

The $^{238}U/^{235}U$ ratio in carbon is low, and the intermediate value of $^{238}U/^{235}U$ in fraction 1 is probably due to physical flotation of some extremely fine, black particles which later dissolved when the decantate was converted in an HNO_3 medium for purification of U by anion exchange.

We estimate the $^{238}U/^{235}U$ ratio in the total acid residue to be ~116 from the values observed in fractions 1, 2 and 6. However, as our residue was prepared from matrix-rich portions, the results of this estimate do not necessarily provide support for the low values reported by Arden[18].

The extremely high value of the $^{238}U/^{235}U$ in fraction 2, when 'spinels' dissolved, seems to be inconsistent with Arden's report[18] of extremely low values of this ratio in residues which had been previously exposed to various oxidizing conditions. Regardless of whether HCl + HF or HNO_3 + HF were used in the first etching stage, Arden observed low values of the $^{238}U/^{235}U$ ratio, ~50, in the final stage of etching when the residues contained extremely small amounts of uranium, 10^{-11} g.

The most significant results of this etching experiment are: the high value of the $^{238}U/^{235}U$ ratio in fraction 2 when 'spinels' dissolved; and the extremely low value of this ratio in fraction 6 when 'carbon' dissolved. Enriched ^{235}U in 'carbon' and its depletion in 'spinels' parallel abundances of the heavy and light isotopes of Xe and Te in these[25–27,29]. If heavy isotopes of Xe and Te in carbon are from actinide fission, it implies that excess ^{235}U there may be due to an initial enrichment of live ^{247}Cm. These large anomalies are unlikely to be artefacts of the acid treatment, such as the selective extraction of radiogenic ^{235}U from 'spinels' because of α-recoil effects, and its adsorption on 'carbon', for the following reasons: (1) active sites for adsorption of uranium onto carbon would be swamped with uranium of normal composition which was released from the silicates during the earlier HCl–HF treatments; (2) the high $^{238}U/^{235}U$ ratio in the spinel-rich

Table 1 Data of Allende HCl–HF residue (154 mg)

fraction 2 is in accordance with the high values of this ratio in the spinel-rich, white inclusions which were mechanically separated from Allende; and (3) we are unaware of any chemical treatments which can separate the isotopes of such dissimilar elements as uranium, xenon and tellurium to produce the unusual isotopic compositions reported in acid-etched residues of Allende. We will, therefore, assume that variations in the $^{238}U/^{235}U$ ratio were produced be the decay of ^{247}Cm in the early Solar System.

The curium–uranium–thorium cosmochronometer

In the following calculations of the duration of galactic nucleosynthesis (T) and the interval Δ, we follow Fowler's[30] model of an exponentially decreasing rate of galactic nucleosynthesis with a last minute spike event. Local variations from a smooth exponential decline in the nucleosynthesis rate do not seriously detract from the general versatility of this model[31]. In fact, the last minute spike[7,8,30] is remarkably similar to recent models of a SN trigger which injected freshly synthesized material into a presolar nebula[16,32] of elements from earlier, collective nucleosynthesis processes.

If the transbismuth nuclides were produced by an r-process at a different site (core[33]?) from the explosive carbon-burning or hydrogen–helium-burning shells where ^{16}O and ^{26}Al were produced[34–36], then the high $^{238}U/^{235}U$ ratio and low concentration of ^{244}Pu in spinel might be explained by early condensation of spinels before mixing with the heavy r-process nuclides[37]. In this regard, note that the uranium which we extracted from 'spinels' represents a mixture of uranium from spinel, chromite and other spinels. Thus, the weakness of our experiment is its failure to set a firm upper limit on the value of the $^{238}U/^{235}U$ ratio which might be found by selective dissolution of the mineral components in our 'spinels'.

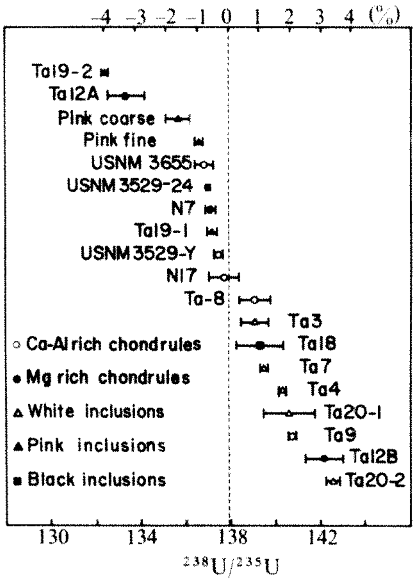

Fig. 2 Uranium isotopic compositions in the Allende inclusions. Pink aggregates, N7 and N17, were described earlier[21]. USNM samples are from the National Museum of Natural History.

Alternatively, if excess ^{16}O and ^{26}Mg are the result of material injected from a nearby SN[16,32], then classical nuclear cosmochronology may be affected[33,38,39]. However, the ^{16}O and ^{26}Al may alternatively have been produced locally, in the early Solar System[40,41]. Moreover, there have been many studies which suggest that isotopic homogeneity, rather than isotopic heterogeneity, was the dominant trait of the presolar nebula, for example, the negative results in attempts to find isotopically anomalous Ca, Sr, Ba and Sm in all Allende inclusions[24,42] analysed, except two Ca–Al-rich ones, and the finding of isotopically normal Sr and Nd in the HCl–HF etched residues of Allende[43]. These findings suggest that it would be premature to dismiss classical cosmochronology.

We will, therefore, use our results to compute values of T and Δ from the Cm–U–Th chronometer and compare these with values of T and Δ suggested by other radionuclides, such as, ^{244}Pu and ^{26}Al. For this calculation, we assume that the value of $^{238}U/^{235}U$ of 137.88 in bulk meteorites and terrestrial rocks is characteristic of solar uranium, although microscopic mineral constituents and inclusions of meteorites contain anomalous uranium.

According to Fowler's[30] model of exponentially declining nucleosynthesis, the production rate, P_A, of isotope A at time t is $P_A(t) = P_A(t=0)\exp(-\Lambda t)$. Thus, the primordial abundance ratio of isotopes A and B at the time of formation of planetary solids can be expressed as:

$$\frac{N_A(T+\Delta)}{N_B(T+\Delta)} = (P_A/P_B)\exp\{(\lambda_B - \lambda_A)\Delta\}$$

$$\times \frac{S\{1-\exp(\Lambda T)\} + (1-S)(\Lambda/\Omega_A)\{1-\exp(\Omega_A T)\}}{S\{1-\exp(\Lambda T)\} + (1-S)(\Lambda/\Omega_B)\{1-\exp(\Omega_B T)\}}. \quad (1)$$

In these equations, Λ is the decay constant of the assumed exponential form for nucelosynthesis, $\Omega_A = \Lambda - \lambda_A$ and $\Omega_B = \Lambda - \lambda_B$ where λ_A and λ_B are the decay constants of A and B, and S is the fraction of elements in the Solar System that was produced by a spike nucleosynthesis event which occurred at time T, at the termination of galactic nucleosynthesis of Solar System material.

To obtain the chronology of r-process nucleosynthesis from ^{247}Cm–U, the degree of fractionation of Cm/U in Solar System material must be known. However, the fractionation factor for ^{247}Cm at $T+\Delta$ is unknown. For simplicity, we therefore assume, in the first case, that the addition of freshly synthesized ^{247}Cm and U in the spike resulted in the present value of N_{235}/N_{238} is 1/137.88 in the Earth and in many bulk meteorites for unfractionated Cm/U abundances, and that the present value of N_{235}/N_{238} of 1/163 in 'spinels' represents the base value for the most extreme Cm/U fractionation, that is, this represents the value when there has been no ^{247}Cm contribution to 'spinels' uranium. Accordingly, the amounts of

^{247}Cm, ^{235}U and ^{238}U in the early Solar System were, assuming the meteorite age to be 4.55×10^3 Myr:

$$\frac{N^{G}_{235}(T+\Delta)+N^{S}_{235}(T+\Delta)+N^{G}_{247}(T+\Delta)+N^{S}_{247}(T+\Delta)}{N^{G}_{238}(T+\Delta)+N^{S}_{238}(T+\Delta)}= (1/137.88)\exp\{(\lambda_{235}-\lambda_{238})(4.55)\}=0.3163 \qquad (2)$$

and the ^{247}Cm-free ratio of ^{235}U/^{238}U was

$$\frac{N^{G}_{235}(T+\Delta)+N^{S}_{235}(T+\Delta)}{N^{G}_{238}(T+\Delta)+N^{S}_{238}(T+\Delta)}= \{1/163\}\exp\{(\lambda_{235}-\lambda_{238})(4.55)\}=0.2675. \qquad (3)$$

In these equations, the superscripts G and S designate contributions from galactic and spike nucleosynthesis, respectively. Then for this case, the ratio of ^{247}Cm to ^{238}U at time $T+\Delta$ is

$$\frac{N^{G+S}_{247}(T+\Delta)}{N^{G+S}_{238}(T+\Delta)}=0.3163-0.2675=0.0487. \qquad (4)$$

For the above model we have three input data which are associated with the r-process, ^{247}Cm/^{238}U, ^{235}U/^{238}U and ^{232}Th/^{238}U. These were used to determine the values of T, Δ, Λ and S, using the values of constants listed in Table 2. For values of $\Lambda=(0.1$ to $1.0)\times 10^{-9}\,\mathrm{yr}^{-1}$ and $S=0.01$ to 0.1, we found that the most internally consistent solution is obtained for $\Lambda=0.6\times 10^{-9}\,\mathrm{yr}^{-1}$ and $S=0.05$. Curves of Δ versus T for $\Lambda=0.6\times 10^{-9}\,\mathrm{yr}^{-1}$ are shown in Fig. 3. This solution yields a galactic age, $T_G=(T+\Delta+4{,}550\,\mathrm{Myr})=9{,}100\pm 2{,}800$ Myr, (assuming $\pm 10\%$ uncertainty in production rates and $\pm 5\%$ uncertainty on the Th/U ratio), and a decay interval $\Delta \sim 8$ Myr, with limits of 0–90 Myr for the above uncertainties.

Detailed calculations including the constraints imposed by the abundances of ^{244}Pu, ^{129}I and ^{26}Al will be presented elsewhere[20]. However, note that the ^{244}Pu/^{238}U curve intersects the ^{235}U/^{238}U (1/163) and ^{232}Th/^{238}U curves at $\Delta \simeq 100$ Myr, if the ^{244}Pu/^{238}U ratio at $t=T+\Delta$ is 0.016 (ref. 44) or 0.035 (ref. 45). However, the curve for ^{244}Pu/^{238}U $=0.087$, which Podosek and Lewis[46] observed in a Ca–Al-rich Allende inclusion crosses the curves of ^{235}U/^{238}U and ^{232}Th/^{238}U at $\Delta=8$ Myr. These calculations are based on values of $\Lambda=0.6\times 10^{-9}\,\mathrm{yr}^{-1}$ (see Fig. 3).

The assumption that the ^{238}U/^{235}U ratio in 'spinels' contains a negligible contribution from spike-produced ^{247}Cm but that 5% of other r-products in spinels came from this last nucleosynthesis spike, may not be correct if spinels formed before contamination with the spike r-products. However, note that the value which we calculated for the initial ^{247}Cm/^{238}U ratio, 0.049, is the same order of magnitude as values reported for the initial ^{244}Pu/^{238}U ratio, 0.016–0.087 (refs 44–46).

The value calculated above for the decay interval, $\Delta \sim 10$ Myr, is somewhat higher than the value of $\Delta < 3$ Myr which Lee *et al.*[24] obtained from data indicating that ^{26}Al/^{27}Al $\simeq 5\times 10^{-5}$ when Ca–Al-rich inclusions of Allende formed. Note, however, that Lorin and Christophe Michel-Lévy[47] found evidence of much higher initial ^{26}Al/^{27}Al ratios, up to 1×10^{-3}, in hibonites in inclusions of Leoville and Allende. Recently Lee *et al.*[48] reported a very low initial ^{26}Al/^{27}Al value of 2×10^{-7} in HAL inclusion of Allende. The difference between initial values of ^{26}Al/^{27}Al in hibonites of Leoville and in HAL inclusion of Allende corresponds to an interval of 9 Myr between the formation times of these objects[41], if the source of Al in these objects originally had the same ^{26}Al/^{27}Al ratio. This suggests that hibonite grains formed directly from freshly synthesized material, or very soon after this material was added to the presolar nebula, and that solidification of 1–10-mm size objects occurred ~10 Myr later.

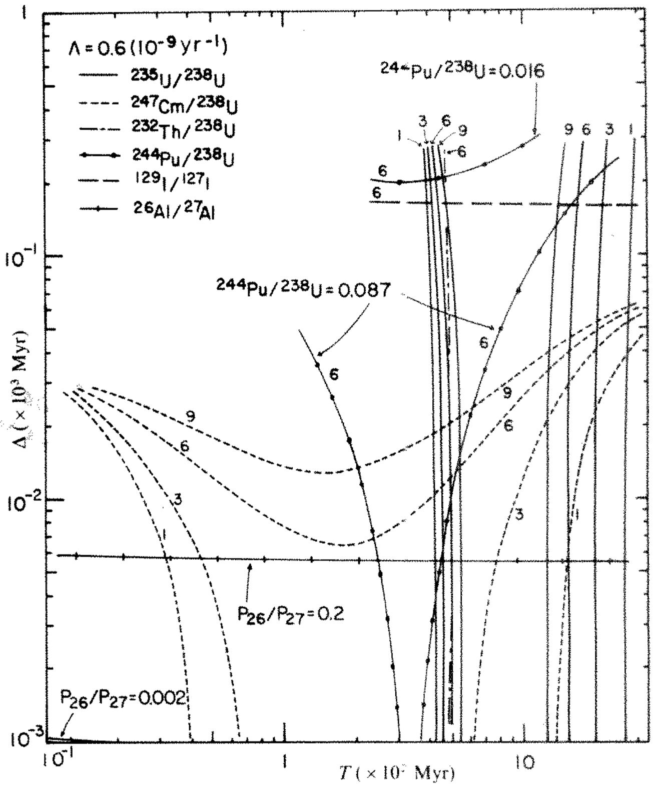

Fig. 3 Trajectories of Δ and T values of the ^{235}U/^{238}U, ^{232}Th/^{238}U, ^{247}Cm/^{238}U, ^{244}Pu/^{238}U and ^{26}Al/^{27}Al ratios for $\Lambda=0.6\times 10^{-9}\,\mathrm{yr}^{-1}$ of case 1. They are calculated following Fowler's model[30] of exponential galactic nucleosynthesis [exp $(-\Lambda T)$] and a last minute spike (S). Numbers on the trajectories are S (%). For the trajectories of ^{232}Th/^{238}U, ^{244}Pu/^{238}U, ^{129}I/^{127}I and ^{26}Al/^{27}Al, only values corresponding to $S=6\%$ are shown. Production ratios assumed for P_{26}/P_{27} are 0.002 and 0.2, and values assumed for the ^{244}Pu/^{238}U ratio at time $T+\Delta$ are 0.087 and 0.016

Conversely, these results may suggest that the production ratio of ^{26}Al/^{27}Al from some thermonuclear process in the SN was about two orders of magnitude higher[36] than that calculated for carbon burning[35,49].

For the second case, we assume that there was no contribution of any transbimuth r-products from the spike to 'spinels'. In this model, we assume that the 'spinels' represent grains which formed in the outer shell of the SN[37] and that these were injected into the presolar nebula, where the average mixture of all r-products is represented by the present value of $(^{238}\mathrm{U}/^{235}\mathrm{U})=137.88$ when no fractionation of Cm/U occurred.

This can be described by analogous forms of the equations used for case 1,

$$\frac{N^{G}_{235}(T+\Delta)+N^{G}_{247}(T+\Delta)}{N^{G}_{238}(T+\Delta)}=0.2675. \qquad (5)$$

If we assume that $N^{G}_{238}(T+\Delta)\simeq N^{G}_{238}(T+\Delta)+N^{S}_{238}(T+\Delta)$, then

$$\frac{N^{S}_{235}(T+\Delta)+N^{S}_{247}(T+\Delta)}{N^{G}_{238}(T+\Delta)}=0.0487. \qquad (6)$$

Because ^{247}Cm decays to ^{235}U, the numerator of equation (6) does not change during the period of free decay and cannot be used to calculate the value of Δ. However, if there is negligible

Table 2 Values of constants used in computations

decay of ^{235}U, ^{238}U and ^{232}Th over the time period Δ, that is, $\lambda_{235}, \lambda_{238}, \lambda_{232} \ll 1/\Delta$, then $N^{G+S}_{235}(T+\Delta) = N^{G+S}_{235}(T)$, and so on, and if we assume that $N^{G+S}_{232}(T) \simeq N^{G}_{232}(T)$, then equation (1) yields $T_G = (9.4 \pm 2.7) \times 10^9$ yr, $\Lambda = 0.45 \times 10^{-9}$ yr^{-1} and $S = 0.02$ for case 2 (where $S = 0$ for all r-products in 'spinels').

If this model is correct, then the Cm/U ratio in 'carbon' has been increased by a fractionation factor of $\simeq 4$. Such a fractionation factor is quite reasonable from thermodynamic considerations[50]. We prefer case 2, where neither Cm nor U from the spike contributed to 'spinels', because case 1 requires a large fractionation of spike-produced Cm/U in 'spinels'. The duration of galactic r-process nucleosynthesis from our calculations, although model dependent, seems to be consistent with the revised age of the Universe which was recently reported from a new calculation of the Hubble constant[51].

For case 2, we assumed that grains of 'spinels' are fresh condensates from the triggering SN event and that this event also contributed transbismuth r-products to the presolar nebula. On the other hand, Lattimer *et al.*[32] note that the difference between values of the decay interval indicated by radiogenic Xe isotopes ($\Delta \sim 100$ Myr) and Mg isotopes ($\Delta \sim 1$ Myr) may imply that the last SN event was a source of ^{26}Al, but not a source of r-products. According to this hypothesis, the presolar nebula consists of interstellar type gas and dust which had been enriched in r-products when the nebula passed through a galactic spiral arm[52] ~100 Myr before this last SN event. If interstellar material had been cycled, by star formation and stellar ejections, with such a frequency[34] that the mean residence time of material in the interstellar medium is short, <100 Myr, then our calculations are compatible with the proposal of Lattimer *et al.*[32]. However, our calculations would not be warranted if the residence time of interstellar material is large, >1,000 Myr, as estimated by Clayton[17].

Conclusion

The Cm–U–Th chronometer yields values of $T = 9{,}000 \pm 3{,}000$ Myr and $\Delta \sim 8$ Myr. This value of Δ is larger than that implied from the decay product of ^{26}Al, $\Delta < 3$ Myr, but smaller than that suggested by the decay products of ^{244}Pu, $\Delta \sim 100$ Myr.

We suggest three possible explanations for the different values of Δ. (1) The short-lived r-products were produced on the last passage of the protosolar cloud through a galactic spiral arm[52], ~10 Myr before ^{26}Al was synthesized[32] in the explosion of a nearby SN which triggered the collapse of the presolar nebula[16]. (2) Both ^{26}Al and the short-lived r-products were produced in the nearby SN but Al condensed from material in outer shells of the SN ~10 Myr before the condensation of r-products, ^{247}Cm and ^{244}Pu, from the stellar interior[33]. Retention of Xe generally started ~100 Myr later, except in such cases as the Ca–Al-rich inclusion of Allende for which the ^{244}Pu–^{136}Xe chronometer indicates $\Delta \simeq 8$ Myr (ref. 46). (3) The ^{26}Al/^{27}Al production rates were different in different regions of the nearby SN, being higher by a factor of ~100 in H–He layers[36] than in that of carbon burning[35]. In this case, the observation of $^{26}\mathrm{Al}/^{27}\mathrm{Al} = 5 \times 10^{-5}$ would correspond to a value of $\Delta \sim 6$ Myr (see Fig. 3).

Alternatively, the primitive solar nebula may have contained large scale elemental and isotopic heterogeneities from the debris of a single SN which produced the bulk of the elements in the Solar System[53]. Note also that the ^{238}U/^{235}U ratio may have been altered by an early cosmic ray irradiation[23,54]. If so, then the calculations reported here, and previously calculated values of T and Δ, are unwarranted.

We thank O. K. Manuel, D. D. Clayton and D. M. Unruh for comments on this manuscript, A. K. Vuletich for assistance with mass spectrometry and Edward Anders for attracting our interest to the HCl–HF residues of Allende. USNM samples were provided by Brian Mason. This research was supported by NASA Interagency Transfer Order T-2407A.

The influence of codon context on genetic code translation

Lionello Bossi* & John R. Roth

Department of Biology, University of Utah, Salt Lake City, Utah 84112

A class of mutations that increase the efficiency of a suppressor tRNA in translating a particular amber codon has been characterized. The increased efficiency is due to a mutation resulting in a change in the mRNA that affects the nucleotide adjacent to the 3′ side of the UAG triplet. Thus the interaction of tRNA with mRNA is influenced by mRNA sequences outside the triplet codon.

THE triplet words of the genetic code are known to be read by transfer RNA molecules which interact with the respective codons on the messenger RNA. The specificity and accuracy of reading are overwhelmingly due to standard base-pairing between three bases on the mRNA (the codon) and three bases in the tRNA (the anticodon). It is generally assumed that no additional nucleotides in the mRNA other than the three residues which make up a codon are involved in the interaction with a single tRNA species. In the past few years, however, several studies have suggested that reading of a given codon may be influenced by mRNA sequences external to this codon; this influence has been described as the effect of the reading context on translation[1–8]. We have closely investigated this aspect of the decoding process and present here direct evidence that mRNA sequence outside of the codon has a role in determining the efficiency of translation.

Mutant tRNAs, acting as informational suppressors, are tRNA species whose activity can be followed individually *in vivo*. In the appropriate genetic system, the measurement of suppression efficiency can be correlated directly with the activity of the suppressor tRNA. It is then possible to analyse various factors that can influence the activity of the tRNA, such as structural alterations of ribosome, tRNA or mRNA. This approach led us to study the effects of a mutation affecting tRNA structure (*hisT*) on the suppression properties of informational suppressors in *Salmonella typhimurium*.

The *hisT* mutation causes the lack of pseudouridine from the anticodon region of several tRNAs[9–12]. In spite of its pleiotropic effects on many tRNA species, the *hisT* mutation does not impair cell viability. The only detectable phenotypic change is the altered regulation (constitutive expression) of the histidine operon, consequent to the lack of two pseudouridine residues from the anticodon region of histidine tRNA[9]. During our study, it became evident that the activity of the glutamine-inserting amber suppressor *supE*[13] (which normally contains two pseudouridine residues in the anticodon region[12,14,15]) is reduced considerably by *hisT*[16] (unpublished results). The reduced efficiency of the suppressor offered the basis for the genetic selection of mutations increasing the efficiency of *supE*. Mutants were isolated in which the inhibitory effect of *hisT* on suppression is overcome by an increase in the efficiency of the translation step at the nonsense site. Interestingly, some of these mutations affect the reading context at the nonsense site by changing the mRNA sequence adjacent to the nonsense codon.

Effect of *hisT* on *supE* suppression efficiency

The ability of *supE* to suppress amber mutations in the *hisD* gene of the *his* operon was tested in both *hisT*$^+$ and *hisT*$^-$ genetic backgrounds. These tests show that at some mutant sites the *hisT* mutation causes a reduction in *supE* efficiency so severe that the mutants are not phenotypically corrected by *supE* in the presence of a *hisT* mutation. For some other mutations, however, suppression by *supE* still occurs in spite of the presence of a *hisT* mutation. Thus, the effect of *hisT* on *supE* efficiency seems to depend on the particular mutant site being read. A detailed description of these experiments will be published elsewhere.

We considered three possible explanations for the site-specificity of the effects of *hisT*. First, some mutant sites may yield a protein with poor activity when suppressed by *supE*. Such sites may require a fully active *supE* tRNA in order to show phenotypic correction. Second, some mutant sites may show strong polarity effects. These sites might require very efficient suppression in order to overcome the tendency to terminate mRNA production. Third, some amber codons may be poorly read by a suppressor tRNA due to the influence of the reading context. That is, the efficiency of the suppressor tRNA in reading a particular site may depend on the nature of the residues in the immediate neighbourhood of that site. UAG codons located in unfavourable reading contexts would require a strong suppressor to overcome these reading difficulties. Such context effects on suppression efficiency have been reported previously[1–7].

Each of these explanations is, in principle, consistent with the initial data presented above if the *hisT* mutation impairs the function of *supE* tRNA. However, there are compelling reasons, outlined below, for rejecting the first two hypotheses.

The first explanation seems untenable because some of the amber sites whose suppressibility is impaired by *hisT* affect the N-terminal portion of the *hisD* protein, which is dispensable for catalytic activity[17,18] (unpublished results of T. Kohno, I. Hoppe and J.R.). It seems unlikely that the nature of the amino acid insertion in this region could seriously affect protein function. This possibility is further contradicted by the behaviour of amber mutation *hisD6404*. As described below, this site has a glutamine residue in the wild-type sequence. The *hisT* mutation impairs the ability of *supE* (a glutamine-inserting suppressor) to suppress *hisD6404*. Thus the *hisT* effect is seen even though the suppressed protein is wild type in structure.

The second hypothesis implies that the *hisT* inhibition of suppression would have greater effects on the correction of strongly polar mutant sites. This seems unlikely in view of the genetic map distribution of sites whose suppression is strongly affected by *hisT*. In general, the polarity effect of nonsense mutations is a function of their position in the gene, with more polar mutations located nearer the promoter-proximal end of the gene[19]. The mutations we have studied show no correlation between map position and effect of *hisT* on their suppressibility by *supE* (data not shown).

Our initial observations are consistent with the idea that reading of a particular amber codon is influenced by the sequence of bases surrounding that codon in the mRNA

(context). The variable effects of *hisT* on suppressibility of different amber mutations might depend on differences in the context of the UAG codons at the various sites. Several possible mechanisms for these effects are discussed later.

If mRNA context influences the readability of a particular codon, then reading efficiency should be altered if the base sequence near that codon is changed. We did this by selecting mutations that improve the suppression efficiency of *supE* for a particular amber site. The dispensable (N-terminal) region of the *hisD* gene offered a convenient system, because the sequence changes in this region that could affect suppression efficiency were not expected to influence the catalytic activity of the suppressed protein.

Isolation of context mutants

In order to select context mutants, a strain was constructed which carries *hisT*, *supE* and a particular amber mutation in *hisD* whose suppression is abolished by *hisT*; such a strain is a histidine auxotroph in spite of the presence of the suppressor. His$^+$ revertants were isolated and screened for individuals that still contained all the parental genetic markers, but had acquired an additional mutational change within the *hisD* gene that restored suppressibility to the amber mutation (change in reading context).

The full genotype of the strain used (TT4242) and the results of the selection are shown in Table 1. The starting amber mutation is *hisD6404*, mapping in the operator-proximal, dispensable region of the *hisD* gene. Mutation *his01242* is a regulatory mutation that causes the *his* operon to be expressed constitutively at high levels[16,20]; the presence of this regulatory mutation eliminates any further effect of *hisT* on operon expression. Mutation *leu-414* is an amber mutation in the *leu* operon whose suppression by *supE* is also abolished by the presence of a *hisT* mutation. As Table 1 shows, the presence of *leu-414* considerably facilitated the search for context mutants in the initial screening. All the His$^+$ revertants arising due to other events (reversion of *hisT*, occurrence of other nonsense suppressor mutations, or any mutation relieving the negative effect of *hisT*) became simultaneously His$^+$ and Leu$^+$. Table 1 shows that this class included the majority of revertants.

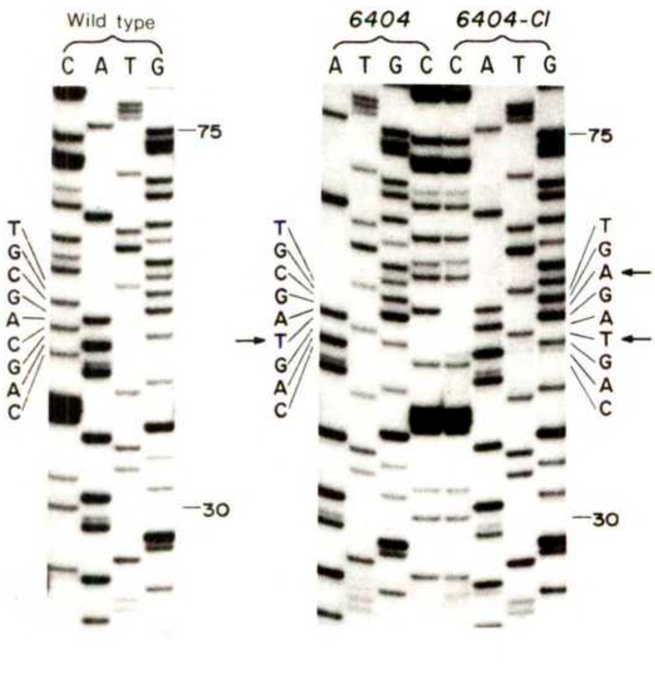

Fig. 1 DNA sequence of *hisD6404* and of its context change. The mutations *hisD6404* and *hisD6404-C1* were placed on M13H0176 (ref. 22) using a genetic procedure (our work in preparation; and unpublished results with H. M. Johnston and S. Lam) which involved the isolation of a Tn5-generated deletion in the *hisG* gene of the transducing phage and subsequent recombination between the phage and a chromosomal *his* region carrying the *hisD* mutations. Single-stranded phage DNA was prepared according to Barnes[22]. The DNA sequence was determined by the procedure described by Sanger *et al.*[23]. Because the orientation of the *his* region present on M13Ho176 is opposite to that on the phage genes, the sequencing gels directly give the *hisD* message sequence. The autoradiograms shown from left to right represent the sequences of wild type, *hisD6404* and *hisD6404-C1*. Two arrows indicate the amber and the context mutations, respectively.

The context mutants were sought among the His$^+$ Leu$^-$ revertants and had to be distinguished only from revertants of the *hisD6404* which had lost the nonsense mutation. This screening could be performed at an early stage of mutant isolation, due to a morphological property of colonies of *Salmonella* strains derepressed for the histidine operon. Such colonies show a wrinkled morphology when grown on 2% glucose, due to interference with cell division caused by high concentration of the *hisH* and *hisF* gene products[21]. When a derepressed operon contains a polar mutation located operator-proximal to *hisH* and *hisF*, the reduced expression of these genes prevents the wrinkled morphology. When this mutation reverts to prototrophy (His$^+$), the morphology of the revertant colonies can be either wrinkled (if the reversion event removes the polarity block), or smooth (if the reversion is due to the activity of a suppressor). (Suppression efficiency is usually insufficient to eliminate polarity completely.) In our case, because of the presence of the regulatory mutation *his01242*, the true revertants of *hisD6404* appeared as wrinkled colonies on the selection plates and could be distinguished from smooth-colony revertants whose His$^+$ character was due to the activity of *supE*. In Table 1 only the smooth His$^+$ Leu$^-$ revertant colonies are reported, all of which therefore are due to increased suppression and are potential context mutants.

A more direct genetic test was carried out on the putative context mutants to verify the continued presence of the *hisD6404* amber mutation. Phage lysates were prepared on the revertants using the generalized transducing bacteriophage P22. The lysates were used to transduce isogenic recipient strains carrying a *his* operon deletion, with and without suppressor *supE*. Because this deletion in the recipient strains completely removes the *hisD* gene, donors carrying the *hisD* mutation can give His$^+$ transductants only with a recipient strain carrying the amber suppressor, *supE*. Results are shown in Table 2. All the six potential context mutants (hereafter designated *hisD6404-C1,2* and so on) give transductants only with the *supE*-carrying recipient. Thus they still contain an amber mutation; DNA sequencing (see later) shows this to be the original *hisD6404* mutation. Furthermore, when the context variants of *hisD6404* were transduced into a recipient also carrying a *hisT* mutation, His$^+$ transductants were seen. This shows that the mutation which relieves *hisT* inhibition of suppression, is present on the same transducing fragment as mutation *hisD6404*.

Other genetic crosses were carried out to rescue *hisD6404* from the *hisD6404-C* (context) revertants. These experiments indicated that the mutations improving *supE* suppression map in the *hisD* gene, very close to *hisD6404* (data not shown).

DNA sequence of *hisD6404* and its context variants

The first structural genes of the histidine operon (*hisG* and *hisD*) have been cloned in both orientations on the single-stranded DNA phage M13 by Barnes[22]. The resulting M13Hol transducing phages make it possible to determine the DNA sequence using the method of Sanger *et al.*[23,24] (W. M. Barnes, manuscript in preparation). Therefore, to determine

Table 1 Isolation of mutants with improved suppressibility of *hisD6404*$_{\text{am}}$

Revertant phenotype	Revertants per 4×10^8 cells
His$^+$ Leu$^+$	105
His$^+$ Leu$^-$	6

The genotype of the parent strain TT4242 is:

his01242 hisD6404$_{\text{am}}$ *leu414*$_{\text{am}}$ *supE20 hisT1504 zej-636*::Tn5*

Cells of TT4242 were grown to stationary phase, and spread (2×10^8 cells per plate) on minimal medium supplemented with 0.3 mM leucine. Spontaneous His$^+$ revertants were isolated and scored for their leucine requirement. Of the His$^+$ Leu$^-$ class only the smooth colonies were saved (see text). The numbers given represent the combined revertants from two cultures.

**zej-636*::Tn5 designates a transposable kanamycin-resistance element (Tn5) co-transducible with the *hisT* locus.

Table 2 Context mutants retain the *hisD6404* mutation

Strain no.	Relevant genotype recipients	His$^+$ transductants with indicated donor strain *hisD* genotype of donor:	
		6404 (TT4242)	*6404-C1* (TT4265)
TT522	*his*Δ	−	−
TT3157	*his*Δ *supE*	+	+
TT3138	*his*Δ *supE hisT*	−	+

Transducing phage P22 was grown on strain TT4242 and on its six His$^+$ Leu$^-$ revertants. The phage lysates were used to transduce the three recipient strains:

TT522 (*his0-F644 zee-1*::Tn*10**)
TT3137 (*his0-F644 zee-1*::Tn*10** *leu-414*$_{\text{am}}$*supE20* *zej-636*::Tn5†)
TT3138 (*his0-F644 zee-1*::Tn*10** *leu-414*$_{\text{am}}$*supE20* *zej-636*::Tn5† *hisT1504*)

His$^+$ transductants were selected on minimal medium supplemented with 0.3 mM leucine (+ indicates that His$^+$ recombinants were observed). All the potential context mutants (isolates 1–6) showed the same behaviour as isolate *6404-C1* (shown above).

**zee-1*::Tn*10* designates a transposable tetracyclin-resistance element (Tn*10*) co-transducible with the histidine operon.

†*zej-636*::Tn5 designates a transposable kanamycin-resistance element (Tn5) co-transducible with the *hisT* locus.

the DNA sequence of *hisD6404* and of the *hisD6404-C* variants, these mutations were placed by recombination onto M13Hol 76 (one of the M13Hol phages[22]). The availability of a detailed restriction map of the *hisG-hisD* region of the *his* operon (Barnes, manuscript in preparation) and of a fine structure genetic map of the *hisD* gene (I. Hoppe and J.R., unpublished results) enabled us to choose a convenient restriction fragment as a primer in the sequencing procedure. Autoradiograms of the sequencing gels for the *hisD* region where the mutations are located are shown in Fig. 1. The inferred mRNA sequences between nucleotides 46 and 54 of the *hisD* gene are shown for wild type, for *hisD6404* and for *hisD6404-C1*, respectively, in Table 3. The result confirms the context hypothesis. The amber mutation *hisD6404* transforms a glutamine codon, CAG, into an amber codon, UAG. The context mutation which permits suppression by *supE* (*hisT*$^-$) generates a change in the residue following the UAG codon, a substitution of adenine for cytosine. All six context mutants (which included two independent groups of isolates) were sequenced. All have the same mutational change as *hisD6404-C1* (data not shown). Thus *hisT* inhibition of *supE* activity at this site can be reversed by changing the reading context of the suppressed nonsense codon.

Basis of the context effects

Initially, two general mechanisms were considered to explain the effect of the context mutation on suppression. First, the *hisD6404* UAG codon may be in a context which requires the presence of pseudouridine in *supE* tRNA (*hisT*$^+$) for the codon to be read efficiently. This suggests that pseudouridine residues in the anticodon region of *supE* tRNA are only essential for reading UAG in certain contexts. By altering context (as in mutant *hisD6404-C1*) one might generate a site which could be read by *supE* tRNA in the absence of the pseudouridine modification. Second, the *hisD6404* UAG codon may be poorly read even by a normal, fully modified suppressor tRNA (*hisT*$^+$). Lack of pseudouridine may impair the ability of *supE* tRNA to read all UAG sites regardless of context effects. This reduction in tRNA efficiency would be critical only at sites that were already poorly read by normally modified suppressor tRNA. The context change might improve readability of the amber codon sufficiently to overcome the *hisT* effect and to provide phenotypic correction.

The two possibilities can be distinguished by quantifying the effect of the context change on the efficiency of *supE* when the suppressor tRNA is fully modified (*hisT*$^+$). The first hypothesis predicts that the context mutation would only improve efficiency of a *supE* tRNA lacking pseudouridine in the anticodon region (*hisT*$^-$). The second hypothesis predicts that the context change would affect the efficiency of normally modified *supE* tRNA (*hisT*$^+$) as well. We have measured the effects of context on *supE* efficiency in both conditions (Table 4). It is clear that codon context strongly affects the activity of *supE* even when the suppressor tRNA is fully modified (*hisT*$^+$); the efficiency of *supE* in reading the same UAG codon varies over a 10-fold range depending on the nature of the base adjacent to the 3′ side of the codon. This suggests that the *hisT* mutation has no role in establishing the context effects (second hypothesis above); rather, the presence of *hisT* reduces (more than 10-fold) the activity of the suppressor at both sites. The *hisT* mutation prevents phenotypic suppression of *hisD6404* because *supE* is initially very inefficient at this site; the reduction in suppression caused by *hisT* reduces the amount of suppressed protein to a level below the threshold required for growth. The context change improves suppressor efficiency and, therefore, can be detected as a His$^+$ revertant in *hisT*$^-$ strains.

Context effects are tRNA specific

Context effects on tRNA efficiency involve aspects of tRNA structure other than simply the anticodon, because different tRNAs with the same anticodon are affected in different ways. Data on the effect of the *hisD6404* context change on the efficiency of various nonsense suppressors are presented in Table 5. A series of strains was constructed which carried *hisD6404* or *hisD6404-C1* and one of a series of amber suppressors. Each strain was assayed for its *hisD* enzyme level; enzymatic activity was taken as a measure of the translation efficiency at the amber site. As Table 5 shows, the context alteration of *hisD6404-C1* does not affect the efficiency of ochre suppressor *supG*; the change increases the efficiencies of amber suppressors *supE* and *supF*, but decreases the efficiency of amber suppressor *supD*.

For two reasons we conclude that the tRNA specificity of context effects is not due to qualitative differences in the suppressed proteins. First, the suppressed site is located in a non-essential part of the *hisD* protein. Second, the same effects of context on various suppressors are seen when polarity relief is used instead of *hisD* activity as a measure of suppressor efficiency. This was shown by assaying the level of *hisB* enzyme (Table 6). The *hisB* gene is located promoter-distal to *hisD* and is subject to polarity effects of the *hisD6404* mutation. While the magnitude of the context effect is reduced in these results, the general nature of the results agrees closely with the *hisD* assays in Table 5.

The results in Tables 5 and 6 provide further information on the nature of context effects. It has been proposed that the context effect on suppression can be explained by assuming

Table 3 mRNA sequence of the context mutant

Wild-type sequence	CAG	CAG	CGU
		↓	
hisD6404 (amber)	CAG	UAG	CGU
			↓
hisD6404-C1 (context mutant)	CAG	UAG	AGU

that the efficiency of peptide termination at a nonsense codon varies depending on the site of that codon[1,2]. Our results argue against this explanation. If the context mutation in *hisD6404-C1* generates a less efficient termination signal, then the change should cause an increase in the efficiency of all suppressors at that site. This is clearly not the case for suppressors *supG* and *supD*. The tRNA specificity of the context effects is important to the possible implications of these effects for coding in general.

Discussion

We have shown that the efficiency of the amber suppressor *supE* in translating the UAG codon can vary over one order of magnitude depending on the nucleotide adjacent to the 3′ side of the codon. The result demonstrates the role of codon context in determining suppression efficiency. In the mutant analysed, the suppressor inserts the same amino acid (glutamine) present in the wild-type sequence, and therefore measurements of enzyme activity directly reflect the actual efficiency of the *supE* tRNA in translation. Other authors have also shown that some site-specific differences in suppressor efficiencies are not due to protein differences[1-7]. Several models have been proposed to explain these effects; one proposes that context effects result from variation in efficiency of termination at the nonsense site[1,2]. The tRNA specificity data presented here argue strongly against that. Although the detailed explanation for context effects is unclear, two alternative hypotheses are consistent with our data.

According to the first, the nucleotide adjacent to the 3′ side of the codon may influence the rate of initial tRNA interaction with the codon. Basically, the increase in the affinity of the *supE* tRNA anticodon for the UAG codon caused by the presence of an adenine residue (instead of a cytosine residue) at the position adjacent to the 3′ side of the UAG, can be explained in two ways: (1) it may permit formation of a fourth base pair (A–U) involving the invariant U residue adjacent to the 5′ side of the tRNA anticodon; or (2) it may increase the stacking energy of the codon–anticodon interaction. A uracil residue is present in the position adjacent to the 5′ side of the anticodon in all the known tRNA species. The possibility that this nucleotide could base-pair with an A residue adjacent to the 3′ end of the codon has been proposed to explain data analogous to ours; Tanaguchi and Weissmann showed that the binding efficiency of fMet-tRNA for the initiation codon, AUG, of the $Q\beta$ coat cistron is increased more than threefold when the G residue adjacent to the 3′ side of the AUG in the wild-type sequence, is replaced by an A residue[8]. The hypothesis that such an additional base-pair is compatible with tRNA structure has been proposed also by Uhlenbeck *et al.*[27], after finding that the molar association constant (in absence of ribosomes) between fMet-tRNA and the tetranucleotide AUGA is more than 10-fold higher than that with AUGC, AUGG, AUGU, or that with the trinucleotide AUG. On the other hand, it is hard to explain the fact that other suppressor tRNAs (all carrying the U residue in the appropriate position) do not show an increase in efficiency at a codon followed by A (Table 5). Therefore, one should consider the alternative possibility that the nucleotide adjacent to the 3′ end of the codon has a role in contributing to the stacking energy of the codon–anticodon interaction. This possibility is suggested by Grosjean *et al.*[28], who have shown the influence of the nucleotide adjacent to the 3′ side of the anticodon on the stacking energy of anticodon–anticodon complexes. The behaviour of suppressors other than *supE* could be explained by assuming that the effect of the nucleotide adjacent to the 3′ end of the codon depends on particular features of the anticodon loop.

An alternative hypothesis to explain the context effects considers that the base change at the 3′ side of the UAG codon generates a new neighbouring codon; the arginine codon, CGU, is replaced by the serine codon AGU. The efficiency of each translation step could depend on optimal 'fitting' of tRNA pairs on the ribosome. This hypothesis implies that tRNA–tRNA interactions occur when these molecules are occupying the A and P sites of the ribosome during translocation. Such interactions could affect the efficiency of the peptide elongation step. According to this hypothesis, *supE* tRNA is able to transfer the growing peptide chain more efficiently to the Ser-tRNA$_{\text{AGU}}$ than to the Arg-tRNA$_{\text{CGU}}$.

Although the possibility of tRNA–tRNA interaction on the ribosome is speculative, several bits of genetic data support the notion. The best characterized frameshift suppressors are mutations which alter the structure of a tRNA such that a four-base code word is read, and the translational reading frame is shifted[29-31]. This indicates that a given tRNA can dictate the distance that the ribosome moves along the message in the translocation step of protein synthesis. This process is easily understood if an incoming tRNA interacts with the incumbent tRNA in order to determine the position of the next code word. The frameshift suppressor tRNA, by occupying a four-base codon forces a codon in the +1 frame to be read by tRNA in the next translation step. The ribosome slavishly translocates this new, improperly positioned tRNA to the peptidyl site in the translocation step.

A recently characterized frameshift suppressor, *sufJ*, further supports the idea that tRNA–tRNA interactions dictate reading frame. The *sufJ* suppressor reads any four-base code word whose first three bases are ACC (our work in preparation). The fact that any base can occupy the fourth position suggests that this fourth base is not actually read.

Table 4 Effect of context on suppression efficiency

Relevant genetic background	*HisD* activity resulting from suppression of indicated site (wild type) -$\underline{\text{CAG}}$C-	 (*hisD6404*) -$\underline{\text{UAG}}$C-	 (*hisD6404-C1*) -$\underline{\text{UAG}}$A-
Wild type	107.3 (TR5830)	<0.2 (TT4427)	<0.2 (TT4428)
supE	100.0 (TT4424)	2.1 (TT4241)	21.2 (TT4268)
supE hisT	93.3 (TT4425)	<0.2 (TT4242)	1.0 (TT4271)

A set of otherwise isogenic strains was built carrying either *hisD*$^+$, or *hisD6404*, or *hisD6404-C1* (context alteration) in addition to combinations of mutant and wild-type alleles of *supE* and *hisT*. The number and the full genotype of these strains is as follows:

TR5830 (*his01242 leu-414*$_{\text{am}}$)
TR4424 (*his01242 leu-414*$_{\text{am}}$*supE20 zej-636*::Tn5*)
TT4425 (*his01242 leu-414*$_{\text{am}}$*supE20 zej-636*::Tn5* *hisT1504*)
TT4427 (*his01242 hisD6404*$_{\text{am}}$*leu-414*$_{\text{am}}$*zej-636*::Tn5* *zeb-618*::Tn*10*†)
TT4241 (*his01242 hisD6404*$_{\text{am}}$*leu-414*$_{\text{am}}$*supE20 zej-636*::Tn5*)
TT4242 (*his01242 hisD6404*$_{\text{am}}$*leu-414*$_{\text{am}}$*supE20 zej-636*::Tn5* *hisT1504*)
TT4428 (*his01242 hisD6404*$_{\text{am}}$*-C1 leu-414*$_{\text{am}}$*zej-636*::Tn5* *zeb-618*::Tn*10*†)
TT4268 (*his01242 hisD6404*$_{\text{am}}$*-C1 leu-414*$_{\text{am}}$*supE20 zej-636*::Tn5*)
TT4271 (*his01242 hisD6404*$_{\text{am}}$*-C1 leu-414*$_{\text{am}}$*supE20 zej-636*::Tn5* *hisT1504*)

Radiological assays of the histidinol dehydrogenase enzymatic activity were carried out according to Ciesla' *et al.*[25]. The value of the activity in strain TT4424 (*hisD*$^+$ *supE*) was taken as 100; all other activities are expressed relative to this value. The results are the average of three determinations.

**zej-636*::Tn5 designates a transposable kanamycin-resistance element co-transducible with the *hisT* locus.

†*zeb-618*::Tn*10* designates a transposable tetracyclin-resistance element inserted at 41 min of the *Salmonella typhimurium* genetic map.

Table 5 Effect of codon context on several suppressors

Suppressor genotype	*HisD* enzyme activity resulting from suppression of indicated site (*hisD6404*) -UAGC-	 (*hisD6404-C1*) -UAGA-
sup^+	<0.2 (TT4427)	<0.2 (TT4428)
supG (*lys*)	0.8 (TT4286)	1.0 (TT4287)
supF (*tyr*)	3.4 (TT4278)	7.7 (TT4280)
supD (*ser*)	16.6 (TT4274)	6.7 (TT4276)
supE (*gln*)	2.0 (TT4241)	19.8 (TT4268)

Isogenic strains were built carrying either *hisD6404* or *hisD6404-C1* and the nonsense suppressors listed. The genotype of these strains is as follows:

TT4286:*his01242 hisD6404*$_{am}$*leu-414*$_{am}$*supG50 zej-636*::Tn5
TT4287:*his01242 hisD6404*$_{am}$*-C1 leu-414*$_{am}$*supG50 zej-636*::Tn5
TT4278:*his01242 hisD6404*$_{am}$*leu-414*$_{am}$*supF30 zej-636*::Tn5
TT4280:*his01242 hisD6404*$_{am}$*-C1 leu-414*$_{am}$*supF30 zej-636*::Tn5
TT4274:*his01242 hisD6404*$_{am}$*leu-414*$_{am}$*supD10 zej-636*::Tn5
TT4276:*his01242 hisD6404*$_{am}$*-C1 leu-414*$_{am}$*supD10 zej-636*::Tn5

The genotypes of sup^+ and *supE* containing strains are in the legend to Table 4. The enzymatic activity of the histidinol dehydrogenase was assayed as described in the legend to Table 4. Enzyme levels presented are relative to the level measured in strain TR5830 ($hisD^+ sup^+$). Results are the average of three determinations.

Table 6 Effect of codon context on the suppressor ability to relieve polarity

Suppressor genotype	*HisB* enzyme activity resulting from relief of polarity at the indicated *HisD* site (*hisD6404*) -UAGC-	 (*hisD6404-C1*) -UAGA-
supF (*tyr*)	5.6 (TT4278)	9.4 (TT4280)
supD (*ser*)	10.6 (TT4274)	5.9 (TT4276)
supE (*gln*)	0.9 (TT4241)	6.0 (TT4268)

HisB enzyme level was determined according to Martin *et al.*[26]. The activity measured in strain TR5830 ($hisD^+ sup^+$) is 17.1. All the values are corrected by subtraction of the *hisB* enzyme level in strains TT4427 (*hisD6404* sup^{WT}) or TT4428 (*hisD6404-C1* sup^{WT}). Strains carrying ochre suppressor *supG* gave *hisB* activity values below the detection level. Strain genotypes are in the legends to Tables 4 and 5.

Instead, the suppressor tRNA may read ACC and sterically prevent any tRNA from occupying the codon immediately adjacent to ACC. Thus the next tRNA must read the next unhindered triplet (out of phase).

If our observations on context effects for nonsense suppression apply to decoding in general, one is led to some interesting conjectures. If the efficiency of reading any particular codon can vary over a 10-fold range, depending on codon context, it is clear that these effects could have enormous influence on the rate of protein synthesis in particular regions. The phenomenon could be used by the cell as an additional regulatory device. According to translation modulation theories, translation rates can be set by the use of codons whose tRNAs are present at a low level in the cell[32–33]. As Stent pointed out[33], modulation of translation would more specifically be achieved by using modulating sequences longer than the codon. Invocation of context effects seems, therefore, especially appropriate. A particular rare codon may or may not have modulating function depending on the reading context in which it is located.

The possibility that context affects translation suggests a role for the minor isoaccepting tRNA species whose presence has been reported in many organisms. Changes in the abundance of these minor species have been observed during changes in growth conditions[34], development[35–37] and neoplasia[38]. It seems possible that these minor tRNA species might be able to read their particular codon when it occurs in a context which is poorly read by the isocoding major tRNA species. Shifts in these minor tRNAs could vary the overall rate of translation or could optimize production of proteins synthesized in large amounts in particular conditions.

Three examples may support these speculations. The first concerns the finding by Zilberstein *et al.*[39] that extracts of interferon-treated cells cannot completely translate haemoglobin mRNA unless a purified minor Leu-tRNA species is added. This minor Leu-tRNA could not be replaced by the major isocoding (CUG) tRNA species. The second case concerns tRNA genes carried by bacteriophage T4 (and other viruses). Guthrie and McClain have shown that one of the T4 tRNAs is essential for phage growth on a natural isolate of *Escherichia coli*[40]. The essential tRNA is a minor Ile-tRNA species recognizing the codon AUA. A tRNA species with the same codon specificity is, of course, already present in the infected host. It seems possible that the viral tRNAs permit translation of T4 messages in which the context of some codons permits only inefficient reading by the tRNA complement of some natural hosts. The third example is the *Bombix mori* posterior silk gland in which a novel Ala-tRNA species appears while huge amounts of silk protein are being produced[37,41]. One can speculate that to produce a large quantity of a particular protein, it may be necessary to eliminate even minor problems of context inherent in translation of message for that protein. The new silk gland Ala-tRNA may serve such a purpose. These three examples can all be interpreted as extreme cases in which there are restrictions of codon context that can be overcome by particular tRNA species. In summary, our data on the tRNA specificity of context effects suggest that any given codon may be read preferentially by one or another member of an isocoding tRNA family, depending on the context in which that codon appears.

We thank Wayne Barnes for facilities, for training L.B. in DNA sequence techniques, and for the communication of unpublished data. We also thank Bruce Ames and Stanley Artz for purified ^{14}C-labelled histidinol, and Fred Winston, Jeffrey Miller and David Botstein for the characterized suppressor mutants of *Salmonella typhimurium*.

Analysis of regulation of *Klebsiella pneumoniae* nitrogen fixation (*nif*) gene cluster with gene fusions

Ray Dixon, Robert R. Eady, Guadalupe Espin, Susan Hill, Maurizio Iaccarino*, Daniel Kahn & Mike Merrick

ARC Unit of Nitrogen Fixation, University of Sussex, Brighton BN1 9RQ, UK

*CNR Istituto Internazionale di Genetica et Biofisica, Via Gugliemo Marconi 10, 80125 Naples, Italy

Gene fusions in which the lac *genes are under the control of each promoter in the* Klebsiella pneumoniae *nitrogen fixation* (nif) *gene cluster have been constructed. These fusions have been used to examine positive control of the cluster and the response of individual genes to repression by ammonia and oxygen. De-repression of* nif *transcriptional units is coordinate and molybdate is required for maximal expression of the structural gene operon, which is autogenously regulated.*

THE process of biological nitrogen fixation, the conversion of nitrogen to ammonia, is rate-limiting in many agricultural areas. Nitrogenase, the enzyme complex which catalyses the reduction of dinitrogen, is comprised of two redox proteins both of which contain iron–sulphur centres and one of which also contains molybdenum[1]. These component proteins are irreversibly inactivated by oxygen. A cofactor (FeMo-co) containing Mo, Fe and S, presumed to carry the active site of nitrogenase, can be separated from the Mo–Fe protein[2]. Both a reductant and ATP are required for enzyme activity[3]; approximately 15 mol of ATP are consumed per mol dinitrogen reduced. In view of this high energy requirement and the extreme oxygen sensitivity of the component proteins it is not surprising that nitrogenase synthesis is tightly controlled.

The nitrogen fixation (*nif*) gene cluster of *Klebsiella pneumoniae* consists of at least 15 genes organized into 5 polycistronic and 3 monocistronic transcriptional units (Fig. 1)[4–7]. The structural genes *nifK* and *nifD* code for the β and α subunits, respectively, of nitrogenase Kp1 (Mo–Fe protein) and *nifH* codes for Kp2 (Fe protein) of nitrogenase. The *nifB*, *nifN* and *nifE* gene products are involved in the synthesis or processing of the iron–molybdenum cofactor, and the *nifM* gene product is required for Kp2 activity[8]. *NifF* and *nifJ* are involved in electron transport to nitrogenase[9]. The phenotype of *nifA* mutants suggests that *nifA* gene product is a positive activator of *nif* transcription[8,10]. The functions of the remaining five gene products are unknown.

Regulatory studies have so far indicated that the nitrogenase structural genes are subject to repression by ammonia and by oxygen[11] and there is some evidence that molybdate is involved in the regulation of nitrogenase[12]. In addition, glutamine synthetase, the product of the *glnA* gene, has been implicated as a general positive effector of enzyme systems which, including nitrogenase, are involved in the assimilation of 'poor' nitrogen sources[13]. There are, however, serious obstacles to studies on regulation of the individual transcriptional units in the *nif* gene cluster, because most of the gene products have not been conclusively identified and there is no simple assay for any of the individual gene products. To overcome these difficulties we have used the recently developed technique of Casadaban and Cohen[14] to construct gene fusions in which the *Escherichia coli lac* genes are fused to a promoter of interest. Such gene fusions have enabled us to monitor the response of each

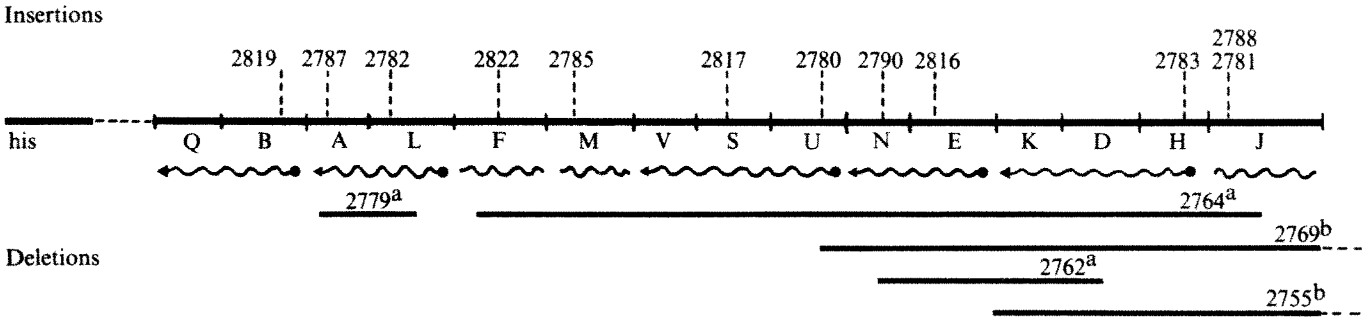

Fig. 1 Map of the *K. pneumoniae nif* gene cluster showing the location of insertions and deletions induced by phage Mud(Ap*lac*). The wavy lines indicate the eight transcriptional units and the arrows show the direction of transcription where known. The map is not drawn to scale. Transposition of Mud(Ap*lac*) into the conjugative plasmid pMF100, which carries the *his–nif* region of the *K. pneumoniae* genome was induced either by induction of an *E. coli* Mud(Ap*lac*) lysogen, UNF511 (*his trp lys lacΔ str*) carrying pMF100 at 37 °C or by infection of *E. coli* strain JC3272 carrying pMF149 (a Mu-sensitive derivative of pMF100) with a mixed lysate of Mu*cts* and Mud(Ap*lac*) at 30 °C. Insertion mutations in the plasmid were selected on the basis of co-transfer of *his* and ampicillin resistance in crosses carried out at 30 °C with an *E. coli* Mu*cts* lysogen, UNF514 (*his trp lacΔ recA56 spc*). In both cases the transposition frequency of Mud(Ap*lac*) was approximately 10^{-3} with respect to plasmid transfer. *nif–lac* fusions were obtained by screening for colonies which failed to grow anaerobically on nitrogen-free (NFDM[20]) agar, but could form blue colonies on NFDM plates containing serine (100 μg ml^{-1}) and the indicator dye 5-bromo-4-chloro-β-D-galactoside (40 μg ml^{-1}). Mud(Ap*lac*) insertions were mapped against a set of *K. pneumoniae nif* point and deletion mutations described in ref. 7. Allele numbers above the map are independent insertions in which β-galactosidase is under the control of a *nif* promoter. Black lines beneath the map represent Mud(Ap*lac*)-induced deletions in which (a) β-galactosidase is repressed by ammonia (under *nif* control) or (*b*) β-galactosidase is constitutive (under the control of a promoter outside *nif*).

Derivatives of pMF100 carrying the Mud(Ap*lac*) insertions with or without a Tn*10* insertion in *nifA* were introduced into various *K. pneumoniae* strains. All strains are *lac*Δ MuhP1 lysogens derived from KP5022 (*nif*$^+$ *hisD2 hsdR1*) or UNF1522 (Δ(*his–nif*) *2633 hsdR1 str*). UNF619 and UNF686 are also *recA*. Cultures were grown anaerobically in bijoux bottles in nitrogen-free medium (NFDM)[20], containing 2 mg ml^{-1} $(NH_4)_2SO_4$ ($+NH_4^+$) or 100 µg ml^{-1} serine in the presence ($-NH_4^+$, +Mo) or absence ($-NH_4^+$, −Mo) of molybdate (100 µM). In the latter case, removal of traces of molybdenum was achieved by extracting both glucose and phosphate with 8-hydroxyquinoline and chloroform[21], and by washing the glassware in 50% nitric acid (v/v). Cells were collected, resuspended in ice-cold saline phosphate buffer containing 100 µg ml^{-1} chloramphenicol and assayed for β-galactosidase using the procedure and units of activity described by Miller[22]. Dashes indicate that the appropriate value was not determined.

*The *nifA2013*::Tn*10* (ref. 7) insertion was transduced onto the plasmids with phage PlCmclr100 by selecting for tetracycline resistance and screening for cotransfer of both tetracycline and ampicillin resistance.

transcriptional unit to various effectors and to determine the kinetics of de-repression of individual operons.

Construction of *nif–lac* fusions

We used phage Mud(Ap*lac*)[14], a defective derivative of Mu which retains Mu transposition functions, carries part of the transposon Tn*3* encoding ampicillin resistance (Ap) (which cannot itself transpose) and has the *lac* structural genes inserted in the phage such that when the phage inserts into a gene in the appropriate orientation, transcription proceeds through the S end of Mu into *lacZ*.

We have selected a large number of *nif–lac* fusions after transposition of Mud(Ap*lac*) into the Nif$^+$ conjugative plasmid pMF100. Around 20% of Mud(Ap*lac*) insertions resulted in a Nif$^-$ phenotype, although the majority of insertion events (261 out of 315 mutants obtained from several independent crosses) produced deletions which mapped to one side of the prophage. *lac* was expressed in some of these deletions and two classes were observed: (1) those with end points within *nif* in which *lac* was under the control of a *nif* promoter and was repressed by ammonia, and (2) those with more extensive deletions in which *lac* was fused to a promoter outside *nif*, resulting in the expression of β-galactosidase in the presence of ammonia (Fig. 1). All *nif–lac* fusions which did not carry adjacent deletions gave poor or no growth on lactose in the presence of ammonia. Precise mapping of these non-deleted strains has shown that the fusions are located in 11 out of 15 *nif* genes, with at least one fusion in each of the transcriptional units (Fig. 1).

Ammonium repression

Measurements of β-galactosidase activity in *K. pneumoniae* strains carrying various fusions suggest that all *nif* promoters respond to NH_4^+ repression, although the extent of repression varies among different fusions (Table 1). These observations confirm and extend previous data on ammonia repression of some of the *nif* transcriptional units as measured by RNA–DNA hybridization experiments[15] or by detection of *nif*-specific polypeptides[8].

Positive control

The *nifA* gene product has been suggested to act as a specific positive control factor for *nif* transcription[8–10]. We have therefore investigated the role of *nifA* in the regulation of the *nif* genes by constructing *nifA*, *nif*::*lac* double mutants. Transposon Tn*10* was inserted into the *nifA* gene, thus inactivating its function, and in all fusions tested, β-galactosidase activity was decreased considerably in the absence of an active *nifA* product (Table 1). Introduction of plasmids carrying a *nifA* mutation and a *nif–lac* fusion into a *nifA*$^+$ background restored β-galactosidase activity (data not shown). However, the *nifA* gene product is not apparently required for transcription from the *nifL* promoter, as significant levels of β-galactosidase were observed in the *nifL* and *nifA* fusions and in the fusion *nif2779*::Mud(Ap*lac*), which is deleted for most of *nifA* and *nifL*.

The properties of various mutations affecting the synthesis or activity of glutamine synthetase suggest that either the enzyme itself or a product of one or more regulatory genes, including *glnF* and *glnG* (*glnR*), acts as a general positive effector for various operons involved in nitrogen metabolism[16,17]. The response of *nif–lac* fusions to two *gln* mutations, *glnA201*, a mutation in the structural gene for glutamine synthetase, and *gln-205*, a *glnA*-linked regulatory mutation which prevents *nif* de-repression (G.E. and M.M. unpublished), is shown in Table 1. Transcription of all *nif* operons is affected by these mutations. This result does not allow us to distinguish whether the positive effector acts at only a single site within *nif* or whether all *nif* transcriptional units are subject to this control. Previous studies on *nif*-specific mutations which are independent of this regulation suggest that the effector may act at a single *nif* promoter and that the other transcripts are positively controlled by a *nif*-specific regulatory protein[18]. Our data are consistent with this model, as we have shown in Table 1 that transcription of the *nifLA* operon is dependent on a *gln* gene product.

The *nifJ* gene showed a unique response to various effectors. A high level of residual activity was observed in the *nifJ* fusion both in *glnA*, *gln-205* and *nifA*:: Tn*10* backgrounds as well as in ammonia-grown cultures (Table 1). Similar results were obtained with an independent *nifJ* fusion, *nifJ2788*::Mud(Ap*lac*). It is possible that there is a less stringent requirement for *nifA* product at the *nifJ* promoter.

Regulation of the *nifHDK* operon

In the majority of cases, no significant difference was observed in the steady-state levels of β-galactosidase when merodiploid strains of genotype *nif*$^+$/*nif*::*lac* were compared with haploid strains of genotype Δ*nif*/*nif*::*lac*. The exception was a *nifH*::*lac* fusion which showed a seven-fold increase in a *nif*$^+$ compared with a total *nif* deletion background (Table 1), suggesting that this operon is autogenously regulated.

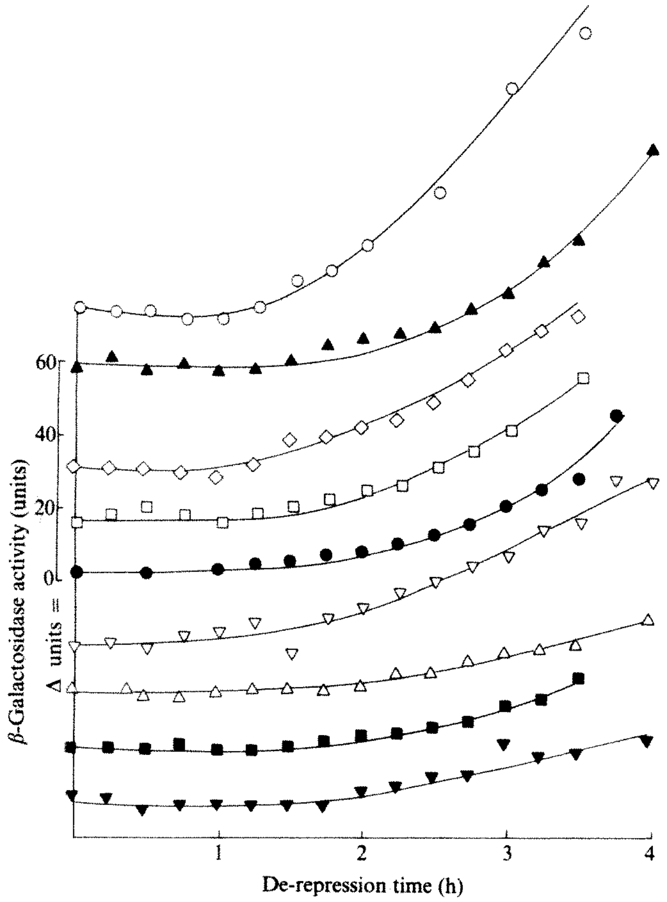

Fig. 2 Kinetics of de-repression of *nif–lac* fusions. Cultures were grown in NFDM plus $(NH_4)_2SO_4$ (1.5 mg ml^{-1}) overnight at 28 °C under N_2, collected by centrifugation and resuspended in NFDM at 25 °C. Cultures were bubbled with N_2 and samples (0.2 ml) removed at the times indicated for estimation of β-galactosidase activity. For clarity the curves are displaced and the data on the ordinate plotted as the change in β-galactosidase activity (units) observed during de-repression. All strains were derivatives of UNF619 (*nif*$^+$ *hisD2 hsdR1 lacΔ recA56 sr1300*::Tn*10* MuhP1) carrying *nif–lac* fusions in pMF100 (shown in Fig. 1). ○, *nifH2783*::Mud(Ap*lac*); ▲, *nifN2790*::Mud(Ap*lac*); ◇, *nifM2785*::Mud(Ap*lac*); □, *nifJ2781*::Mud(Ap*lac*); ●, *nifF2822*::Mud(Ap*lac*); ▽, *nifU2780*::Mud(Ap*lac*); △, *nifB2819*::Mud(Ap*lac*); ■, *nifL2782*::Mud(Ap*lac*); ▼, *nifA2787*::Mud(Ap*lac*).

Because the *nifH*::Mud(Ap*lac*) insertion exerts a strong polar effect on *nifD* and *nifK*, it is possible that any of the products of the operon could affect the level of *nifH* expression. Table 2 shows the β-galactosidase activities of merodiploid strains carrying various mutations in *trans* to a *nifH*::*lac* fusion on the *K. pneumoniae* chromosome. (Levels of activity were generally lower than those with *nifH*::*lac* located on the plasmid (Table 1), suggesting a possible effect of plasmid copy number, and in these experiments there was a threefold increase in the diploid (*nifH*::*lac*/*nif*$^+$) strain compared with the haploid (*nifH*::*lac*) level.) When the plasmid carried a Tn7 insertion in *nifK* or *nifD* or a deletion extending from *nifL* into *nifD*, β-galactosidase activities were 33–55% of the *nif*$^+$ level. However, not all Tn7 insertions in *nifH* gave a significant decrease in β-galactosidase activity (Table 2); this may reflect differences in polarity exhibited by Tn7 insertions in *nifH*. Only three out of seven Tn7 insertions in *nifH* had reduced levels of activity, whereas two *nifD* and three *nifK* insertions exhibited less than 55% of the *nif*$^+$ control (data not shown). These results suggest that the *nifK* and/or *nifD* gene products are involved in regulation of the operon. As none of the mutations tested can complement the *nifH*::*lac* insertion, nitrogenase activity *per se* is not required for stimulation of *nifH* transcription.

Involvement of molybdenum

Molybdenum is essential for nitrogenase activity, as it is a component of the iron–molybdenum cofactor of Kp1 protein. Hence, growth on molecular nitrogen is dependent on the presence of molybdate in the medium. As there is conflicting evidence concerning the involvement of molybdate in the regulation of nitrogenase synthesis in *K. pneumoniae*[12,19], we have re-examined this question using *nif–lac* fusion strains grown in the presence or absence of molybdate (100 μM). The absence of molybdate did not affect the β-galactosidase activity of ammonia-grown *nif–lac* fusion strains. None of the operons showed an absolute requirement for molybdate for de-repression and, in the haploid situation, β-galactosidase activities did not differ significantly in the presence or absence of molybdate (Table 1). Thus, molybdate has no regulatory function *per se*. In the diploid situation, only the *nif*$^+$/*nifH*::*lac* strain responded to molybdate addition and *lac* expression was increased sevenfold (Table 1). These results show that both the presence of molybdate and product(s) of the *nifHDK* operon are required for maximal expression from the *nifH* promoter. It is therefore most likely that a molybdoprotein, presumably Kp1 protein, is involved in autogenous regulation of the operon. We have been unable to distinguish whether the presence of molybdate influences the stability of this protein or whether insertion of molybdenum into Kp1 is necessary for the formation of a regulatory active species.

Oxygen repression

Oxygen represses nitrogenase synthesis as well as inactivating the nitrogenase component proteins[11]. Synthesis of β-galactosidase from all the *nif* promoters was inhibited in both *nif*$^+$ and *nif* deletion backgrounds when NH_4^+-grown cultures were resuspended in N-free medium and bubbled vigorously with air for 6 h. The degree of expression among different fusions varied from 3% (*nifH*) to 43% (*nifL*) of the activity obtained with control cultures sparged with nitrogen.

Additional experiments were carried out in an oxystat in which a defined and constant dissolved oxygen tension (D.O.T.) could be maintained. When a *nif*$^+$ strain was grown in ammonia, resuspended in N-free medium and maintained at a D.O.T. of 0.5%, de-repression was inhibited and synthesis of nitrogenase polypeptides could not be detected in pulse-labelling experiments (S. Hill and C. Kennedy, unpublished observations). Synthesis of β-galactosidase from the *nifH* promoter was also repressed as expected in these conditions, but synthesis from the *nifL* promoter in both *nif*$^+$ and *nif* deletion backgrounds was unaffected (Table 3). Thus, oxygen repression of the *nifHDK* operon is not mediated by inhibiting transcription at the *nifLA* promoter, at least at low oxygen tensions. At higher D.O.T.s (3% and 5%, Table 3) the *nifL*::*lac* fusion was apparently subject to oxygen repression as predicted from the bubbling experiments. The *nifHDK* operon is, therefore, far more sensitive to oxygen repression than the *nifLA* operon.

Table 2 Effect of mutations in *trans* on β-galactosidase synthesis from *nifH*::*lac*

Plasmid allele in *trans*	β-Galactosidase units	% *nif*$^+$
—	385 ± 35	30
nif$^+$	1,269 ± 107	100
nifK2185::Tn7	481 ± 90	38
nifD2197::Tn7	530 ± 20	42
nifD2210::Tn7	410 ± 3	32
nifΔ(L-D)8758	618 ± 68	49
nifH2191::Tn7	1,095 ± 25	87
nifH2212::Tn7	1,137 ± 67	90
nifH2213::Tn7	533 ± 37	42

Derivatives of plasmid pRD1 carrying *nifΔ(L-D)8758* or Tn7 insertions in *nifH*, *nifD* or *nifK* (ref. 7) were introduced into UNF725 (*nifH2783*::Mud(Ap*lac*) *hsdR1 lacΔ recA56 sr1300*::Tn*10* MuhPl). Cultures were grown and assayed for β-galactosidase activity as in Table 1.

Table 3 Effect of oxygen on β-galactosidase activity in *nifL* and *nifH* fusions

		Units of β-galactosidase activity under O_2 as % of that under N_2			
Fusion allele on plasmid	Strain background	Cultures bubbled with air	Cultures maintained at a D.O.T. (% saturation) of:		
			0.5	3.0	5.0
nifL2782	Δ(*his–nif*)	32 ± 9	123 ± 10	68	54 ± 6
	nif$^+$	43 ± 17	116 ± 3	64	—
nifH2783	Δ(*his–nif*)	10 ± 3	32 ± 3	—	—
	nif$^+$	3 ± 1	15 ± 3	—	—

Cultures were grown in NFDM[20] plus excess NH_4^+ overnight at 30 °C under N_2, collected by centrifugation and resuspended in NFDM at 30 °C. β-galactosidase activity was measured after vigorously bubbling 5 ml aliquots of culture with either air or N_2 for 6 h. Alternatively, β-galactosidase activity was determined after 4.5 h exposure either to the indicated D.O.T. in an oxystat supplied with air plus N_2, or to N_2. —, Not tested.

Kinetics of *nif* de-repression

Pulse-labelling experiments on cultures released from NH_4^+ repression have shown that the *nifK*, *nifD* and *nifH* polypeptides are synthesized approximately 1 h before nitrogenase activity can be detected, indicating either that de-repression of *nif* operons is not coordinate or that there is a rate-limiting step in establishing a functional nitrogenase system[11]. To examine this question more thoroughly, the onset and rate of de-repression for diploid (*nif*$^+$/*nif*::*lac*) fusion strains have been determined following transfer from NH_4^+ to N-free medium. The appearance of nitrogenase activity measured by acetylene reduction was reproducible in all strains tested, occurring 2–2.5 h after transfer to N-free medium. Control experiments in which rifampicin (100 µg ml^{-1}) was added before de-repression, indicated that there was no significant increase or decrease in the residual level of β-galactosidase activity in the absence of *nif* transcription. The onset of β-galactosidase de-repression occurred at 1–1.5 h in all cases, but the rates of enzyme synthesis varied among the different fusions (Fig. 2). Although the levels of β-galactosidase activity in fusion strains do not necessarily represent the efficiencies of the various *nif* promoters, the de-repression curve for *nifH* agrees well with pulse-labelling data on the rate of nitrogenase synthesis during de-repression[11], and the relative amounts of β-galactosidase synthesized from the other promoters generally correlate with the relative rates of synthesis of detectable *nif*-specific polypeptides observed on polyacrylamide gels. Note that synthesis of β-galactosidase from the *nifA*, *nifL* and *nifB* promoters occurred initially at a slower rate than with the other fusions. The slow de-repression of *nifB* may account for the late appearance of acetylene-reducing activity. Consistent with this hypothesis, nitrogenase activity of crude extracts prepared from cultures in the 'early' stages of de-repression is stimulated by addition of purified FeMo-co (R.R.E., unpublished results).

To examine regulation of the *nifHDK* operon in more detail, we also compared the de-repression kinetics of *nifH* diploid and haploid strains grown in the presence and absence of molybdate. Three typical curves are shown in Fig. 3: *a*, The *nif*$^+$/*nifH*::*lac* diploid fusion in the presence of molybdate showed a linear increase in β-galactosidase activity from the onset of de-repression for at least 7 h after transfer from NH_4^+ to N-free medium. *b*, The *nifH*::*lac* haploid strain, grown either with or without molybdate, initiated de-repression of β-galactosidase as in *a* but subsequently showed a cut-off in synthesis after 3.5–4 h in N-free medium. The *nif*$^+$/*nifH*::*lac* diploid strain in the absence of molybdate also showed a cut-off similar to that of the haploid strain. (For simplicity only the curve for the haploid *nifH*::*lac* fusion in the presence of molybdate is shown in Fig. 3.) *c*, A *nifH*::*lac*, *nifA*::Tn*10* double mutant showed no increase in β-galactosidase activity in the presence of molybdate, indicating that the *nifA* product is necessary for the onset of de-repression.

Thus, de-repression of the operon is clearly initiated in the absence of molybdate or in the haploid strain lacking the *nifH*, *nifD* and *nifK* products. The cut-off indicates there is an insufficient level of a regulatory molecule to maintain transcription from the *nifH* promoter in these conditions.

Discussion

Our data suggest that all the operons in the *nif* gene cluster are subject to positive control, which is ultimately mediated either by glutamine synthetase itself or by a gene product involved in glutamine synthetase regulation. We assume that this positive effector activates transcription at the *nifLA* promoter and that the *nifA* product specifically promotes transcription of other *nif* operons. Alternatively, it is conceivable that the positive effector involved in glutamine synthetase regulation is required in addition to the *nifA* product at these promoters. We have also shown that the *nifHDK* operon is subject to autogenous regulation and that the availability of molybdate and at least the *nifK* and *nifD* gene products are required for maximal expression from the operon promoter. This conclusion is also consistent with the finding that the level of Kp2 protein is low in strains carrying insertion mutations in *nifK* and *nifD*[4,8]. In wild-type nitrogen-fixing bacteria, autogenous regulation of the *nifHDK* operon might provide a useful mechanism for preventing synthesis of inactive nitrogenase.

All transcriptional units in the *nif* gene cluster are repressed by ammonia and as there is no evidence for a *nif*-specific repressor which responds to ammonia, it is possible that this repression is mediated through the level of a *gln* gene product. The latter control system is probably not involved in oxygen repression because mutants which produce nitrogenase in the

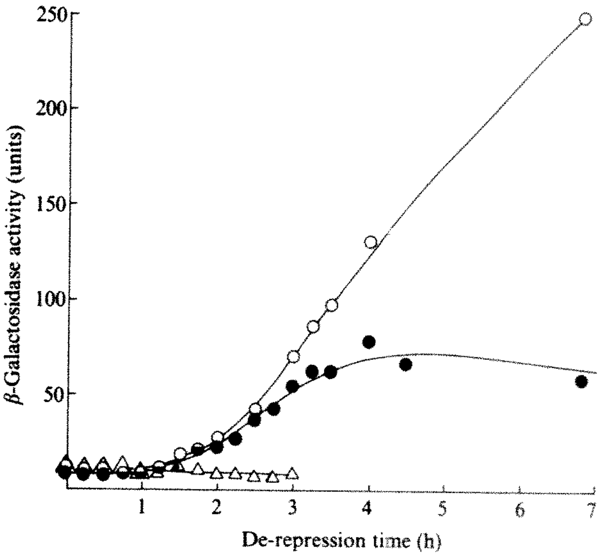

Fig. 3 Effect of strain background on de-repression kinetics of *nifH*::*lac*. Cultures were grown and assayed for β-galactosidase activity as in Fig. 2. Strains were derivatives of UNF619 and UNF686 described in Table 1 legend. *a*, *nif*$^+$/*nifH2783*::Mud(Ap*lac*) (○); *b*, Δ(*his–nif*)/*nifH2783*::Mud(Ap*lac*) (●); *c*, Δ(*his–nif*)/*nifH2783*::Mud(Ap*lac*), *nifA2013*::Tn*10* (△). When grown in the absence of molybdate both diploid (*nif*$^+$/*nifH*::*lac*) and haploid (*nifH*::*lac*) strains gave similar curves to ●. For description of curves *a–c*, see text.

presence of ammonia remain subject to oxygen regulation[11]. It is also unlikely that the products of the *nifHDK* operon are involved in oxygen repression because the level of β-galactosidase activity in a haploid polar *nifH::lac* fusion strain was lower under a D.O.T. of 0.5% than the control under nitrogen. It is possible that one of the other products of the *nif* gene cluster acts as an oxygen sensor and can mediate oxygen repression at a low D.O.T., whereas at higher oxygen concentrations there is a more general effect on the *nif* gene cluster which may also extend to other oxygen-repressible systems in the cell.

The isolation of regulatory mutations in each of the *nif* transcriptional units should considerably enhance our knowledge of the regulation of this complex gene cluster.

We thank Dawn Allitt, Marie Clark, Simon Harrison and Eugene Kavanagh for technical assistance, John Postgate for constructive criticism of the manuscript, and Malcolm Casadaban for supplying unpublished information and useful strains. M.I. and D.K. were supported by EMBO fellowships.

Comet Bradfield (1979l), discovered shortly after perihelion, on Christmas day 1979, is characterized by a retrograde orbit of period ≈250 yr. This orbit was very favourable for observation by the IUE satellite[1], and the first observations, the preliminary results of which are reported here, were made on 10 and 11 January 1980. Previously, comprehensive vacuum UV cometary spectra were available only for Comet West (1976VI) from rocket observations[2,3] and Comet Seargent (1978m) obtained with IUE[4], hence three comets have now been observed in the wavelength region where most of the major constituents are detectable spectroscopically. The UV spectra of these comets are remarkably similar, despite large differences between them in the gas-to-dust ratio and the different heliocentric distances at which the observations were made, and although the statistical basis is still very small, the implication for cosmogony is that nearly all comets have the same primary composition and origin.

At the time of these observations the comet was 0.71 AU from the Sun, 0.61 AU from Earth, and had a total visual magnitude ≈4. The visual appearance of the comet was diffuse with a weak central condensation and with only a slight trace of an ion tail. The comet could be tracked on its centre of brightness by the fine error sensor of the IUE. Drift was found to be no more than 1–2 arc s h^{-1}. All observations were made with the large (10 × 20 arc s) apertures of the spectrographs and the pointing accuracy was verified by the presence of the weak continuum near 2,900 Å in the centre of the slit.

The short wavelength spectrum is shown in a 2-h exposure in Fig. 1. The vertical scale has been reduced to average surface brightness per Å in the 10 × 20 arc s slit. As noted below, the use of the large slit permits a limited amount of spatial imaging on extended sources[5] to a resolution of ≈6 arc s, but the spectra presented here represent the average over the entire slit. The dominant features in the spectrum other than H I Lyα which is highly over-exposed are O I λ1,302, C I λλ1,561, 1,657 and 1,931 and S I λ1,813, as in the spectrum of Comet West[2,3]. The brightness in a given line or multiplet is obtained by integrating over the instrumental spectral band-pass which varies from ≈6 Å for a point source to ≈11 Å for a diffuse source uniformly filling the entire aperture. Table 1 gives the average brightness for these features. The C II λ1,335 multiplet and CO fourth positive bands observed by Feldman and Brune[2], are present in the smoothed spectrum of Fig. 1 slightly above the noise at about the same level relative to the C I lines as in the spectrum of Comet West. It is surprising that the spectrum of Comet

Table 1 Average brightness of spectral features at 0.71 AU

Species	Wavelength (Å)	Brightness (kR)
H I Lyα	1,216	160
O I	1,304	0.33
C I	1,561	0.12
	1,657	0.55
	1,931	0.05
S I	1,807–1,826	0.26
CS (0,0)	2,576	1.40
(0,1)	2,663	0.15
CO_2^+	2,890	0.60

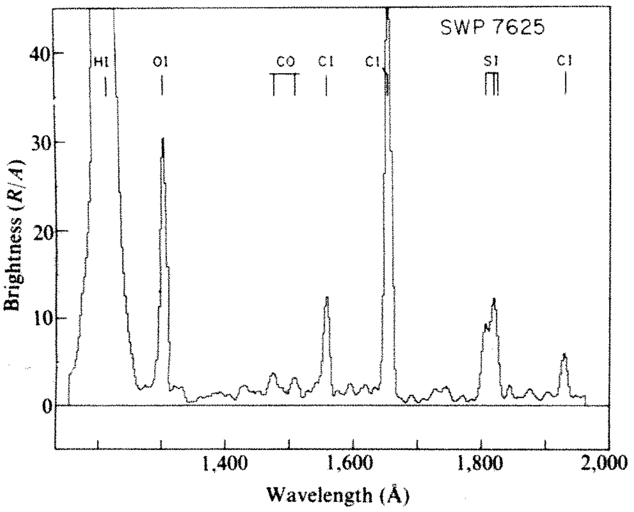

Fig. 1 Low dispersion, short wavelength spectrum of Comet Bradfield taken with the IUE spectrograph slit centred on the visible centre of brightness on 10 January 1980. The exposure time was 2 h.

Bradfield is so similar to that of Comet West considering the differences in appearance, heliocentric distance and gas production rate at the times of observation as well as the difference in projected slit area of the two instruments. This suggests that reactions among the neutral and ionized species in the inner coma may not play a significant part in altering the composition of the coma following photodestruction of the mother molecules evaporated from the cometary nucleus.

The average brightness of the H I Lyα emission, which is saturated in the spectrum of Fig. 1, is determined from a 60-s exposure and is found to be 160 kR which indicates an optically thick atomic hydrogen column along the line-of-sight to the centre of the coma. The O I multiplet at 1,302 A is nearly optically thick as it is excited by resonance scattering of the solar λ1,302 lines because the heliocentric velocity of the comet was 24 km s^{-1}. In previous observations of Comets Kohoutek and West[2] this velocity was ≈50 km s^{-1} which shifted the cometary oxygen absorption outside the solar line profile and it was assumed that fluorescent pumping by solar H I Lyβ radiation was the excitation source[6].

A 2-h exposure of the long wavelength spectrum is shown in Fig. 2. Once again the dominant features are the CO$^+$, CS, $CO_2{}^+$, and OH bands identified previously[3], but now the identification of CS is confirmed by the presence of the (0,1) band at 2,663 Å and the (1,0) band at 2,507 Å in addition to the saturated (0,0) band at 2,576 Å, all three of which are degraded towards the red. The three OH bands are also saturated but the average brightness of these bands can be found from shorter exposures. These are all listed in Table 1. The weak continuum observed near 2,750 and 2,950 Å suggests a very small dust-to-gas ratio for this comet, consistent with visual observations.

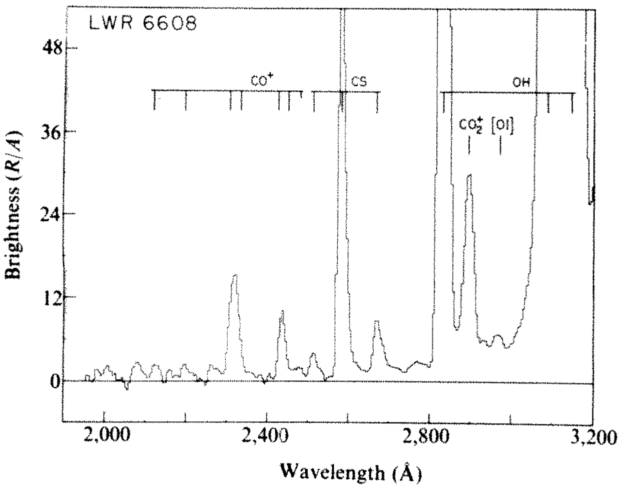

Fig. 2 Same as Fig. 1, but a 2-h exposure with the long wavelength spectrograph.

One peculiarity of this spectrum is the absence (or extreme weakness) of the (0,0) and (1,0) bands of the CO$^+$ first negative system near 2,190 and 2,112 Å, respectively. Both of these bands are also absent or very weak in the IUE spectrum of Comet Seargent[4]. In the rocket spectra of Comet West[2,3] the (0,0) band was the strongest CO$^+$ feature. It does not seem likely that fluorescent pumping by solar radiation can explain this difference as the observed strong bands near 2,300 (0,1 and 1,2) and 2,420 Å (0,2 and 1,3) originate on the same $v'=0$ and 1 levels of the upper $B^2\Sigma^+$ state of CO$^+$ and in an optically thin ion coma the band intensities would be proportional to the Franck–Condon factors for the transitions. One possibility is that the CO$^+$ in our field of view is optically thick along the line-of-sight in the $v''=0$ ground state and as a result (0,0) and (1,0) band photons are re-absorbed and pumped into transitions such as (0,1) and (1,2). The difference with the Comet West data can be explained by the difference in field of view, 5 × 35 arc min for the experiment of Feldman and Brune[2] compared with 10 × 20 arc s for IUE, a factor of ≈3,200 in solid angle. Thus, most of the radiation observed by Feldman and Brune is from CO$^+$ significantly further away from the nucleus where the CO$^+$ is not optically thick along the line-of-sight, and the relative band intensities are close to the theoretically expected values. A consequence of this explanation is the inference that CO$^+$ is produced in large abundance within 3,000 km of the nucleus. However, this hypothesis is not consistent with visual spectra obtained later in the month (January 30.0) which showed only very weak emission in the CO$^+$ comet tail bands near 4,000 Å (C. McCracken, personal communication) and only a faint visual ion tail.

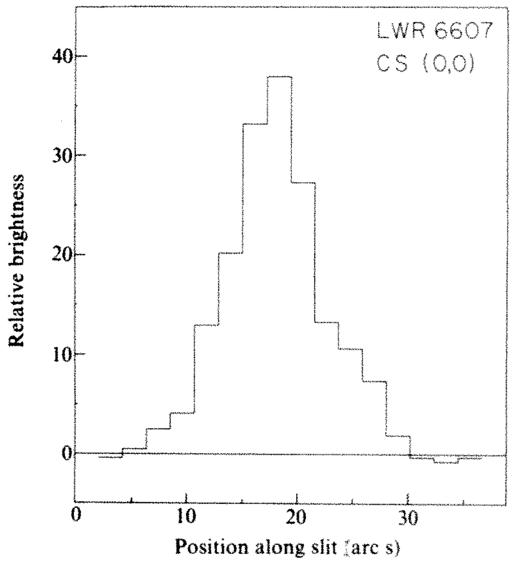

Fig. 3 Variation of the brightness of the CS (0,0) band at 2,576 Å across the spectrograph slit. At the instrumental resolution of 6 arc s, the CS seems to have a point-source origin.

Several very weak features were observed in both Fig. 1 and Fig. 2 and may, in fact, be real emission features such as additional CO fourth positive bands or the [O I] line at 2,972 Å. There is strong evidence that the [O I] 2,972 Å feature is real as it is also present above the dust continuum in the spectra of Comet West[2,3]. This transition (^1S–^3P), known to atmospheric spectroscopists as the 'trans-auroral' line of oxygen, is produced at 5% of the rate of the 'auroral green line' at 5,577 Å (^1S–^1D). The green line has been proposed[7] but not conclusively identified in cometary spectra due to the masking effect of the solar scattered continuum, the nearby (1,2) Swan band of C_2 and the presence of this line in the night airglow, but it is clear that oxygen in the ^1S state is produced in the coma. Preliminary calculations indicate that direct photodissociation of H_2O by solar H I Lyα radiation is sufficient to account for the observed surface brightness of the λ2,972 Å feature.

The spatial variations of the UV emissions can be studied in two ways. For those emissions with short scale lengths there is an appreciable variation in brightness within the 10 × 20 arc s aperture of the spectrographs and the variation can be mapped with a spatial resolution of ≈6 arc s. Otherwise it is necessary to take several different exposures with the spectrograph slit offset by a known amount from the centre of visual brightness of the coma. An example of the former is the CS (0,0) band at 2,576 Å, for which the spatial variation in the large slit from a 30-min exposure is shown in Fig. 3. The horizontal scale is the linear distance from the centre of the coma appropriate to the Earth–comet distance at the time of observation. The sharp decrease in brightness away from the centre of the comet suggests a ρ^{-1} brightness dependence characteristic of a parent molecule density distribution which varies as R^{-2} close to the nucleus, where R is the distance from the centre of the comet and ρ is the distance from the centre projected onto the sky. It is thus very probable that CS exists as a parent molecule in the cometary ice or is the dissociation product of an extremely short-lived parent molecule.

The second technique, several exposures centred at different distances from the visible centre of brightness, is shown for the OH (0,0) band at 3,090 Å in Fig. 4. The three data points are compared with the predictions of a Haser model[8] to give both the scale length (at 1 AU) and the OH production rate. However, the results are sensitive to the choice of the assumed H_2O outflow velocity and for our purpose we took extreme cases of 0.5 and 1.0 km s^{-1}. The other parameters needed[9] are the H_2O lifetime, 8.2×10^4 s, and the OH outflow velocity, 1.15 km s^{-1}. The two curves in Fig. 4, virtually indistinguishable from each other, correspond to values of $\tau_{OH} = 1.0 \times 10^5$ s and 5.0×10^4 s for the respective values of $v_{H_2O} = 0.5$ and 1.0 km s^{-1}. The corresponding values of the OH (and presumably H_2O) production rate at 0.71 AU are $Q_{OH} = 1 \times 10^{29}$ s^{-1} and 2×10^{29} s^{-1}, respectively. The range of deduced values of τ_{OH} (at 1 AU) is in accord with the theoretical value of 7.5×10^4 s given by Jackson[10] for a heliocentric velocity of 24 km s^{-1}. According to Festou[9], the lifetime derived by means of Haser's model is a lower limit to that obtained from a model which properly accounts for the spatial distribution of the OH radicals produced by photodissociation. The water production rate, reduced to 1 AU, of 0.5–1×10^{29} s^{-1}, is considerably lower than that of several 'new' comets as given by Keller and Lillie[11], consistent with the identification of this comet as a long-period comet which has made numerous passes through the inner Solar System.

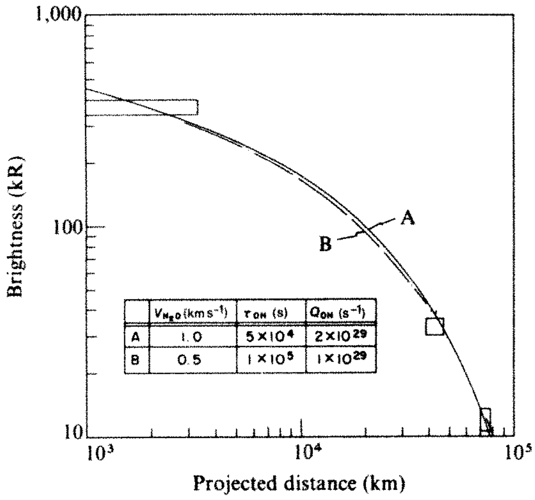

Fig. 4 Comparison of the OH (0,0) band brightness profile with a radial outflow model using the parameters defined in the insert. Data from three exposures are shown as rectangular boxes, the horizontal size being the projected length of the spectrograph slit on the comet and the vertical size the measurement uncertainty.

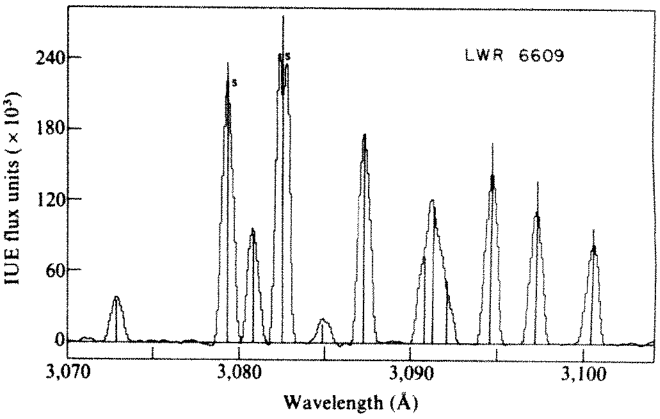

Fig. 5 High dispersion spectrum of the OH (0,0) band taken from a 15-min exposure. The wavelengths shown are vacuum wavelengths. The ordinate is in IUE flux units which are not corrected for the absolute spectral response of the instrument. The theoretical intensities have been multiplied by the approximate spectral response curve of the long-wavelength camera which varies steeply in this spectral region. The $P_1(1)$ line near 3,082 Å was saturated (S) in the observed spectrum and is off-scale in the theoretical calculation.

Assuming that CS is evaporated from the nucleus with the same outflow velocity as H_2O, it is possible to determine the relative production rate of these two molecules. A g-factor for the CS (0,0) band at 2,576 Å of 7×10^{-4} photons per s per molecule at 1 AU was adopted which leads to a value of the ratio $Q_{CS}/Q_{H_2O} \approx 5 \times 10^{-4}$. Thus, although CS is a prominent feature of the UV cometary spectrum it is clearly only a minor species in the comet.

The high resolution capability of the IUE spectrographs was used to study further the resonance fluorescence excitation of the OH (0,0) band, the strongest emission feature in the cometary spectrum. A 15-min, high-dispersion exposure is shown in Fig. 5, along with the predicted relative intensities as calculated for the heliocentric distance, r, and radial velocity, $\dot{r}$, at the time of observation[12]. The excellent agreement between theory and observation over the velocity range 24–28 km s^{-1} indicates that no process other than fluorescence is important in controlling the OH level populations. The dependence of the spectrum on $\dot{r}$ is strikingly illustrated by comparison of Fig. 5 with a similar, high-dispersion spectrum of this band from Comet Seargent (1,978m) (ref. 4), which differed in heliocentric radial velocity by ~10 km s^{-1}. The large changes in the spectrum with radial velocity indicate that the fluorescence efficiency (g-factor) is also a function of radial velocity. The velocity dependent g-factors, needed to convert low resolution fluxes to column densities as above, were obtained from this high resolution analysis.

These new results are only the preliminary analysis of the data obtained at the first opportunity for IUE observations of Comet Bradfield. Observations were continued, at the rate of one a week corresponding to increments in heliocentric distance of ~0.1 AU, through February, and should provide important information about the variation of the production rates of the UV active species with distance from the Sun. As the first comet to be so regularly observed in the vacuum UV, Comet Bradfield will greatly increase our understanding of the physics and chemistry of the cometary atmosphere.

We thank the IUE Observatory staff for acquisition and reduction of the data and for all their assistance. B. G. Marsden and M. P. Candy provided up-to-the-minute ephemerides. The work at Johns Hopkins University is supported by NASA grant NSG 5393.

Note added in proof: Further analysis has disclosed that the features at 2,321 and 2,436 Å are incorrectly identified as CO$^+$; rather they are a Mulliken band of C_2 and the second order HILyα image, respectively. The absence of CO$^+$ bands in the UV is thus consistent with the absence of this species in the visible spectrum.

Tidal effects on the mass profile of galactic haloes

Avishai Dekel*, Myron Lecar† & Jacob Shaham*

*Racah Institute of Physics, The Hebrew University of Jerusalem, Jerusalem, Israel
†Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts 02138

Most spiral galaxies are believed to be embedded in dark massive haloes[1,2]. The main observational evidence for their presence is the rotation curves of edge-on disks at large radii measured both by optical[3,23] and radio (21 cm)[4] techniques: rotation velocities remain constant to distances of several tens of kiloparsecs, far beyond the main visible bodies of the galaxies. This suggests the existence of a dark halo whose mass, if spherical, varies linearly with distance R from the galactic centre and hence has a density profile which falls off as R^{-2}. The extended 'flat' shape of the haloes poses a problem for most theoretical hypotheses of galaxy formation because simulations of collapse[5–8] and of violent mergers[9] predict a spherical density profile which is rather Hubble-like ($\rho \propto R^{-3}$) or even steeper. The time scale for two-body relaxation, which can lead to a flatter, isothermal, density profile, is much larger than the Hubble time. If, as Gunn[10] and Gott[6] have suggested, secondary cosmological infall produces the $\rho \propto R^{-2}$ haloes, special initial conditions are required: (1) the central perturbation, which is the progenitor of the galaxy, needs to be initially embedded in a bound homogeneous background—an assumption which might not be fully justified for relatively isolated galaxies; and, (2) the infall must be such that there is no dissipation so that most of the mass should already be in the form of compact objects before halo formation. We suggest, as an alternative mechanism, tidal interactions between haloes, or possibly between their smaller building blocks, while in the hierarchical gravitational clustering process. In this process typical tidal encounters are slow, such that relative orbital velocities of the interacting systems are comparable to the internal velocities of the stars in each system. The two systems are slightly unbound.

Our suggestion is based on N-body simulations which we performed to study the tidal effects of such encounters on the mass-profile of spherical systems[11]. On adopting the common view, that the dark material is not gaseous[12–14] but is rather composed of condensed bodies (such as unevolved low-mass stars, dead remnants of old stars, and primordial black holes[15]), a dissipationless N-body system was assumed to represent properly a galactic halo. The numerical experiments were based on the N-body code developed by Aarseth[7,16,17]. It integrates the equations of motion of N softened particles, which interact through a potential

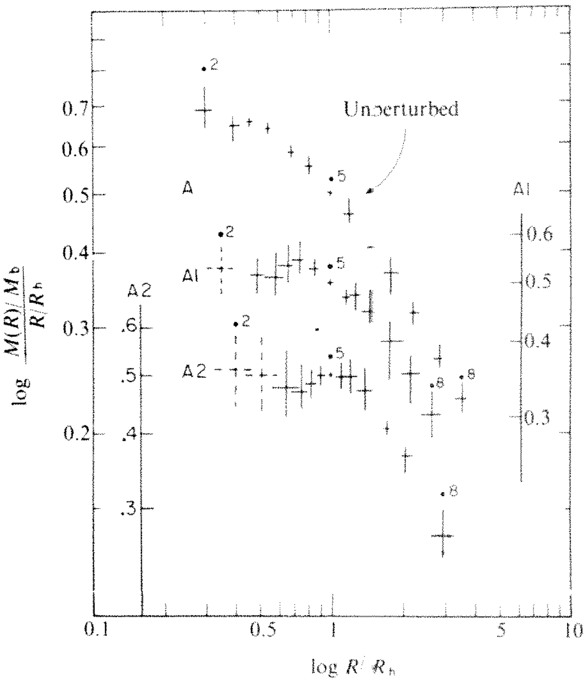

Fig. 1 Rotation curves of two tidally perturbed haloes, A1 and A2, are compared with the unperturbed one at the same final time. The mass and the radius are in fractional units relative to the mass, M_b, and the half-mass-radius, R_h, of the remnant bound system. The symbols correspond to given fractions of the bound mass, separated by 5%, and the error bars correspond to temporal deviations over three successive crossing-times. The curves are vertically shifted by a factor of 1/2 relative to each other. The parameters for the cases A1 and A2 are the following, perturber mass/halo mass = 2; relative velocity at closest approach = 1.05 the parabolic velocity; closest approach distance = 4.6 R_h, 2.8 R_h; fractional mass loss = 0.22, 0.33; final R_h/original R_h = 0.8, 0.74. Note that both the fractional and absolute flat regions become more extended.

$$\phi_{ij} = -Gm_i m_j/[(r_i - r_j)^2 + \varepsilon^2]^{\frac{1}{2}}. \qquad (1)$$

The softening parameter, ε, is chosen to suppress the two-body relaxation effects that arise due to the small number of particles in our experiment.

In our experiments, a 250-body system was tidally perturbed by a point perturber of comparable mass. The encounter velocities were slightly above parabolic and the closest approach distances, p, were between 2.5 R_h and 5 R_h, where R_h was the half-mass-radius. In such conditions, each 'shell' of stars expands, gradual stripping occurs outside ~R_h and up to one-third of the original mass may become unbound. As Fig. 1 shows, the effect on a system which initially has a decreasing $M(R)/R$ profile ($\rho \propto R^{-3}$) is to steepen the profile in the outer parts, and to produce, or extend, an inner region of constant $M(R)/R$, to encompass 50–70% of the bound mass. Hence, this mechanism, whose exact relaxation nature is not yet understood theoretically, produces systems which might show flat rotation curves over a large fraction of their mass (but not a relaxed flat outer envelope, as was discussed previously[18,19]). Tandem encounters of the same system tend to strip the outer parts and produce a smaller system, which retains a flat inner profile.

Most of the stripped stars in our simulations did not become bound to the perturber but rather escaped from the two-body system altogether. This indicates that stripped material from a realistic, N-body, perturber would not become bound to the perturbed system and, therefore, have no substantial effect on its mass profile. We therefore assume that

0028-0836/80/280135-02$01.00

our results for a point perturber are, for similar p values, also qualitatively representative for an N-body perturber. This assumption is supported by the consistency of our results for the energy-gain and mass-loss with those obtained by other simulations of encounters between identical systems[11]. The substantial amount of stripped material might remain bound to a larger group, forming a common background halo which might later infall and produce even more extended envelopes around the haloes.

If slow hyperbolic encounters are to be considered responsible for $M \propto R$ profiles, one should estimate how frequently they occur in a cosmological context. Tidal encounters are found to be effective whenever $p \leqslant 5\,R_h$, so that the geometrical cross-section for such an encounter is much larger than that for a merger, which occurs for $p \leqslant 2.5\,R_h$ (refs 9, 20, 21). The time scale for mergers in a small group is estimated analytically to be of the order of the dynamical time scale of the group[22], and N-body simulations show that about one-third of the galaxies have undergone mergers, mostly in the first generation of their clustering. One may, therefore, conclude that the proposed mechanism is quite relevant in small groups.

A weak lower limit on the rate of encounters can be estimated for 'field' galaxies. A straightforward *nσv* calculation shows that the number, N, of effective encounters since the epoch of halo formation, Z_{form}, is

$$N \sim 0.05\,\Omega_0\,(1+Z_{\text{form}})^2 \left(\frac{R_h}{60\,\text{kpc}\,h_{50}^{-1}}\right)\left(\frac{v}{300\,\text{km s}^{-1}}\right) \qquad (2)$$

where v is the typical peculiar velocity of galaxies. Each quantity in equation (2) has uncertainties but N does seem to be a number of the order of unity. There might be an additional contribution to N from dark haloes which do not have visible cores (galaxies)[13].

The suggested mechanism predicts a correlation between the degree of clustering of a galaxy (be it a field galaxy, a member of a small group or a member of a large one) and the fractional extension of its $M \propto R$ region. Note also that tidal encounters lead to haloes which are both less massive and have larger fractional $M \propto R$ regions, whereas cosmological infall should lead to larger $M \propto R$ regions in more massive haloes.

Tidal interactions might also be helpful in the merger picture for halo formation, as suggested by White and Rees[22]. There, each merger is preceded and followed by several tidal encounters which might reproduce inner $M \propto R$ regions even when the mergers themselves may steepen their profiles[9].

Another important indication from our results is the tendency for complete removal of haloes after many encounters. This is seen from the fact that, as a result of a tidal encounter, each 'shell' of stars expands, so that most parts of the system become less bound, an easy target for further stripping. It is expected, therefore, that galaxies now in rich clusters have lost most of their haloes due to successive encounters during their clustering process, and that galaxies observed to have haloes could not have undergone too many tidal encounters.

We thank Dr Sverre J. Aarseth for his code and help, Drs S. Michael Fall and Martin J. Rees for helpful comments.

Interpretation of type I OH maser sources

W. H. Kegel

Institut für Theoretische Physik der Johann Wolfgang Goethe-Universität, Frankfurt am Main, FRG

D. A. Varshalovich

Ioffe Physical Technical Institute of the Academy of Sciences of the USSR, Leningrad, USSR

OH maser sources of type I, which are related to regions of star formation, have been known for more than a decade. However, despite great effort no satisfactory theoretical interpretation has yet been given. (For general reviews on cosmic masers see refs 1–5.) A model for the interpretation of type I OH maser sources is suggested here. This model combines the effect of velocity and magnetic field gradients with radiative pumping by means of the ($^2\Pi_{3/2}$, $J=5/2 \rightarrow {}^2\Pi_{1/2}$, $J=5/2$) transition. Due to an overlap of particular hyperfine components, inversion of the 1,665 MHz line is favoured.

Type I OH maser sources are characterized by an extreme intensity corresponding to a radiation temperature up to 10^{13} K in one or both of the main lines, the 1,665 MHz-line usually being the stronger, and by a high degree of circular polarization (up to 90%).

Schemes involving optical pumping[6–11], chemical pumping[12,13], and collisional pumping (refs 12, 15, 16, and C. H. Townes and W. D. Gwinn, unpublished data) have been used to explain the intensities. Although all these mechanisms may produce population inversions, difficulties arise when a more quantitative interpretation of the observations is attempted. For example, consider a radiative pumping scheme: on one hand it is not easy (though possible) to have enough pump photons to explain the observed high luminosities in the radio lines, on the other hand it is difficult to have an efficient pump mechanism and a large absolute value of the optical thickness in the maser line at the same time, because the absolute value of the optical thickness of the pump line along the same line of sight is in general larger than that of the maser line[4]. Note also that the upper and the lower levels of either of the main lines are distinguished only by their parity, while all other quantum numbers are identical. Thus to every spectral line connecting to the lower level there is a corresponding line connecting to the upper level. Inversion can, therefore, come about only by difference effects and not by selection rules.

To explain the high degree of polarization a model has been proposed which invokes gradients of the velocity and the magnetic field[17,18]. If the velocity and the magnetic field change along the line of sight, it can be hypothesized that in a certain region for a particular direction of propagation, the derivatives of the frequency shifts of the maser line due to the Doppler and the Zeeman effect just cancel each other out. This leads to a larger absolute value of the optical depth than one would have without Zeeman splitting.

If κ is the absorption coefficient

$$\kappa = \kappa_0 \exp\{-(\Delta v/\Delta v_{\text{th}})^2\} \qquad (1)$$

0028-0836/80/280136-03$01.00

we estimate the optical thickness in the line by

$$\tau = \kappa_0 \Delta l \qquad (2)$$

where Δl is the path length along the line of sight over which the frequency shift changes by an amount corresponding to the thermal width $\Delta\nu_{th}$ of the line. Using a Taylor expansion for the radial velocity (v_r) and the magnetic field (H); we obtain for the frequency shift along the line of sight:

$$\Delta\nu \simeq (\Delta\nu)_0 + \left[\frac{\nu_0}{c}\frac{\mathrm{d}v_r}{\mathrm{d}l} + \gamma\frac{\mathrm{d}H}{\mathrm{d}l}\right]\cdot\Delta l + \frac{1}{2}\left[\frac{\nu_0}{c}\cdot\frac{\mathrm{d}^2 v_r}{\mathrm{d}l^2} + \gamma\frac{\mathrm{d}^2 H}{\mathrm{d}l^2}\right]\cdot(\Delta l)^2 \qquad (3)$$

($\gamma = 3.31$ MHz Oe^{-1} for the 1,665 MHz-line and 1.99 MHz Oe^{-1} for the 1,667 MHz-line.)

For those lines for which the Zeeman effect is not important we can estimate Δl from the linear term in equation (3):

$$\Delta l_1 = \left|\frac{v_{th}}{\mathrm{d}v_r/\mathrm{d}l}\right|. \qquad (4)$$

If, however,

$$\frac{\nu_0}{c}\frac{\mathrm{d}v_r}{\mathrm{d}l} + \gamma\frac{\mathrm{d}H}{\mathrm{d}l} = 0 \qquad (5)$$

the linear term in equation (3) cancels and we have to determine Δl from the second-order term.

$$\Delta l_2 = \left|\frac{2v_{th}}{\dfrac{d^2 v_r}{\mathrm{d}l^2} + \dfrac{c\gamma}{\nu_0}\dfrac{\mathrm{d}^2 H}{\mathrm{d}l^2}}\right|^{1/2} \qquad (6)$$

As γ has a different sign for the different Zeeman components, this increase in the optical depth occurs only in one of the Zeeman components while in the other there is a decrease.

Thus, if this mechanism were operating, one would expect the maser radiation to consist mainly of only one of the Zeeman components. Observations show that in most cases the right hand and the left hand circularly polarized radiation come from different volume elements.

We suggest that type I OH masers may be due to a combination of the above effect with a particular scheme of optical pumping. For this we note that the relative Zeeman splitting ($\Delta\lambda/\lambda$) is much larger for the radio lines than for the IR lines. Thus, if condition (3) is satisfied for the maser line, the same cannot be true for the IR lines. Therefore we can apparently construct a model in which the absolute value of the optical depth in the maser line is large while that in a potential pump line stays at moderate values ($\tau \sim 1$).

To achieve the pumping we consider the effect of overlap of IR-lines; such pumping schemes have been suggested elsewhere[19,20]. Note that any IR-pumping scheme which is to invert the main lines has to use transitions with $\Delta J = 0$. Among these, the transitions connecting the states with $J = 5/2$ have the largest overlap and seem therefore to be the most important. According to the frequencies given by Destombes *et al.*[21], in the ($^2\Pi_{3/2}$, $J = 5/2$)→($^2\Pi_{1/2}$, $J = 5/2$) multiplet there is an almost complete overlap between two main lines, the ($F = 3^- \rightarrow F = 3^+$) and the ($F = 2^- \rightarrow F = 2^+$) transitions. The frequency difference is 0.5 MHz, corresponding to $\Delta\nu/\nu \simeq 8 \times 10^{-8}$, which is considerably less than the line width for any reasonable temperature. In contrast, the frequency difference between the ($F = 3^+ \rightarrow F = 3^-$) and the ($F = 2^+ \rightarrow F = 2^-$) transitions is 57.5 MHz corresponding to $\Delta\nu/\nu = 0.9 \times 10^{-5}$, which is much wider than typical line widths in OH-maser sources (see Fig. 1). Thus the optical depth in the first pair of lines is about twice that for the latter. If we now consider the radiation from an IR-source outside the OH-cloud, at a point within the cloud at which the optical thickness in the non-overlapping IR-lines is about unity, the intensity in the overlapping lines is about one-third of that in the non-overlapping ones. Thus the rate of absorption from the lower half of the ($^2\Pi_{3/2}$, $J = 5/2$) Λ-doublet is ~6 times larger than that from the upper half. (A factor or two comes from the fact that the non-overlapping lines cover a wider frequency range.) This effect produces a population inversion in the ($^2\Pi_{3/2}$, $J = 5/2$)-state as well as in the ($^2\Pi_{1/2}$, $J = 5/2$)-state. Both are transferred to the ground state by the other IR-transitions.

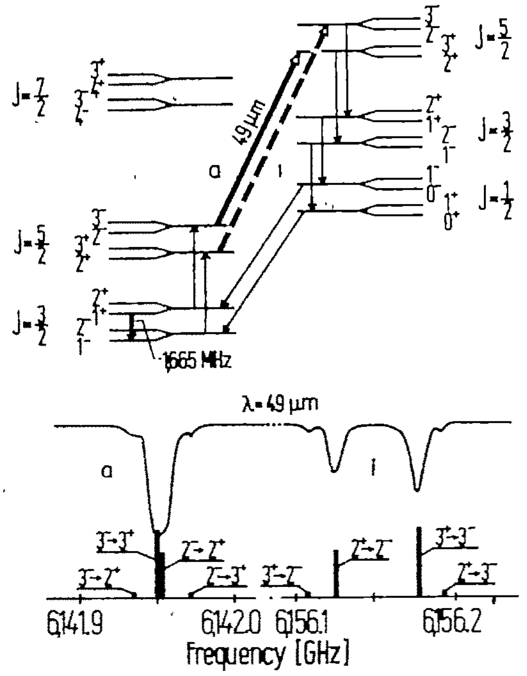

Fig. 1 Energy level diagram of the OH molecule (not to scale) and spectrum of the 49 μm multiplet.

The total number of absorbed pump photons is proportional to $L_{\nu,\mathrm{IR}} \cdot \Delta\nu_p$. The maser region is determined by Δl_2 (equation (6)). As the Zeeman effect is not important for the IR-lines, $\Delta\nu_p$ is much wider than the thermal line width and we can approximate

$$\Delta\nu_p = \frac{\nu_{p,0}}{c}\frac{\mathrm{d}v_r}{\mathrm{d}l}\Delta l_2 = \nu_{p,0}\frac{v_{th}}{c}\frac{\Delta l_2}{\Delta l_1}. \qquad (7)$$

$L_{\nu,\mathrm{IR}}$ may be estimated either from models for IR-sources or from measurements. For W3(OH) $L_{\nu,\mathrm{IR}}$ was determined[22] to be of the order of 4×10^{25} erg s^{-1} Hz^{-1} at $\lambda = 49$ μm.

We now make some quantitative estimates using an oversimplified model. As type I OH-masers occur in regions of star formation, it seems reasonable to consider a collapsing cloud with a central IR-source. If we assume that the kinetic energy density is larger than the magnetic energy density everywhere, the hydrodynamics of the collapse is essentially not altered by the magnetic field and we may assume radial symmetry (the magnetic field lines will also be essentially radial).

For free infall, we have

$$v(r) = v_0 (r_0/r)^{1/2} \qquad (8)$$

$$n(r) = n_0 (r_0/r)^{3/2} \qquad (9)$$

$$H(r) = H_0 (r_0/r)^2. \qquad (10)$$

In this model condition (3) is satisfied if

$$r^{1/2}(3p^2 - r^2) = \alpha(r^2 - p^2)^{1/2} \qquad (11)$$

where p is the impact parameter of the line of sight and

$$\alpha = \frac{4c\gamma H_0 r_0^{3/2}}{\nu_0 v_0}. \tag{12}$$

For simplicity we consider the central ray ($p=0$) only. Along this the maser region is around r_m which is determined from equation (11) to be

$$r_m = (-\alpha)^{2/3}. \tag{13}$$

With $p=0$ we find

$$\frac{\Delta l_2}{\Delta l_1} = \left[\frac{2v_0 r_0^{1/2}}{3v_{th}(-\alpha)^{1/3}}\right]^{1/2}. \tag{14}$$

This ratio, which is independent of r_0, gives the increase of the optical depth of the maser line over the value without Zeeman effect. It also corresponds to the ratio $\Delta\nu_p$ to the thermal width of the pump line. If we assume $v_0 = 5\,\mathrm{km\,s^{-1}}$, $H_0 = 10^{-3}$ Oe and $T_{kin} = 50\,\mathrm{K}$, which seem to be reasonable parameters, we have $\alpha = 0.48\, r_0^{3/2}$ and $\Delta l_1/\Delta l_2 \simeq 4.4$.

We estimate the number of available pump photons on one side by

$$W_{ph} \simeq 4\pi r_s^2 \cdot \pi B_\nu(T_s)\Delta\nu_p \tag{15}$$

where r_s and T_s are the radius and the temperature of the central IR-source. With $r_s \simeq 10^{15}\,\mathrm{cm}$ and $T_s \simeq 300\,\mathrm{K}$ we obtain $W_{ph} \simeq 10^{44}$ photons $\mathrm{s^{-1}}$ which seems to be about of the right order of magnitude. If, on the other side we estimate W_{ph} from the IR-luminosity measured[22] for W3(OH), we obtain about two orders of magnitude more photons. For these photons to be absorbed, the optical depth in the pump lines has to be about unity, that is we have to have $\Delta l_2 \kappa \simeq 1$. With the above assumed parameters this leads to the requirement that $n_{OH} \cdot r_0 \simeq 10^{17}\,\mathrm{cm^{-2}}$. With $r_0 \simeq 10^{16}\,\mathrm{cm}$ this requires an OH density of about $10\,\mathrm{cm^{-3}}$ or with $n_{OH}/n_{H_2} \simeq 10^{-5}$ a hydrogen density of $\sim 10^6\,\mathrm{cm^{-3}}$, which seem to be reasonable.

These estimates show that the proposed scheme may indeed explain the observed properties of type I OH-sources. In particular it explains: (1) the large differences in the relative intensities for the different subsources, these are because the intensity depends on the gradients of the radial velocity and the magnetic field along the line of sight, which vary much more than other physical parameters; (2) the high degree of polarization; (3) why in general the 1,665 MHz-line is more intense than the 1,667 MHz-line. This is expected if in the maser region the number of 49 μm-photons absorbed in the ($F = 2^+ \rightarrow F = 2^-$) transition is larger than that absorbed in the ($F = 3^+ \rightarrow F = 3^-$) transition. This is based on the lowest order consideration in which the satellite transitions ($\Delta F \neq \Delta J$) in the IR-lines are neglected. In this approximation the pump routes for the 1,665 MHz and the 1,667 MHz-line are decoupled and may be considered independently of each other. The number of photons absorbed in a line per cm³ per s is $\kappa I \Delta\nu$ with $I = I_0 e^{-\tau}$. If we further assume that the ratio of the occupation numbers of the different hyperfine components of the ($^2\Pi_{3/2}$, $J = 5/2$)-state corresponds to that of their statistical weights (7/5), the ratio of the absorption coefficients of the pump lines is also given by that number. It then follows, that the number of photons absorbed in the ($F = 2^+ \rightarrow F = 2^-$) transition of the 49 μm-line is larger than that of the ($F = 3^+ \rightarrow F = 3^-$) transition if the optical thickness τ of the latter is larger than 0.31. In more detailed investigations, however, one has to consider the complete multi-level system containing all levels and transitions possibly involved in the pumping scheme.

From the conservation of angular momentum, the IR-lines which provide the pumping would also be expected to be circularly polarized.

This work was performed while D.A.V. was a guest at the Institut für Theoretische Astrophysik, Heidelberg. His visit was supported by the Deutsche Forschungsgemeinschaft. This research is part of the Sonderforschungsbereich 132, which is also sponsored by the Deutsche Forschungsgemeinschaft.

Iodine-129, with a half life of 15.7 Myr (ref. 1), is one of the longest lived of the cosmogenic radionuclides. Although the primordial supply of ^{129}I is now extinct, ^{129}I is continuously being produced in the atmosphere primarily by cosmic ray reactions on xenon[2], in the Earth primarily by spontaneous fission of ^{238}U (ref. 3), and in meteorites and the Moon primarily by proton and neutron induced reactions on Te and Ba (ref. 4). The relatively large quantity of ^{129}I introduced into the environment from the nuclear age may be useful as a tracer in groundwater hydrology[5]. Fissiogenic ^{129}I in large granite formations (batholiths) could be used to establish the suitability of these sites for long term nuclear waste storage, because groundwater movement would carry away the more soluble iodides and disturb the equilibrium ^{129}I/^{238}U ratio. The concentration of ^{129}I in meteorites can be combined with results for shorter-lived radionuclides to provide information on the constancy of the galactic cosmic ray flux over longer time scales than previously possible and also on the preterrestrial history of meteorites. We have applied the new atom counting technique to ^{129}I analysis with a sensitivity (the minimum number of atoms in the sample required to obtain a quantitative result) of less than 10^7 atoms of ^{129}I in a 1-mg sample. An AgI standard with a known ^{129}I/^{127}I ratio of 10^{-11} was determined to ±10%, and the background contribution from a reagent grade AgI sample gave an upper limit to the ratio of about 3×10^{-13}. We used a time-of-flight measurement to distinguish ^{129}I from the stable ^{127}I ions that were not separated by the mass analysis system. Our results for the meteorites Bruderheim and Dhajala represent the first direct (that is, not inferred[6] from radiogenic Xe) determination of ^{129}I in meteorites. A Xe molecular negative ion was discovered but we show that it is not a problem for ^{129}I analysis.

0028-0836/80/280138-03$01.00

Because of its long half life, ^{129}I measurement by counting its β decay is not very sensitive and is useful only for samples with high activity[7]. Although our mass spectrometry measurements of ^{129}I are the first to use an accelerator, McHugh and Sheffield[8] used a three stage mass spectrometer with a negative ion sputter source to detect carrier free ^{129}I with a sensitivity near 10^9 atoms for samples with a ^{129}I/^{127}I ratio of about 10^{-7}. Their measurements were limited by interference from the ^{127}I tail and from molecular ions near mass 129 such as $^{97}MoO_2^-$ which could not be differentiated from $^{129}I^-$.

The neutron activation technique has been quite successful, with numerous reports[3,9] of ^{129}I measurements in natural samples with sensitivities typically in the range 10^{10}–10^{12} atoms. The neutron activation technique involves counting 12-h ^{130}I produced from the ^{129}I(n, γ) ^{130}I reaction in a high flux reactor. A careful chemical pre-separation is used to reduce interference from reactions such as ^{133}Cs(n, α)^{130}I and induced fission on uranium. Interference from 13-day ^{126}I produced by ^{127}I(n, 2n) often limits the sensitivity[2,3], and for this reason Rook *et al.*[10] followed neutron activation with isotope separation of mass 130 and then used β–γ coincidence counting of ^{130}I. The sensitivity was improved somewhat for samples with high ^{127}I content but this procedure still does not discriminate against ^{130}I produced from trace impurities and from the ^{127}I(3n, γ) ^{130}I multistep reaction[2]. By contrast, our method offers simplified sample preparation, a single analysis step taking $<$1h, no interference from impurities, background only from the ^{127}I tail, and a potential improvement in sensitivity by several orders of magnitude. This will allow ^{129}I measurements in considerably smaller samples, and will not require the use of natural iodine concentrators such as animal thyroids, seaweed, and brine.

The apparatus used in the present work is the same as that used for ^{36}Cl (ref. 11) and ^{26}Al (ref. 12) except that the final ionization detector was replaced with a 2.2-m time-of-flight (TOF) detector. The ^{129}I can be identified on the basis of mass alone as the only stable isobar of ^{129}I is ^{129}Xe, a noble gas that is not expected[13] to form negative ions (but see below). However, interference is expected from the stable ^{127}I, two mass units away. The I^- beam (1–5μA) produced from NaI or AgI samples in the Cs sputter source was accelerated to the 5 MV tandem terminal, stripped of several electrons, then accelerated again to ground potential. Charge state +5 ions with an energy of 30 MeV were selected by the 90° analysing magnet and 10° electrostatic deflector. These analysers eliminated all molecules and gave a combined resolution in M/q of ~0.5% FWHM. Although the ^{129}I is thus separated by 3 FWHM from the ^{127}I, a combination of charge exchange and scattering in the acceleration tubes and analysers allowed up to 200 counts per s (c.p.s.) of ^{127}I to pass into the detector. As the interfering $^{127}I^{5+}$ ions passed two magnetic analysers, most of them had the same magnetic rigidity (ME/q^2) as the $^{129}I^{5+}$ ions at the detector and therefore differed by 1.5% in energy (E) and in velocity ($\propto (E/M)^{\frac{1}{2}}$). Heavy-ion detectors are not available with an energy resolution adequate to resolve ions at this mass and energy, so we measured the velocity with TOF. The start signal was obtained[14,15] from the electrons produced by the iodine ions passing through a 5 μg cm^{-2} carbon foil; the stop signal was obtained from a 100-mm^2 area Si surface barrier detector. The Si detector also gave an energy signal adequate to resolve ions in lower charge states having nearly the same E/q and velocity.

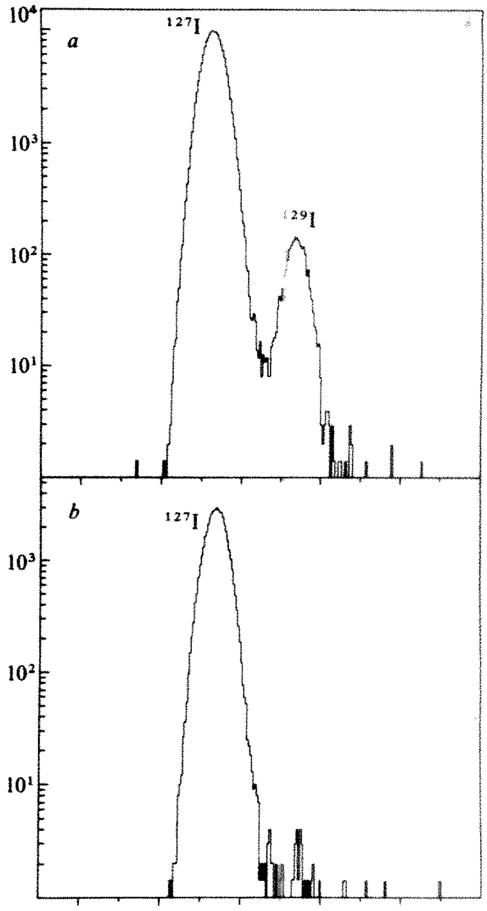

Fig. 1 Time-of-flight spectra for runs on: *a*, an AgI sample enriched to $^{129}I/^{127}I = 10^{-11}$; *b*, AgI made from reagent grade NaI. These events have been gated with a window on the total energy signal. The peaks are separated by 5.2 ns and the overall time resolution is 1.2 ns FWHM.

Table 1 Measured ^{129}I concentrations

Sample	AgI weight (mg)	Counting time (min)	Total ^{129}I (counts)	$^{129}I/^{127}I$ (10^{-12} g per g)	^{129} atoms in sample

NSRL-21801, Dhajala*	1	33	88	7 ± 2‡	3.3×10^7

*The two meteorite samples were obtained from 6.74 g and 22.2 g of Bruderheim and Dhajala. For these and the chemistry blank ~1 mg of iodine carrier and 5 mg of AgCl were added.

†The two enriched samples (ICN Cat. no. 67325) had an expected $^{129}I/^{127}I$ ratio of $(9.8 \pm 0.5) \times 10^{-12}$.

‡The meteorite results for the $^{129}I/^{127}I$ ratio were normalized to the chemistry standard.

TOF spectra for runs on the standard and blank (Fig. 1) show that the ^{127}I peak is adequately resolved for samples having an $^{129}I/^{127}I$ ratio down to about 10^{-12}. We determined that the apparent levelling off of the ^{127}I tail at the ^{129}I location in the TOF spectrum for the blank was not due to ^{129}I or ^{129}Xe in the sample by moving the analysers off the mass 129 peak and noting that the intensity of the tail remained a factor of ~10^3 below the ^{127}I peak. The ^{127}I rejection factor for each of the analysis stages was approximately as follows: inflection magnet, 3; 90° magnet, 10^5; electrostatic analyser, 10^4; TOF, 10^3.

Although Xe^- is probably unstable, XeF^- has been accelerated in tandems (H. E. Wegner and P. Thieberger, personal communication) and xenon may form other stable or metastable molecular negative ions. As Xe is a likely contaminant in the samples and in the residual gas of the ion source, we felt that it was important to determine whether there is any ^{129}Xe contribution to the mass 129 peak. With the analysis system set for ^{129}I from the reagent AgI blank, pure Xe gas was introduced into the source until the pressure increased a factor of two to 5×10^{-5} torr. The mass 129 counting rate then increased from 1 c.p.m. (which corresponded to a background level of $^{129}I/^{127}I = 6\times10^{-13}$) to 5 c.p.m. Further optimization with a source geometry more appropriate for a gas sample led to a maximum counting rate of 3,500 c.p.m., and this dropped by more than a factor of 100 soon after the gas was turned off. A mass scan with the inflection magnet (which directly follows the ion source) revealed that the Xe was being injected into the tandem as a molecular negative ion with $M/q = -131$ (such as $^{129}XeH_2^-$) although the $^{129}Xe^-$ ion could not be completely ruled out because of the limited resolution of the inflection magnet. (The resolution of the post-acceleration analysis and TOF were adequate to positively identify mass 129, charge state 5 ions. This, together with the high counting rate that was correlated with Xe pressure, is strong evidence that we were counting only $^{129}Xe^{5+}$). The counting rate was low compared to what might be expected from the $\sim10^{10}$ Xe atoms being exposed to Cs in the sputter source. This can be explained if the probability of forming the (molecular) negative ion is low, if the cross-section for destruction in electric and magnetic fields is high, or if the ion is metastable with a life time short compared with the 15 μs trip to the terminal of the tandem. We estimate that if the residual gas in the source contains Xe in atmospheric concentrations (1.1 p.p.m.) and the Xe content of the samples is low (<1 p.p.m.) then the ^{129}Xe will not contribute to the ^{129}I background until a sensitivity for ^{129}I of one part in 10^{18} is reached.

The $^{129}I/^{127}I$ ratios (Table 1) were obtained by cycling the magnets between the two isotopes: the ^{129}I was counted for 3–5 min, then the $^{127}I^{5+}$ current was measured in a Faraday cup following the 90° analyser. The transmission efficiency of the TOF detector ($\sim$30%) was continuously monitored with the ^{127}I ions. The 1σ errors are estimated from the scatter in the individual cycles and reflect both statistics and random fluctuations in the ion source output and accelerator transmission. Systematic errors such as those due to mass fractionation and current calibration contributes an additional uncertainty of $\sim$20% to results for the standards, but most of these effects cancel out for the meteorite results because they are reported as ratios to the standard.

Preparation of the meteorite samples and an interpretation of their ^{129}I content will be subjects of another paper. The results given in Table 1 demonstrate that 10–20 g of meteorite are adequate for detailed ^{129}I analysis. The upper limit for the $^{129}I/^{127}I$ ratio of 0.3×10^{-12} for the reagent blank implies that the background level for a 1 mg AgI sample corresponds to less than 2×10^6 atoms of ^{129}I.

We are presently modifying the apparatus to reduce the ^{127}I tail and increase the sensitivity. A new inflection magnet with a resolution $M/\Delta M$ of better than 150 will reduce the number of $^{127}I^-$ ions that are injected into the accelerator by 2 or 3 orders of magnitude and will also reduce the contribution from a Xe molecular negative ion. This magnet, together with improved vacuum in the electrostatic analyser, should reduce the ^{127}I interference so that it no longer limits the sensitivity. At the same time the sensitivity will be further improved by increasing the $^{127}I^-$ beam current to over 10 μA with a new ion source and by obtaining better transmission in the TOF detector. We anticipate being able to measure $^{129}I/^{127}I$ ratios in 1-mg iodide samples below 10^{-15}, a level that has already been reached with ^{36}Cl detection[16].

We thank T. S. Lund and the rest of the NSRL staff for technical assistance. This work was supported by the NSF Grant 77-29843 and in part by the NSERC of Canada. R. P. B. is a Killam fellow.

Channel CO_2 in cordierites

Th. Armbruster & F. D. Bloss

Department of Geological Sciences, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

The formulae commonly cited for cordierite usually ignore the occupants of the structural channels that run parallel to the c-axis. Recently, however, it has been shown[1] that two of the more common channel occupants, Na^+ and molecular H_2O, significantly modify cordierite's refractive indices (α, β, γ), optic angle ($2V_x$), unit cell dimensions, and the distortion index (Δ) defined by Miyashiro[2]. Indeed, for 11 natural cordierites, excluding indialites, Δ correlates almost entirely with channel Na^+ and/or H_2O and with R_a, the average radius of the ions occupying the octahedral sites, but not (as long believed) with Al/Si ordering. After heating at 800 °C for 6 h, Δ increased for the four crystals remeasured, and $2V_x$ increased for the nine optically (−) crystals but decreased to below 90° for the two optically (+) crystals. Selkregg and Bloss[1] attributed these effects to loss of channel H_2O and/or Na^+ but did not explain why the two (+) crystals became (−) after heating. We report here that loss of molecular CO_2, a frequently reported channel occupant[3–5], was the reason. We observe that for Mg-cordierite, $2V_x$ is $\sim$87° if its channels are vacant, decreases to 45° or less as channel H_2O increases and increases to 114° with increasing channel CO_2 (but no H_2O). Channel CO_2 is apparently the long-sought-for cause of optically (+) cordierites.

The previously unexplained occurrences of (+) and (−) cordierites on opposite sides of a fault[6] probably represent control of CO_2 distribution by the fault. The seemingly capricious variation of $2V_x$, for cordierites with comparable Mg/Fe ratios, probably results from channel occupancy by varying proportions of H_2O and CO_2 and, perhaps, other channel occupants. In view of the importance of the channel occupants, the formula for cordierite should perhaps be

$$\mathrm{Na}_{x+2y}(\mathrm{Mg,Fe,Mn})^{\mathrm{vi}}_{2-y}(\mathrm{Al}_{4-x}\mathrm{Be}_x\mathrm{Si}_5)^{\mathrm{iv}}\mathrm{O}_{18}\cdot n[\mathrm{H_2O,CO_2}]$$

where y allows for vacancies in the octahedral sites[1,7] which, like substitution of Be^{2+} for Al^{3+}, seem to correlate with channel Na^+. The formula does not accommodate the tetrahedral vacancies reported by Wallace and Wenk[7], or additional channel occupants, but these might be relatively minor in amount and effect.

Cordierite occurs in a wide variety of metamorphic and igneous rocks and, by its presence or absence, conveys information regarding their conditions of formation. In the ceramic industry, its easy synthesis and high resistance to thermal shock favour its use in spark plugs, catalytic supports to treat automobile exhaust and, in the future, for fabrication of turbine engines. Consequently, solution of the long-standing

0028–0836/80/280140–02$01.00

mystery of why some cordierites are optically (+) but most are (−) seemed important because the factors involved, whether chemical or structural, might influence the stability and conditions of formation of cordierite.

Spindle stage studies[8] of 20 natural cordierites disclosed five to be optically (+) with $2V_x > 90°$. Microprobe analyses revealed no significant compositional differences that correlated with optic sign. However, IR spectra between 200 cm^{-1} and 4,000 cm^{-1} exhibited not only H_2O bands, but also CO_2 absorption bands near 2,350 cm^{-1}. These were intense for the (+) cordierites but weaker for the (−) cordierites. Refractive indices measured to 0.0005 by the double variation method disclosed that the (+) cordierites possessed higher refractive indices and birefringence (γ–α) compared with optically (−) crystals with the same iron content. When heated to 800–1,200 °C to expel the more volatile channel occupants, $2V_x$ increased for the (−) crystals but decreased for the (+) crystals.

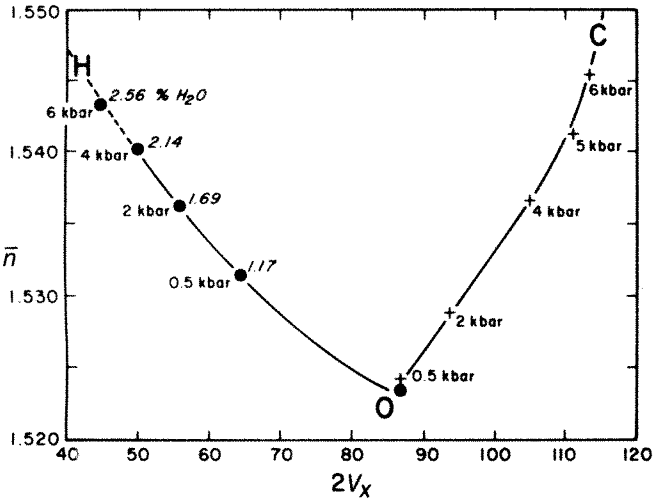

Fig. 1 Plot of the average index $\bar{n}$ [$\bar{n} = (\alpha + \beta + \gamma)/3$] versus $2V_x$ (averaged for wavelengths 400, 666 and 900 nm) for White Well cordierite after tempering at 1,300 °C for 30 h (point O), for this same material after CO_2 was forced into it at increasing CO_2 pressures (plus signs on line OC), and after H_2O was forced into it (● on line HO). The weight percentages of H_2O were estimated using the equations of Medenbach *et al.*[9]. Weight percentages of CO_2 are yet to be determined but the increase in $\bar{n}$ clearly shows that increasing quantities of CO_2 are being forced into the channels as CO_2 pressure increases.

The influence of channel CO_2 and H_2O on the optical properties of Mg-cordierite was more directly investigated using a (−) cordierite from White Well, Australia ($a = 17.065$Å, $b = 9.724$Å, $c = 9.346$Å; optic orientation, $a = Z$, $b = Y$, $c = X$). This specimen's optical properties were measured before and after tempering for 30 h at 1,300 °C in air to expel channel CO_2 and H_2O. Crystals thus tempered were also examined after being annealed for 30 days at 600 °C and at various pressures of H_2O and of CO_2 (from decomposition of $Ag_2C_2O_4$). The results (Fig. 1) clearly reveal the opposite effects on $2V_x$ of CO_2 and H_2O; however, both increase the average index $\bar{n}$ [$\bar{n} = (\alpha + \beta + \gamma)/3$]. Surprisingly, IR spectra of the tempered material taken before its rehydration or recarbonation revealed Si–OH groups and/or H_2O that either survived the 1,300 °C heating or re-entered after heating. Microprobe analyses showed that about half of the channel Na had also survived this heating.

Table 1 reveals that the birefringence (γ–α) increases significantly with CO_2 and that the distortion index Δ decreases significantly with channel H_2O and CO_2. Thus decarbonation of a CO_2-rich cordierite by heating will cause Δ to increase whereas $2V_x$ and (γ–α) will decrease. This inverse correlation between $2V_x$ and Δ as channel CO_2 increases thus opposes the statement of Miyashiro[2] that, in general, the larger Δ, the larger $2V_x$ will be.

Table 1 Optical properties, cell edges* and distortion index Δ for the White Well cordierite†

	Natural	Tempered	Carbonated at 4 kbar	Hydrated at 4 kbar
α	1.5345	1.5235	1.5326	1.5386

†Optic orientation, $c = X$, $b = Y$, $a = Z$.
‡Average of measurements at 400, 666, and 900 nm.

IR spectra for single cordierite crystals[3] were later interpreted[4] as showing that 80% of the channel CO_2 molecules were aligned perpendicular to c ($= X$) with the other 20% possibly aligned parallel to c. The increases in refractive indices produced by carbonation of the tempered White Well cordierite—$\Delta\alpha = 0.0091$, $\Delta\beta = 0.0127$, $\Delta\gamma = 0.0181$; average increase 0.0133—suggest a dominant alignment of CO_2 parallel to the a-axis ($= Z$) because $\Delta\gamma$ significantly exceeds the average index increase of 0.0133. Alignment of CO_2 molecules parallel to the c-axis is not supported by this present evidence because $\Delta\alpha$ ($= 0.0091$) is significantly below the average increase of 0.0133.

The marked increase in refractive indices with channel CO_2 for cordierite suggests that H_2O contents, if calculated using the measured refractive indices and Fe contents for cordierite[10], will be too high when significant CO_2 is also present. Work in progress indicates that the amounts and relative proportions of channel H_2O and CO_2 will be readily determinable for single crystals of cordierite if spindle-stage measurements of $2V_x$ and refractive indices are followed by microprobe analyses for Na, Fe, Mg, and Mn. We know of no other technique, so relatively simple and routine, that can determine the same data for a single grain. Knowledge of the relative proportions and amounts of the volatile species trapped in the channels of cordierite has potential use as an indicator of metamorphic and magmatic fluids.

We thank Professors G. V. Gibbs, D. A. Hewitt, P. H. Ribbe, and D. R. Wones for criticism of the manuscript and other aid. We also thank Professor Lucian Zelazny for use of the IR equipment in his laboratory. H. R. Wenk loaned us a preprint of the Wallace and Wenk paper.

A fault plane solution for the Carlisle earthquake, 26 December 1979

Geoffrey King

Department of Geodesy and Geophysics, Madingley Rise, Madingley Road, Cambridge CB3 0EZ, UK

Deformation at plate boundaries is well determined from the fault parameters of large earthquakes but within plates relatively little is known. Although other methods of measuring *in situ* stress are available only intra-plate earthquakes provide information about stresses at depths of several kilometres[1]. Accurate location and the determination of fault parameters for intra-plate earthquakes is difficult because such earthquakes are rare and generally too small to be widely recorded. This problem has been overcome in parts of the eastern USA by installing permanent dense seismometer networks, and brief aftershock studies of the type described here. Our aftershock study has provided an accurate location of a significant UK earthquake, and a reliable measure of compression direction in a region of Europe distant from the influence of Alpine motion.

On the 26 December 1979 at 03h 57min an earthquake occurred north of Carlisle. The same day the Institute of Geological Sciences (IGS) in Edinburgh reported the shock to be $m_b = 5.0$ and probably located close to Longtown. Their assessment of epicentral position was based on the occurrence, earlier in 1979, of three smaller shocks (now taken to be foreshocks) which occurred in the area. The region has some history of activity with an earthquake occurring in 1786 which was felt at distances of 300 km (similar to the recent earthquake) and a sequence of four earthquakes in 1901 (ref. 2).

Damage from the earthquake was slight but created wide publicity and interest. A preliminary survey of intensity was determined by telephoning local police stations in the area and confirmed the IGS view that an epicentre near Longtown was probable. On the basis of the foregoing evidence, an aftershock study using Sprengnether MEQ800 smoked drum recorders was initiated. Eight instruments were taken by car to Carlisle, arriving in heavy rain and floods, and one instrument was installed at 1800 GMT on the same day as the earthquake. A small earthquake at 05.39 on 27 December confirmed, with a 1.1 s S–P time, that the aftershock sequence was likely to be close to Longtown. An array of instruments indicated in Fig. 1 was deployed. A maximum of seven stations were operated simultaneously. Station 1 was moved because of site noise. Other changes in instrument disposition were carried out in response to preliminary locations with a view to optimizing location accuracy and fault plane solution resolution.

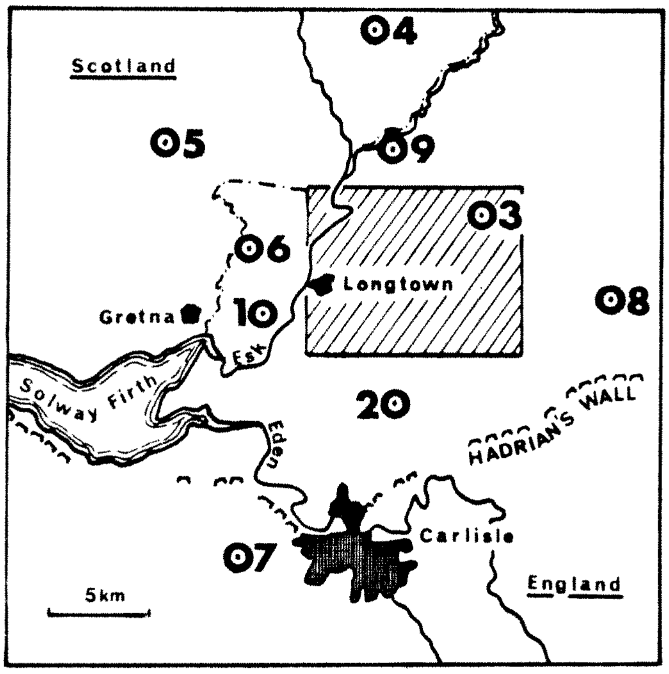

Fig. 1 The area of the survey showing station locations. The shaded area is enlarged in Fig. 2.

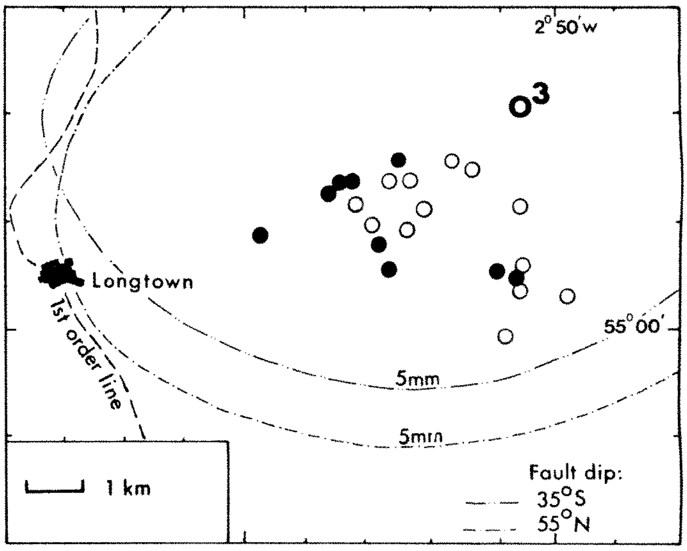

Fig. 2 Epicentral locations. ●, Shocks located with an error less than 1 km; ○, shocks located with an error less than 2 km. The 5-mm contour of predicted uplift is shown for both possible fault planes. The route of a first-order levelling line is also shown. The velocity model used for the locations and the fault plane solution was marginally the best of a set used to test the stability of the locations. It had a 3.3 km s^{-1} layer 1-km thick, a 5.0 km s^{-1} layer 4-km thick, a 5.7 km s^{-1} layer 15-km thick and the Moho velocity was taken to be 8.0 km s^{-1}. Because of the obvious lateral variation of the geology of the region on a scale comparable with the size of the seismograph array and the model insensitivity of the location procedure, the model adopted has no definite geological significance.

Selecting good sites proved impossible with many seismometers placed in the muddy middles of rain flooded fields. This reduced noise from rural roads and noise from the many trees and bushes. However, despite these difficulties, good low noise records were obtained. During the evening of 27 December temperatures dropped well below freezing and the ground remained frozen until after the stations were removed. The improvement of coupling was substantial and some seismometers were chipped out of the ice with difficulty. There was no wind during the recording period and cultural noise was generally low, only increasing on the 2 January 1980; 1 January, 1980 was particularly quiet. Low noise at this time was particularly fortunate as a major burst of seismic activity started in the early hours of the New Year with the major aftershock ($m_b = 3$) of the sequence occurring at 05.06 GMT.

Twenty-seven earthquakes were recorded on four or more stations. Of these 22 provided satisfactory hypocentral locations (with errors less than 2 km) and nine were located to

0028-0836/80/280142-02$01.00

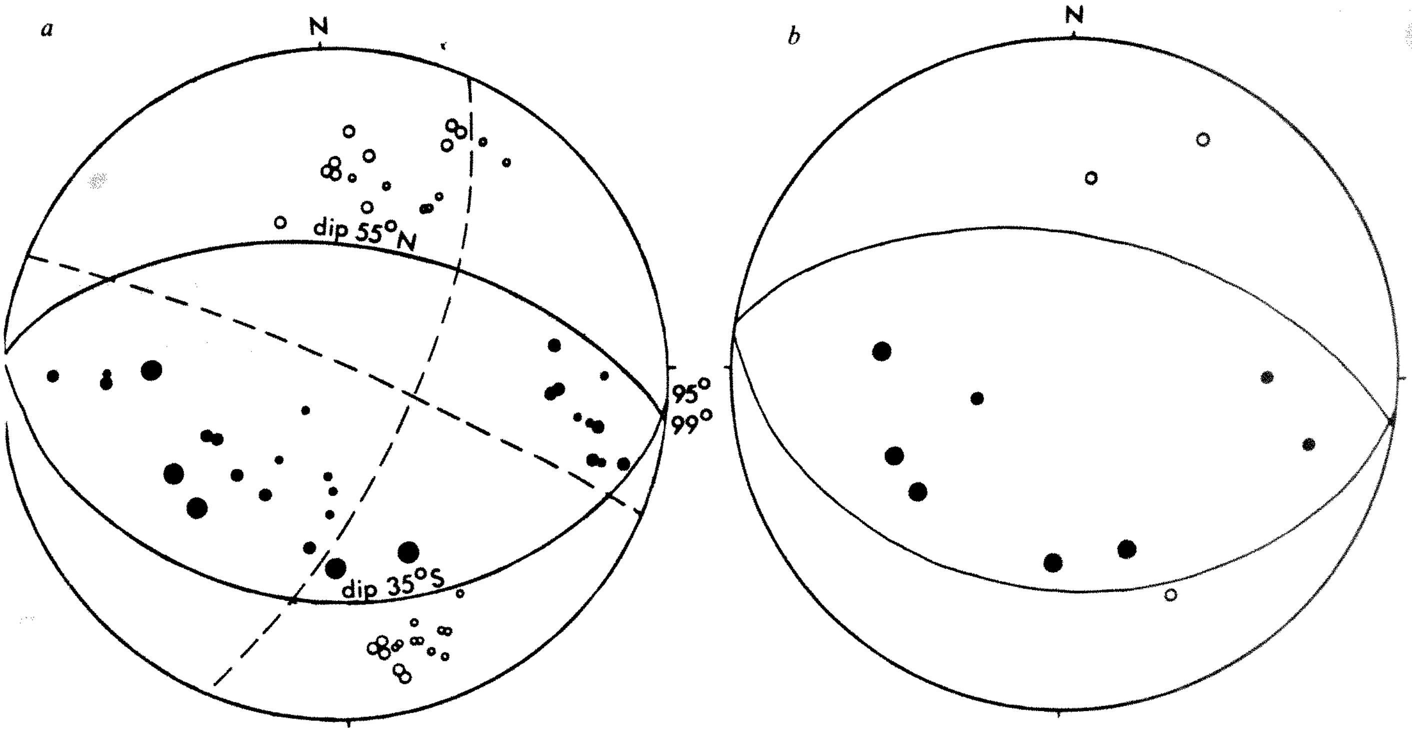

Fig. 3 *a*, Composite fault plane solution for the earthquakes shown in Fig. 2. Large circles, well located earthquakes; small circles, moderately located earthquakes: solid circles, compressions; open circles, dilatations. The very large circles are distant stations, and are all compressional. These latter data constrain the solution to be thrusting shown by solid lines and not strike-slip shown by dotted lines (the aftershock distribution also supports this conclusion). The nodal planes strike at 99° or 95° with dips of 35°S or 55°N respectively. *b*, The fault plane solution using only data for the aftershock at 05.06 GMT on 1 January 1980.

within 1 km. Location was carried out using the HYP071 location program[3] using a rough estimate of velocity structure. No reliable information is available to constrain the shallow velocity structure apart from a general knowledge of the geology and travel time residuals in the location process. However, even velocity structures that caused systematic station residuals to appear did not change most locations by more than 1 km.

Many first motions were clearly readable. These are shown as a composite fault plane solution in Fig. 3*a*. The data from the portable stations alone do not exclude the possibility of a strike-slip solution. However, first motion data from more distant permanent stations for the main shock and some aftershocks exclude the strike-slip possibility.

The consistency of the fault plane solution also indicates that the chosen velocity structure was satisfactory and that the hypocentral depths which range between 3 and 12 km (mostly clustered near 7 km) are reasonable. However, an examination of the depth distribution of aftershocks does not provide any guide to which of the nodal planes in the fault plane solution is the orientation of the fault plane. The scatter suggests that more than one fault plane was involved in the aftershock sequence.

Using the relations described by Kanamori and Anderson[4] the magnitude of the earthquake can be converted to an approximate moment of 8×10^{23} dyn cm. Using a rigidity modulus of 3×10^{11} dyn cm^{-2} and assuming a typical displacement to fault diameter ratio of 10^{-4} (a stress drop of 30 bar) the earthquake source could have been an average of 30 cm of slip on a plane 3.5 km in diameter. The aftershock distribution which has dimensions not much greater than 3.5 km independently supports this rough estimate.

Using a dislocation model[5] the surface displacements for the earthquake can be calculated from the foregoing results. An uplift of 2 cm is expected approximately above the epicentre and the area over which displacement greater than 0.5 cm is predicted is shown in Fig. 3. A first-order levelling line crosses the region[6] and displacements on this line should be observable.

No direct guide to the nature of the source is provided from the geology of the area. In the region of the aftershocks the surface is covered by alluvium generally not more than a few tens of metres thick. Beneath this is some 600 m of Triassic sandstone with shales (perhaps with conglomerates at the base) and this in turn overlies 800–1,600 m of Carboniferous limestones interbedded with sandstones. The Carboniferous rests unconformably on Upper Silurian sediments (greywakes) folded and probably tilted near to vertical. This sequence is thought to extend to a depth of around 12 km.

All hypocentral locations lie within the Upper Silurian which is extensively faulted where it is exposed. Recent work has drawn attention to a major suture in these formations (the Iapetus suture) thought to pass through the region of the earthquake[7,8]. It is possible that the Carlisle earthquake is a reactivation of planes of weakness broadly associated with this suture.

I thank Graham Nielson and Chris Browitt of the IGS Edinburgh for advice and information, and Jerry Leggett for describing the geology of the region. The NERC are thanked for providing equipment and rapidly funding the venture. Peter King and Moira Dunlop provided field assistance.

Ocean bottom seismograph measurements in the Central Aleutians

Cliff Frohlich*, John G. Caldwell†, Alexander Malahoff‡, Gary V. Latham* & Jeff Lawton*

*Marine Science Institute, University of Texas, 700 The Strand, Galveston, Texas 77550
†4806 Grapevine, Houston, Texas 77045
‡National Ocean Survey, Cx4 NOAA Administration, Rockville, Maryland 20852

Bathymetric profiles of most oceanic trench regions show a well-defined outer rise seawards of the trench with numerous normal faults between the trench axis and the crest of the outer rise. Several investigators (see ref. 1 for review) have shown that the gross bathymetric features can be modelled quite well if they result from a simple mechanical bending of the subducting lithospheric plate. These results have encouraged searches for seismic evidence of the bending stresses predicted by the models. However, the available teleseismic studies[2] do not determine precisely the relative depths of events on the outer rise, or the precise locations of events relative to the trench. In 1979 we successfully deployed nine ocean-bottom seismometers[3] (OBS) which operated for 6 weeks on the outer trench slope in the Central Aleutians between the trench axis and the crest of the outer rise (Fig. 1). The locations, depths and focal mechanisms of the earthquakes located by this network all strongly support the bending hypothesis. In particular, we observed a band of seismicity on the outer trench slope extending ~60 km seaward of the trench axis (Fig. 1). The shallow events (Fig. 2) exhibit normal faulting (Fig. 3) and suggest tension in the upper part of the plate, while the deeper events (Fig. 2) exhibit thrusting mechanisms and suggest compression (Fig. 3). We suggest here that low magnitude seismic activity may be a common feature associated with the well-known normal faulting on the outer trench slope.

The 1979 OBS network located about 100 earthquakes (Fig. 1), including 30 events seaward of the trench axis. Eight of the OBS stations were deployed in an array (Fig. 1) of interlocking triangles with a station spacing of ~30 km. These eight stations covered a rectangular area ~40 km wide, extending from the trench axis to ~60 km seaward of the trench axis. A ninth station (Fig. 1) was deployed ~120 km seaward of the trench axis. No events were located more than 60 km seaward of the trench axis, and (S–P) times observed at the seawardmost station suggest that no such events occurred.

Nineteen of these events were located within about 20 km of the array, and 11 should have especially well determined depths, as they were observed at four or more stations with at least some observations of both P and S phases. Of these 11 events, the depths of seven were shallower than 13 km below sea level, or within about 6 km of the ocean floor, and the remaining four events were located with depths between 30 and 50 km below sea level. None of these earthquakes were located between depths of 13 and 30 km. The station spacing of 30 km allows the determination of relative depths with a precision of 10–15 km for events within or near the station network. Although location using alternate velocity models alters the depths determined for the events, the group of seven events shallower than 13 km remained distinctly shallower than the group of four events deeper than 30 km when these events were located using several different velocity models.

Previously, very little seismic activity has been reported seaward of the trench axis near the site of the present study. Near the trench only one teleseismic event with a tensional focal mechanism has been reported within ~400 km of our network[2,4], the event of 22 February 1958, with magnitude 6.75. No events were located seaward of the trench by a network of eight OBS stations that operated on the inner trench wall for 6 weeks in 1978 (Fig. 1). In addition, none of the events located seaward of the trench by the 1979 OBS network were located by the Adak network of seven land stations (Fig. 1) on the volcanic islands ~140 km north of the trench. In this region only 10 events, all with magnitude between 3.0 and 4.9, have been located by the Adak land network[5] since its installation in 1974. Apparently events seaward of the trench axis are seldom observed by stations landward of the trench either because phases from them are attenuated by structures in or near the trench, or else simply because most of the events are quite small. However, our data show that events with magnitudes of 2.0 and smaller do occur quite regularly in the zone seaward of the trench axis.

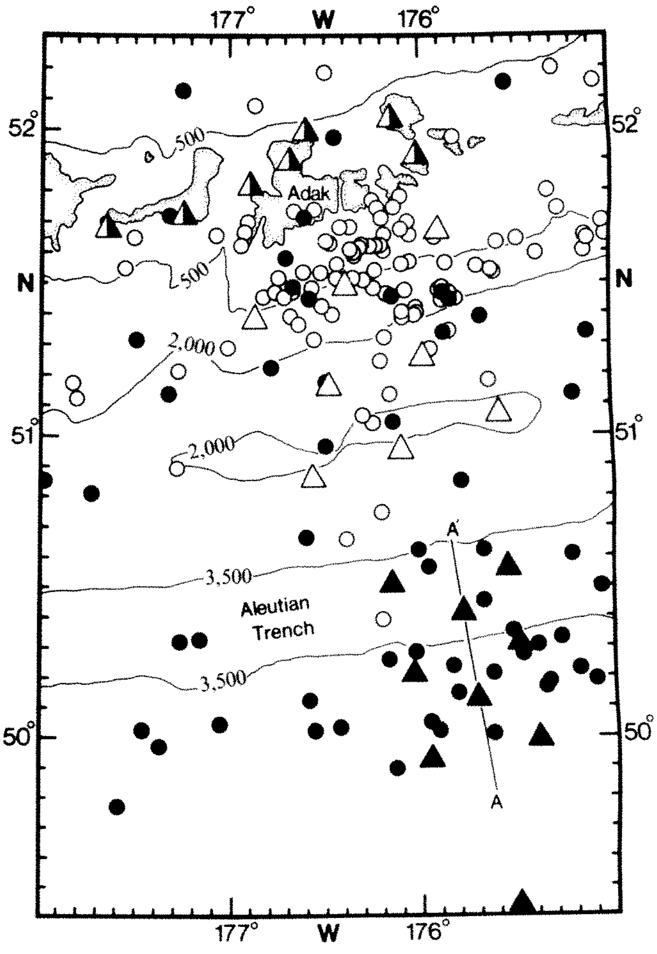

Fig. 1 Location of OBS and land stations in the Central Aleutians, and events located by the 1978 and 1979 OBS network; ▲, 1979 OBS station; △, 1978 OBS station; ◭, land station; ●, earthquake located by 1979 OBS stations; ○, earthquake located by 1978 OBS stations. Bathymetric contours are in fathoms. These events were located by using a program written by C.F. and a layered crustal structure similar to that used by Engdahl[5]. The line between A and A′ shows the location of the cross-section in Fig. 2.

With one exception, all the clear first motions of the events within our net were compressions (Fig. 3). For the shallow events, these compressional observations all lie near the edge of the projection of the focal sphere. This does not constrain the focal planes, but for a double couple mechanism, the observations are consistent only with normal faulting. For the deeper events, all the first motions lie in the centre of the projection of the focal sphere. As before, these observations do

0028–0836/80/280144–02$01.00

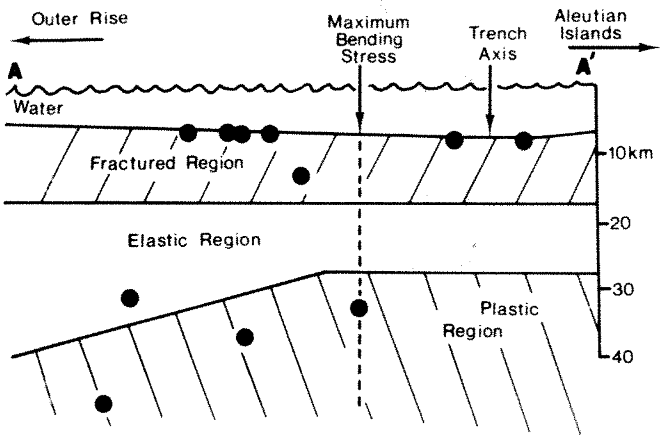

Fig. 2 Vertical cross-section perpendicular to strike of Aleutian Trench (Fig. 1) showing depths of 11 especially well-recorded earthquakes (●) that occurred within or close to the 1979 OBS network (no vertical exaggeration). Note that the Pacific plate extends to the left of the figure, and that it becomes subducted to the right of the figure beneath the Aleutian Islands. The depth chosen for each of these events is that of the minimum weighted r.m.s. residual on plots of r.m.s. residual versus depth. The location of the zone of maximum bending stress as well as the extent of the fractured, elastic and plastic regions were determined by Caldwell[7] from a study of the bathymetry in the Central Aleutians. For a model with a horizontal compressive stress of 5 kbar, he found that the effective elastic thickness of the lithosphere was ~55 km about 120 km seaward of the trench axis, but that the bending causes the elastic portion of the lithosphere to thin to ~10 km near where the maximum bending stress occurs 18 km seaward of the trench axis. Beneath the elastic zone, the compressional stresses exceed the elastic yield stress, producing earthquakes with compressional (thrusting) mechanisms below a depth of ~25 km. The upper 10–15 km of the lithosphere is a region of little strength[2,8], where extensional fractures produce normal faulting events.

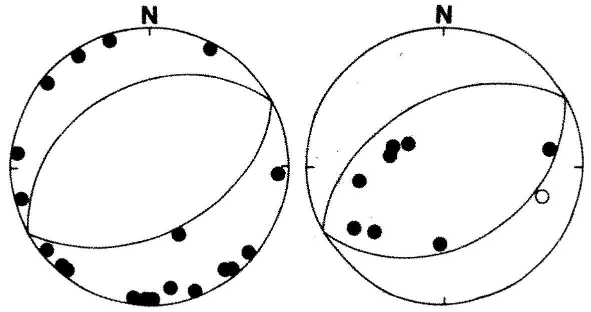
not constrain the focal planes, but in this case are consistent only with a thrusting mechanism.

These observations are consistent with normal faulting mechanisms in a shallow zone of extension a few km deep, overlying a quiet zone extending to a depth of ~30 km, which in turn overlies a zone of compression between 30 and 50 km which produces thrusting events. These results are quantitatively consistent with an elastic–plastic model[6] of the lithosphere with parameters determined solely from the bathymetry in the Central Aleutians[7] (Fig. 2). The extremely shallow events with tensional mechanisms are produced by extensional failure in the weak upper portion of the bending plate, while the deeper events occur where the compressional bending stresses exceed the yield stresses in the lower portion of the plate. From our data, the presence of seismicity seaward of the trench axis (Fig. 1) suggests that the yield stress is exceeded to at least 60 km from the trench axis.



Shallower events Deeper events

Fig. 3 Composite first motions for the seven shallowest events and the four deeper events that appear in the cross-section (Fig. 2). Compressions (●) and dilatations (○) are plotted on an equal area lower hemisphere projection. The focal planes shown are not constrained by the available first motions, but show clearly that the shallow events are consistent with tensional stresses oriented normal to the trench axis, whereas the deeper events are consistent with compressional stresses oriented normal to the trench axis.

Although we have determined reliable depths for only a few events, the present study provides the strongest seismic evidence available suggesting that plate bending occurs on the outer trench slope. Previously, earthquakes whose (S–P) times indicated they occurred seaward of the trench have been detected by an isolated OBS station on the outer trench slope[9], but this station could not locate the events. The uncertainty in the locations of our located events (Fig. 2) is considerably smaller than is possible for teleseismically located events, although our results are generally consistent with teleseismic observations of events seaward of the trench in several island arcs[2,10].

We thank Selena Billington and Wayne Pennington for useful discussions, and Jim Dorman, A. K. Ibrahim and Don Forsyth for reviewing an earlier version of this manuscript. This work was funded by the National Ocean Survey under contract MO-A01-78-00-4120, and cooperative agreement NA79AA-H-0082. We also appreciate the hospitality and support of the captain and crew of the NOAA ship Discoverer, from which we deployed the OBS stations.

Northern Hemisphere sea-ice and glacial development in the late Cenozoic

Stanley V. Margolis

Department of Oceanography, University of Hawaii, Honolulu, Hawaii 96822

Yvonne Herman

Department of Geology, Washington State University, Pullman, Washington 99164

Evidence for the initiation of glacial ice-rafting, and for the development of sea-ice cover has been found in sediment cores from the central Arctic Ocean spanning early Pliocene (~4.5 Myr BP) to Recent time. The glacial evidence reported here includes ice-rafted quartz grains, exhibiting glacially formed surface features, and benthic foraminifera endemic to continental shelves in core sediments from the Alpha Rise. The oldest evidence of ice-rafting occurs in sediments palaeomagnetically dated at ~4.5 Myr BP. Variations in sediment facies indicate varying climatic regimes, and degrees of icecover in the Arctic Ocean since early Pliocene time.

Planktonic foraminiferal fauna compositions and surface features of quartz sand grain in sedimentary cores recovered from drifting ice platforms in the Arctic Ocean from the crest and upper flank provinces of the Alpha Cordillera (Table 1) have been analysed to determine the history of sea ice

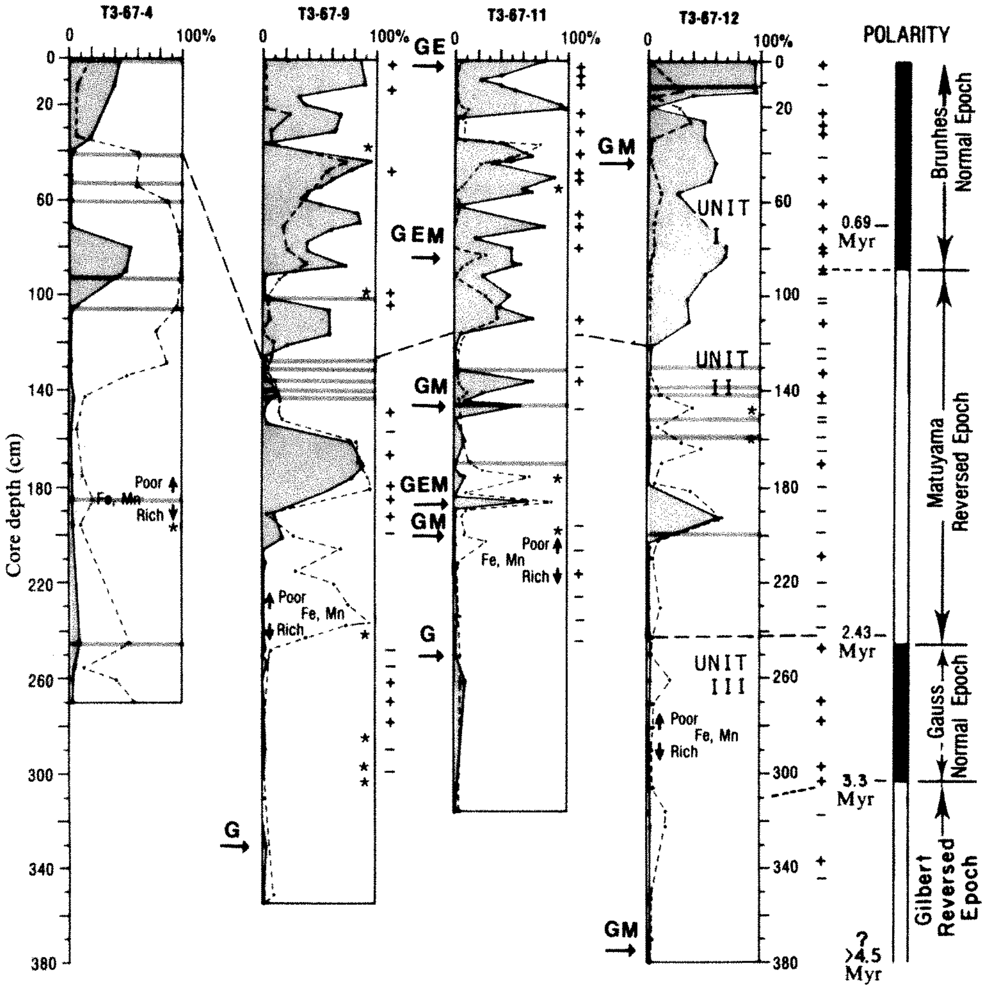

Fig. 1 Palaeomagnetic time scale[1] (right) and percentage of microfauna in coarse fraction (>62 µm) in cores T3-67-4, -9, -11, and -12. Shaded areas, microfauna; white areas, clastic particles. Dashed line and dots represents the percentage of the total planktonic foraminiferal population composed of *G. quinqueloba* and *G. egelida*. Dark horizontal bands are zones in which benthic foraminifers constitute 10% of the total fauna. *, low latitude planktonic foraminifera; +, −, magnetic polarity determinations[1, 11–18]. Dashed lines between cores show age and unit correlations based on palaeomagnetics and lithology. Arrows indicate levels from the cores where quartz sand grains were analysed, and the letters on top of arrows indicate environmental determinations: G, glacial surface features; M, marine (subaqueous abrasion) features; E, aeolian features[3,4]. Figure modified after ref. 2.

development, iceberg production and polar ice-cap growth of the surrounding continents. Magnetic stratigraphy of these cores[1] and radiometric dates, together with biostratigraphic and lithological correlations (Fig. 1), provide age control points since the early Pliocene[2]. N. D. Opdyke (personal communication) has suggested that core T3-67-12 contains the Gauss/Gilbert boundary at a depth of about 310 cm, and that the bottom of the core is between 4.5 and 5 Myr old. R. Z. Poore (personal communication) thinks that the bottom of this core is still in Gauss sediments with a maximum age of ~3.0 Myr. Opdyke's interpretation is shown in Fig. 1. Within this time interval, we have recognized three major oceanic sediment regimes in the Arctic, here represented as climatic units. The earliest, Unit III, contains sediments deposited between ~4.5 and 2.5 Myr (ref. 1) and consist of manganese–iron micronodule-bearing red clays. Rock fragments and mineral grains of ice-rafted origin were identified from three samples from this unit (Fig. 1). As this represents perhaps the oldest described evidence of Arctic Ocean ice-rafting, confirmation of the glacial (ice-rafted) origin of these sediments was sought by scanning electron microscopic examination of surface features on sand grains for environmental determinations[3,4]. Quartz sand grains from Unit III from sediments ~4.5 Myr BP (ref. 1) exhibit surface features (Fig. 2) consistent with a cycle of glacial abrasion before their transport to this region from the surrounding shelves and/or continents. Quartz sand grains were selected from the >62 µm washed fraction from representative sections of each climatic unit. The samples examined are indicated by arrows on Fig. 1. Two samples, not illustrated, from Drill Station A-4 (Table 1) which contains sediments of Brunhes age belonging to Unit I were also examined and found to contain glacial and glacial marine features. About 50 grains were selected randomly from each sample, to represent the range of sizes and shapes present. The grains were petrographically examined to ensure that they were unicrystalline quartz, and then examined by scanning electron microscopy to determine the occurrence and distribution of environmentally diagnostic surface features as described in refs 3, 4. A more thorough presentation of these data will be published elsewhere. Grains also show evidence of subaqueous abrasion (Fig. 2) indicative of either current or wave action after the glacial abrasion. The grains examined from these samples correspond to the 'glacial' and 'glacial marine' categories[3,4]. Sand grains such as these could be derived from glacial deposits from the continental regions surrounding the Arctic Ocean, as well as from shelves, and transported by icebergs, shelf ice, or sea ice hundreds of kilometres to their present site.

The funa in sediments from Unit III is sparse, constituting <1% of coarse fraction (>62 µm, Fig. 2). The planktonic foraminifera are dominated by the robust, polar, left-coiling *Neogloboquadrina pachyderma* complex, some of which are corroded. Shell fragments are abundant, and the solution susceptible tests of juvenile specimens are rare in this unit.

Scattered occurrences of low latitude planktonic foraminifers in this unit as well as in the 'foraminifera-poor' layers of Units II and I have been reported elsewhere[2,5] (Figs 1,3). Their presence was suggested to be due to transport by ocean currents from the Atlantic and Pacific during periods of more active water exchange between the Arctic and adjacent oceans[6] or to transport by shelf ice (Y. H. unpublished data). Barents Sea data indicate that shells of planktonic organisms carried from low latitudes by the warm Norway Current and deposited on the floor of the Barents Shelf may have been incorporated into grounded shelf ice. Subsequently, during periods of calving and drift over the Arctic, the incorporated debris was dropped to the sea floor. Benthic foraminifera are represented by deep-water (solution-resistant) agglutinated forms and robust, calcareous elements^{2,5}. Rare, shallow-water elements are also present, indicating transport by icebergs and/or islands from shelf areas^{2,5}.

The Unit III/II boundary is defined by simultaneous lithological and faunal changes, and coincides very roughly with the Gauss/Matuyama boundary (Fig. 1). The change is from the red clays in Unit III to tan silts in Unit II, which contain more abundant coarse ice-rafted sediments. Ice-rafted quartz sand grains from this unit differ from those of Unit III not only in abundance, but also in their surface features. Grains from Unit II show a greater percentage of subaqueous abrasion, overgrowths, and also aeolian features in comparison to features of glacial origin (Fig. 2). The aeolian/subaqueous/glacial combination are typical of periglacial environments presently found in Alaska^{3}.

Planktonic foraminifers in Unit II are dominated by the extant subpolar species *Globigerina egelida* and *Globigerina quinqueloba*. These two solution susceptible species constitute up to 99% of the fauna in cores raised from depths shallower than ~2,400 m; however, their relative abundance decreases considerably in deeper water sediments^{2,5} (Figs 1 and 3). The right-coiling subpolar *N. pachyderma* complex attains highest frequencies in this unit's sediments^{5} (Fig. 3).

The benthic foraminifers have both deep- and shallow-water representatives. Among the latter, species belonging to *Elphidium*, endemic to continental shelves, are abundantly represented, constituting up to 50% of the benthic elements (Fig. 3). Deep-water species are varied, both calcareous and arenaceous elements being common^{5}.

The Unit II/I boundary is again defined by both faunal and lithological changes, and occurs near the Brunhes/Matuyama magnetic boundary^{2} (Fig. 1). Brunhes sediments, representing the last major climatic regime, are composed of alternating foraminifera-rich and foraminifera-poor layers. The former represent conditions similar to those prevailing today (perennial sea–ice cover)^{5}; the latter perhaps short, milder, lower salinity intervals, comparable to those of the Matuyama epoch. The planktonic fauna is dominated by the polar left-coiling *N. pachyderma* complex; however, *G. quinqueloba*, capable of withstanding low salinities (Y.H. unpublished data), attains high frequencies near several of the foram-rich/foram-poor boundaries; benthic foraminifers are varied and ice-rafted debris is scattered throughout Brunhes sediments (Figs 1 and 3).

Two samples from the foram-rich zones of Unit I show surface features indicative of glacial marine and aeolian periglacial origin (Fig. 2), while grains from the foram-poor zones show typical glacial surface features similar to those from Unit II Matuyama sediments.

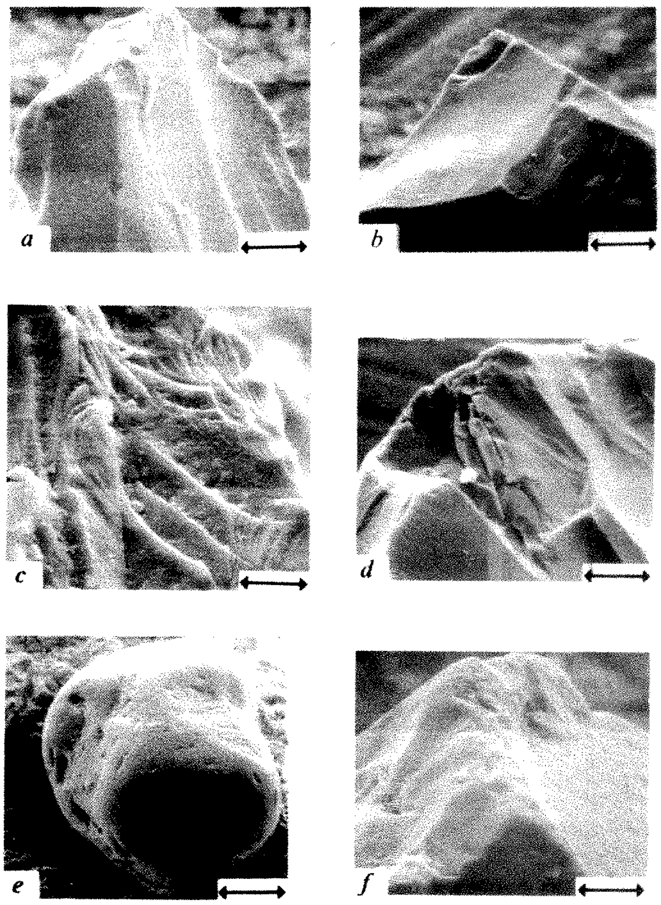

Fig. 2 Scanning electron micrographs of quartz sand grains from Arctic Ocean cores shown in Fig. 1. *a*, Sand grain from core T3-67-9, 330 cm depth (Unit III). Showing sharp angular outline, step shaped fractures and conchoidal fractures; typical of grains subject to glacial action, scale bar, 20 μm. *b*, Edge of quartz grain from core T3-67-12, 375 cm depth (Unit III), showing conchoidal fractures, semi-parallel steps, striations, and other features shown in *a*, scale bar, 20 μm. *c*, Sand grain from core T3-67-11, 85 cm depth (Unit I) showing high relief, large breakage blocks and conchoidal fractures typical of grains of glacial origin, scale bar, 10 μm. *d*, Grain from core T3-67-11, 188 cm depth (Unit II) showing typical glacial surface features over a larger area of the grain, scale bar, 20 μm. *e*, Grain from core T3-67-11, 188 cm depth (Unit II) showing abrasion features and rounded outline typical of grains with a history of marine-subaqueous transport, scale bar, 200 μm. *f*, Grain from core T3-67-9, 330 cm depth (Unit III) showing glacial features modified by aeolian features along right-hand margin, and on centre ridge, scale bar, 20 μm.

The differences between quartz grains from the three units can be summarized as follows: samples from Unit III contain fewer and smaller (<250 μm) grains and higher percentage of rounded aeolian and subaqueously abraded grains. Grains with glacial evidence also show superimposed features of subaqueous and aeolian origin. Samples from Unit II contain a greater number of large (>250 μm) and angular grains, exhibiting a mixture of aeolian and subaqueously abraded features. Unit I samples contain many large angular grains of glacial origin, with relatively few grains of mixed transport cycles.

Table 1 Locations, depths and lengths of cores

Core	Lat.	Long.	Depth (m)	Length (cm)
D.St.A.2	83°52′N	168°12′W	1,521	206
D.St.A.4	84°21′N	168°49′W	2,041	116
T3-67-3	79°11′N	175°09′W	2,285	380
T3-67-4	79°22.7′N	174°46′W	1,760	272
T3-67-9	79°37.9′N	172°07′W	2,237	356
T3-67-11	79°34.9′N	172°30′W	2,810	250
T3-67-12	80°21.9′N	173°33′W	2,867	374

The number of quartz grains of glacial increases in progressively younger sediments, while there is a decrease in the number of grains exhibiting features of mixed origins. In Brunhes sediments, however, there seems to be periods during which sediment transport conditions similar to those of the Matuyama prevailed.

There is relatively little information on pre-Pleistocene sediments from the Arctic Ocean. Ling *et al.*^{7} reported evidence for a warm, ice-free Arctic Ocean during Eocene and later times. A warm, temperate Arctic climate for the Palaeogene is discussed by Frakes and Kemp^{8}. The evidence of vigorous vertical mixing and relatively high biological production of the Arctic surface water preclude the existence of perennial ice cover between the late Miocene and the late Pliocene^{2,5,9}.

About 2.5 Myr ago a dramatic change in the structure of the Arctic Ocean water masses occurred, including the inception of density stratification. A stable, low-salinity, surface-water mass,

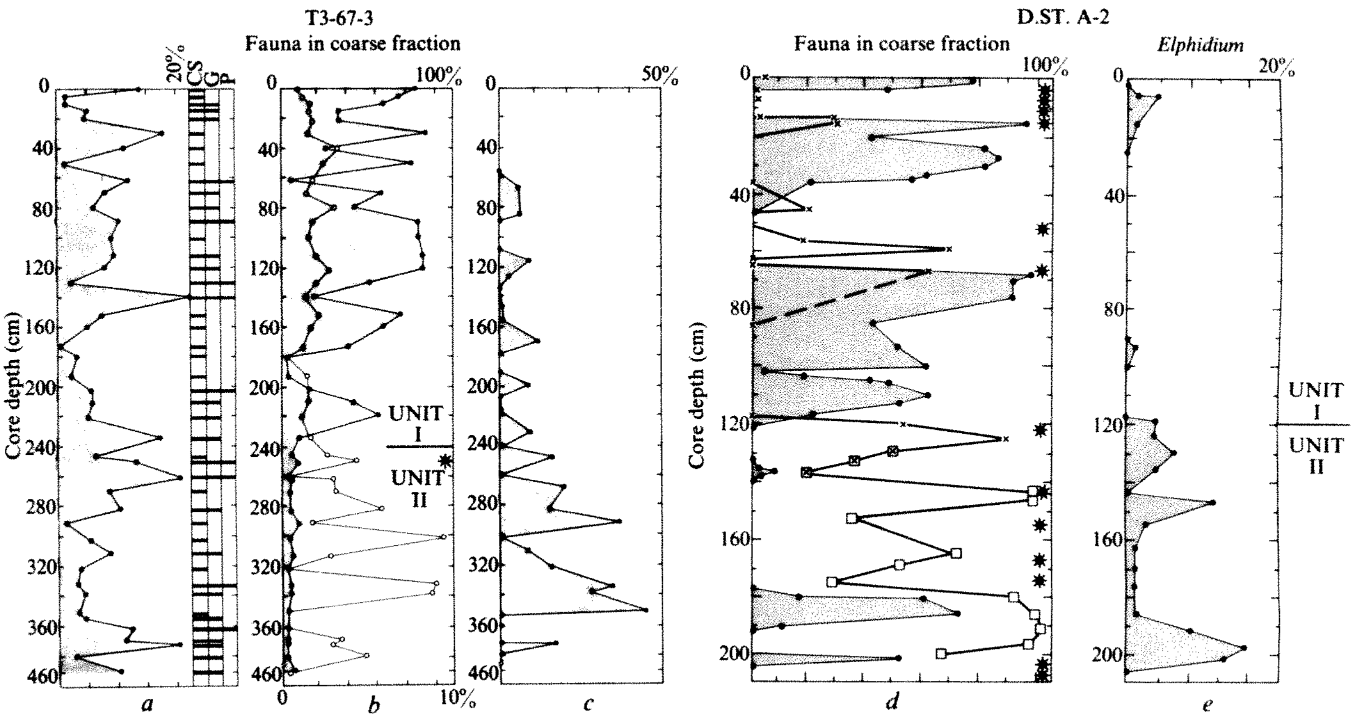

Fig. 3 Core T3-67-3. *a*, Percentage of coarse fraction (>62 μm). CS, coarse sand; G, granules; P, pebbles. *b*, Percentage of microfauna in the coarse fraction (>62 μm). (Modified after ref. 2.) Drill Station A2.

essential for sea ice formation, was developed at this time[2,5]. Whether temperatures were sufficiently low for pack ice to form, even seasonally, cannot be ascertained for certain with the present data. While most data suggest that global Matuyama temperatures were higher than Brunhes temperatures (see refs 11–17), Kennett[18] interprets his results to indicate the opposite. It can be assumed, however, that given the stratification, sea-ice cover was present during the winter. A major climatic threshold was crossed ~0.7 Myr ago, when, as a result of continued global cooling, perennial sea-ice cover developed over the Arctic Ocean[2,5].

Clark, however, has stated that the Arctic Ocean has been covered continuously with perennial ice from the middle Cenozoic to the present and that the ice cover was much thicker during the deposition of the 'foraminifera-poor beds' than today[19]. At present, the ice attains thicknesses of 3–4 m at the end of winter, decreasing to ~2–3 m in summer[20]. Field observations and theoretical calculations indicate that sea ice reaches an equilibrium thickness at ~4 m (ref. 21). Furthermore, evidence exists for much drier climates, with reduced snowfall during glacial episodes in the north polar region. This is a direct consequence of increased continentality caused by broadening of coastal plains due to lowered sea level[9], and reduction of moisture available to the atmosphere when ice covered extensive land and ocean areas.

Recently discovered calcareous nannofossils in Unit III sediments as well as in 'foraminifera-poor zones' and in transition sediments between foraminifera-poor and foraminifera-rich zones also preclude the existence of perennial ice cover during the deposition of these sediments[22] and further supports the interpretation of Herman[2,5] concerning the evolution Arctic oceanic-climate during the past 5 Myr.

Glacial–marine (ice-rafted) sediment was previously reported from the North Pacific Ocean by Krinsley[23] who found glacial surface features on quartz grains of late Pliocene age from DSDP site 178 (Alaskan Abyssal Plain). Other investigators[24–26] found evidence of ice-rafting in the North Pacific, Bering Sea, and the Norwegian–Greenland Seas in sediments of middle Pliocene age (≃2.4–3 Myr old), which is consistent with the oxygen isotopic evidence for major development of Northern Hemisphere glaciers about this time[27]. One core raised at site 344 (76°08.98′N; 07°52.52′E) contains glacial marine sediments throughout the Pliocene. It is not certain whether the entire Pliocene was recovered nor what processes of sedimentation were responsible for the deposition of the glacial marine debris: "ice rafting, turbidity currents or sedimentary suspension in water" has been suggested.

Occurrence of ice-rafted quartz sand grains and shallow-water benthic foraminifers endemic to continental shelves on the crest and upper flank provinces of the Alpha Rise in sediments deposited ~4.5 Myr ago[2] firmly establishes that high latitude Northern Hemisphere mountain glaciers developed and perhaps extended to sea level at least as early as the early Pliocene. In addition, the variations in sediment types, microfaunal and floral compositions, and abundance of ice-rafted and glacially produced detritus, all indicate the history of development of ice cover in the Arctic Ocean. Corroboration by similar data from other Arctic Ocean sites would make this date highly significant with respect to our understanding of the chronology of Northern Hemisphere glaciations and the eventual onset of the Pleistocene glacial/interglacial climatic cycles. Oxygen isotope analysis of calcareous foraminifera and nannoplankton from these cores is planned to correlate these sediment sequences with isotopic stratigraphies established elsewhere in the world's oceans.

We thank Kenneth Hunkins and his colleagues for collecting the cores, R. R. Capo and Floyd W. McCoy for sampling and shipping the core samples, D. M. Hopkins, R. Poore and J. Kennet for reviews. Coring operations were supported by several ONR grants to K.H. Curatorial services were supported by Lament-Doherty Geological Observatory grants ONR N00014-75-C-0210 and NSF DES 72-01568 A03. S.V.M. was supported by NSF grants OCE76-81961 and OCE78-25283, and by RHREP grants to Y.H.

Why are distasteful prey not cryptic?

John L. Gittleman & Paul H. Harvey

School of Biological Sciences, University of Sussex, Falmer,
Brighton BN1 9QG, UK

Bright coloration among unpalatable prey is common[1]. Turner[2] has suggested that, as with Fisher's explanation for the evolution of distastefulness itself[3], such aposematic coloration has been favoured by kin selection. Distasteful aposematic prey tend to live in kin groups and predators sampling from such groups will learn to avoid conspicuous prey more readily than cryptic prey and, as a consequence, fewer members of conspicuous kin groups are preyed upon[2,4–6]. We know of no clear evidence that vertebrate predators take fewer trials when learning to avoid conspicuous rather than cryptic distasteful prey[6,7]. Here we report results from a series of experiments that provide such evidence.

For 3 days post-hatch, male Warren Sex-Link chicks were fed on dyed blue and green chick crumbs of equal size, hue and texture, that were presented on a grey background against which we could detect no selective predation[8]. On day 4, individual chicks were placed in a holding box for 1 min before being released through a sliding door into a testing arena (80 × 60 cm) with a hardboard painted floor. The floor was interchangeably blue or green and on it were scattered 1,000 chick crumbs which had been made distasteful (by including 4 g quinine sulphate and 2 g mustard powder per 100 ml of dye solution). At this density the crumbs do not act as background to each other and selective predation by the chicks is similar to that at lower densities[9]. The crumbs were all the same colour, either blue or green. Individual chicks were allowed to feed for 2 min and were retested every hour for 13 h, that being the number of trials after which each chick had refused food on at least one occasion. Details of housing, lighting conditions, food preparation, the testing arena and feeding before experimentation, are as described elsewhere[7]. There were four treatments—floor and food blue, floor and food green, floor blue and food green, floor green and food blue—with nine chicks assigned to each.

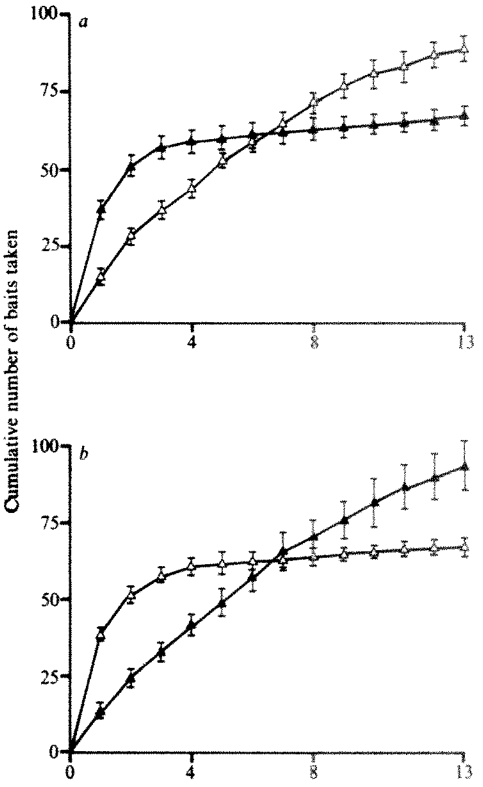

Fig. 1 Cumulative number of baits taken in successive trials. Experimental series: *a*, background green; *b*, background blue. Closed symbols represent experiments with blue food and open symbols green food. 95% confidence limits are shown.

The number of crumbs taken during the first (n_1) and subsequent trials (n_s), together with the number of trials before each chick refused food for the first time are shown in Table 1. In the first trial, more blue than green baits were taken when each was presented on a green background (Mann–Whitney $U = 0$, $P < 0.01$). Similarly, during the first trial more green were taken than blue when each was presented on a blue background ($U = 0$, $P < 0.01$). This we interpret as demonstrating crypticity of the crumbs against matching backgrounds. However, by the final trial the situation had changed: more green baits than blue had been taken ($n_1 + n_s$) against the green background ($U = 2$, $P < 0.01$), and more blue baits than green had been taken on the blue background ($U = 0$, $P < 0.01$). From the results shown in Fig. 1 it is apparent that the responses to the two treatments in each experiment were still diverging when testing was stopped.

These experiments indicate that chicks learn to avoid conspicuous more readily than cryptic distasteful prey. One or both of two mechanisms could be operating. First, the

appearance of conspicuous prey *per se* is learned more readily than that of cryptic prey. Second, eating large numbers of prey in a short time is a more powerful reinforcer than eating even greater numbers of prey over a longer time period. Either mechanism provides a proximate explanation for the functional hypothesis. Note that in these trials the chicks were not offered a food choice and that, therefore, the experiments do not mimic the evolution of aposematic coloration[7]. Whether the effect described here is large enough to favour the evolution of conspicuous coloration among unpalatable prey depends on various behavioural parameters, such as prey group size and the availability of other foods to the predator, in addition to the degree of unpalatability or toxicity of the prey.

We thank Dr P. P. G. Bateson for suggesting the type of experimental design used here, Dr J. R. Krebs for introducing us to the problem, Drs J. J. D. Greenwood and P. J. Greenwood for helpful criticism, and Mr Martyn Stenning for technical assistance.

Dopaminergic A10 neurones are involved in cognitive functions

Hervé Simon*†, Bernard Scatton‡ & Michel Le Moal*

* Laboratoire de Neurobiologie des Comportements, Université de Bordeaux II, 146 Rue Léo Saignat, 33076 Bordeaux Cedex, France

Delayed response tasks are widely considered to be particularly sensitive in demonstrating cognitive deficits after lesions of the prefrontal cortex in all species of mammals[1]. In rodents, these deficits are usually tested in a T-maze and are more pronounced after lesion of the anterior part of the striatum than after prefrontal cortex ablation[2]. In effect, the striatum is capable of assuming cortical functions either when the prefrontal cortex is poorly developed as in the lower mammals[3] or immature as in the early life of primates[4]. The prefrontal cortex and anterior striatum—the so-called prefrontal system[5]—are functionally and anatomically related. The prefrontal area specifically involved in delayed alternation[6] receives projections from the mediodorsal thalamic nucleus (MD)[7] and sends axons to the anterior striatum as well as to the MD[3,7]. Recently, a detailed anatomical study of the connections of the prefrontal system revealed the existence of important projections from the mesencephalic dopaminergic A10 neurones and the mediodorsal nucleus that converge on the prefrontal cortex[8]. Axons of the A10 system also project to the anterior part of the striatum[9,10]. The influence of dopaminergic A10 neurones on frontal lobe functions remains obscure, but some observations concerning the behavioural, pharmacological and biochemical effects of neuroleptics and psychostimulants have supported the idea that these dopaminergic neurones could have a role in the pathogenesis of schizophrenia[11–13]. Furthermore, the major symptoms observed in schizophrenic patients such as cognitive and attention disturbances have been attributed to a dysfunction of both prefrontal cortex and striatum[14–16]. Thus, in addition to their anatomical connections, the dopaminergic A10 neurones may be functionally related to the prefrontal cortex and striatum. These data encouraged us to investigate whether A10 neurones are functionally related to the prefrontal system and in particular if they are involved in cognitive processes measured in a delayed alternation task. We demonstrate here that selective lesions of dopaminergic A10 neurones in the rat produce a severe and specific impairment in retention of delayed alternation. On anatomical and behavioural grounds the dopaminergic A10 system could therefore be considered as a rather better indicator of frontal system function than the mediodorsal thalamic nucleus.

Fifteen male Sprague–Dawley rats (300–350 g) received, under ketamine anaesthesia (150 mg kg^{-1} intraperitoneally (i.p.)), bilateral stainless steel guide cannulae (0.65 mm) aimed 6.5 mm above the A10 cell bodies region. Stereotaxic coordinates were: 4 mm posterior to the bregma, 0.5 mm lateral to the midline and 2.2 mm below skull surface. Fifteen days after surgery, the delayed alternation experiment began according to the procedure of Wikmark *et al.*[2]. Briefly, animals deprived of food for 12 h were trained to enter alternately each arm of a T-maze for food with a fixed time between trials. Twenty-one trials were carried out daily until each rat made five errors or less in 3 consecutive days (91.66% of correct responses in 60 trials).

After the learning period, the animals were divided into control ($c = 6$) and experimental ($e = 9$) groups receiving vehicle or 6-hydroxydopamine (6-OHDA, 2 μg $\mu\mathrm{l}^{-1}$) injections respectively. The injections were made in unanaesthetized animals by lowering bilaterally an injection needle (0.30 mm) through the guide cannulae to the region of A10 cells (8.7 mm below the skull surface). A second injection was performed in similar conditions 3 d later. After another 10 d, the animals were tested for retention of delayed alternation according to the same paradigm as that used in the learning sessions. Training continued until the pre-injection criterion was reached.

Post-operative performances and gross behavioural analysis showed that experimental (6-OHDA–A10) animals presented a severe impairment in retention of delayed alternation. As indicated in Table 1, control rats showed no deterioration in performance between pre- and post-operative behavioural testing, as the number of errors was not statistically different. Moreover, the number of trials in retention was only slightly higher than the number of 60 trials imposed to reach the criterion. On the other hand, the 6-OHDA–A10 rats performed badly. In the first 60 post-injection trials, the 6-OHDA–A10 rats made many more errors than the control group ($t = 7.1$; $P < 0.001$). There was no difference in the errors made by the

Table 1 Learning and retention scores of delayed alternation responses

	Errors in the last 60 pre-operative and in the first 60 post-operative trials (mean ± s.e.m.)		No. of trials to reach criterion (mean ± s.e.m.)	
Group (*n*)	Pre-operative	Post-operative	Pre-operative	Post-operative
Control (6)	4.7 ± 0.3	5.1 ± 0.7	146.6 ± 12.3	70 ± 4.5
6-OHDA–A10 (9)	4.7 ± 0.2	19.6 ± 1.2*	148.9 ± 10	313.3 ± 33.9

There was a significant difference between control and experimental (6-OHDA–A10) groups in the number of errors in the first 60 post-operative trials and the number of post-operative trials needed to reach the criterion (Student's *t*-test, $P < 0.001$). As indicated by the number of errors in the first 60 post-operative trials compared with the last 60 pre-operative trials, the control animals did not show any deterioration of performance. On the contrary, many more post-operative than pre-operative trials were needed by the experimental (6-OHDA–A10) rats to reach the criterion (*paired test, $P < 0.01$).

Table 2 Learning and retention scores of visual discrimination

Group	(n)	Errors in the first 60 trials (mean ± s.e.m.) Post-operative	No. of trials to reach the criterion (mean ± s.e.m.) Pre-operative	Post-operative
Control	(5)	6.6 ± 0.5	116 ± 4	72 ± 5
6-OHDA–A10	(7)	6.3 ± 0.4	111.4 ± 6	71.4 ± 4

No statistical difference was observed between control and 6-OHDA–A10 lesioned rats. The number of trials for all rats in retention was only slightly greater than the 60 trials imposed to reach the criterion.

Table 3 Dopamine and serotonin contents after 6-OHDA injection (2 × 2 $\mu g\ \mu l^{-1}$) in the region of dopaminergic A10 cell bodies

		Dopamine (ng per g)			Serotonin (ng per g)	
Group	(n)	Frontal cortex	Nucleus accumbens	Anterior striatum	Frontal cortex	Hippocampus
Control	(6)	126 ± 10	8,290 ± 590	8,190 ± 1,310	539 ± 62	342 ± 33
6-OHDA–A10	(9)	39.7 ± 5.7	1,260 ± 150	2,230 ± 670	495 ± 26	241 ± 25

Note that 6-OHDA–A10 rats showed a big depletion of dopamine in forebrain projections, whereas serotonin levels were not significantly modified in the frontal cortex and decreased only slightly in the hippocampus. Values are mean ± s.e.m.

6-OHDA–A10 group between the first 60 post-operative trials (32.66%) and the first 60 initial trials in the learning period (32.40%). Post-operatively, the number of trials to reach the criterion was greater in 6-OHDA–A10 rats compared not only with the control group ($t = 5.6$; $P < 0.001$) but also with their own pre-injection level of performance ($t = 5$; $P < 0.001$). Gross behavioural analysis showed that, during the pre-operative learning of the delayed alternation response, the two groups of rats exhibited collateral behaviours such as rearing, stopping and returning before entering the chosen arm of the T-maze. These collateral behaviours were frequently observed at the beginning of acquisition and then disappeared progressively as the number of errors decreased. Post-operatively it was observed that the 6-OHDA–A10 rats demonstrated more collateral behaviours than the control rats. This difference was particularly evident during the 20 trials of the third post-operative session, that is when the control rats nearly reached the criterion (mean of rearings: $e = 2.10$, $c = 0.33$; stops: $e = 4.2$, $c = 2$; returns: $e = 2.20$, $c = 0.67$). According to these results the mean running time from the start box to the goal box of the T-maze was greater in 6-OHDA–A10 rats ($e = 4.5$ s, $c = 2.08$ s; Student's t-test: $t = 6.9$; $P < 0.001$). This running time did not shorten during the following trials, possibly indicating that post-operatively the experimental animals did not really relearn the task but rather developed a new strategy to reach the criterion. These behavioural observations might explain the nature of the deficit observed in the delayed task after lesion of A10 neurones. The experimental animals showed post-operatively more collateral or 'irrelevant' behaviours because they presented attentional deficits manifested by an enhanced distractibility or responsiveness to environmental stimuli. This renders the animals unable to select relevant information. In this respect, it is interesting that the frontal syndrome has also been interpreted in terms of attentional deficits[17].

Whatever the nature of the perturbation observed, the specificity of our results could be criticized. First, considering the fact that the experimental animals reached the food reward more slowly than control animals, the retention impairment could be explained by motivational deficits. To test this hypothesis, animals were trained in a straight alley divided into a start box, a runway and a goal box containing food reward. The running time for deprived animals to reach the goal box was considered as an index of their motivational state. Each animal was made to run daily in 10 consecutive trials over a period of 5 d. At the end of the experiment, it was found that the running time did not differ between the experimental (mean: 6.28 ± 1.31 s) and the control groups (mean: 5.93 ± 1.12 s). Second, it remained important to investigate if the perturbation observed in the delayed alternation task was not the result of more general learning disabilities. In this respect, it has been found that prefrontal lesioned animals have deficits in delayed alternation but not in discrimination tasks[1]. To test the specificity of a perturbation of delayed alternation after lesion of A10 neurones we carried out an additional experiment. Twelve naive rats maintained on 90% of *ad libitum* body weight, were trained in a Y-maze of the Lashley type for a visual discrimination task. Food reward signaled by light was randomly placed in the right or left arm of the maze. Twenty trials took place daily until the animals reached the criterion of 90% correct responses (6 errors or less in 3 consecutive sessions of 20 trials each). Then, the rats were divided into control ($n = 5$) and experimental ($n = 7$) groups. The control group rats received a saline injection and the experimental group 6-OHDA injections in the A10 cell bodies region, strictly according to the procedure previously used for the delayed alternation test. Fifteen days after the injections the rats were tested for retention of visual discrimination. As indicated in Table 2, the number of trials to reach the criterion and the mean of errors in the first 60 post-operative trials are similar for the two groups of rats.

At the end of the behavioural experiments, animals were decapitated and the brain quickly removed. The posterior part of the brain was kept out for histological examination of injection sites and the anterior part was used for biochemical assays as described previously[18]. Table 3 shows the biochemical results. Note that brain dopamine content of 6-OHDA rats was greatly depleted in the forebrain projections of A10 cell bodies such as the frontal cortex (−68.5%), the nucleus accumbens (−84.8%) and the anterior part of the striatum (−72.8%), whereas endogenous serotonin corresponding to raphe projections was not modified in the frontal cortex or only slightly decreased in the hippocampus (−29.5%).

In conclusion, our results suggest that the dopaminergic A10 neurones have a fundamental role in the processes required for the retention of the delayed alternation response. Supporting this view, it has recently been found that 6-OHDA injections in the frontal cortex of the monkey[19] and rat[20] or in the striatum of the rat[20,21] disrupted the delayed alternation response.

Moreover, we have demonstrated the critical influence of brainstem neurones on higher mental functions, such as cognitive processes, which have often been attributed exclusively to the prefrontal cortex. It could be considered that the sensory information reaching the A10 neurones[22] and conveyed to the prefrontal cortex and striatum are of particular importance for the normal functioning of the prefrontal system. Careful analysis of these A10–prefrontal system interrelations may be of special interest for future research dealing with cognitive representational functions and some pathophysiological states.

The role of ventral bundle noradrenergic neurones in sensory components of sexual behaviour and coitus-induced pseudopregnancy

S. Hansen, E. J. Stanfield & B. J. Everitt*

Department of Anatomy, University of Cambridge, Downing Street, Cambridge CB2 3DY, UK

Interaction of the female rat with the male in standardized laboratory conditions is characterized by two categories of behaviour. The first, known as proceptive behaviour, consists of a series of rapid movements by which she approaches and leaves the male, hopping and darting and wiggling her ears[1]. This behaviour, which is a response to visual, olfactory, and probably auditory cues from the male, serves to attract his sexual interest. As soon as the male mounts her, this behaviour is abruptly terminated and is replaced by a second (receptive) pattern[1]. The female becomes completely immobile and dorsiflexes her vertebral column to display a lordotic posture, which exposes her vagina and facilitates intromission by the male; this pattern results from tactile stimulation received by the female from the male as he mounts her[2,3]. Both these behaviours are under endocrine control since the female rat will only show them if she is exposed to the ovarian hormones oestradiol and progesterone[4]. However, proceptivity and receptivity clearly differ with regard to the neural mechanisms responsible for their activation, since different groups of afferent stimuli are required to set them in motion. We now show that a specific part of the ascending systems of noradrenergic neurones in the brain, that is carried in the ventral noradrenergic bundle[5], is critically involved in the mechanisms by which tactile stimuli elicit receptive, but not proceptive, behaviour in the female rat. The same system is also involved in the process by which genital stimuli activate another neuroendocrine phenomenon, the induction of pseudopregnancy.

The first experiment was carried out on ovariectomized animals injected daily with a low dose of oestradiol monobenzoate (0.2 μg) and with a single injection of progesterone (0.5 mg) between 4 and 6 hours before behavioural testing. Figure 1*a* shows that animals in which an electrolytic lesion of the ventral noradrenergic bundle had been made (Fig. 2) continued to display proceptive behaviours towards the male. However, in contrast to controls (who showed high levels of receptivity) ventral noradrenergic bundle-lesioned animals displayed greatly reduced levels of lordosis (receptive behaviour). The procedure was then repeated except that instead of an electrolytic lesion, 6-hydroxydopamine (6-OHDA) was injected at the same site. This neurotoxin induces selective degeneration of noradrenergic neurones when placed discretely in the small dose and volume (2 μg base in 0.5 μl Ringer's solution) used here[6]. Figure 1*a* shows that this resulted in similar behavioural consequences, females continuing to show proceptive behaviour, but only low levels of lordosis when they were mounted by the male. Table 1 shows that both electrolytic lesions (Fig. 2) and those produced by the neurotoxin 6-OHDA (Fig. 2) produced similar neurochemical changes, in that noradrenaline uptake in the hypothalamus was substantially decreased, whereas that in the cerebral cortex (which is supplied by the dorsal noradrenergic pathway) was unaffected. Very little or no nonspecific damage was seen around the site of injection of 6-OHDA and careful histological examination revealed that lemniscal and spinothalamic projections were undamaged. These experiments therefore suggest that the behavioural results that we observed were produced specifically by decreasing the noradrenaline content of the subcortical brain after a ventral noradrenergic bundle lesion.

The second experiment was carried out on intact animals showing regular oestrous cycles. The vagina of each rat was covered with tape to prevent intromissions during sexual interaction and so avoid episodes of pregnancy or pseudopregnancy. Such animals show recurrent periods of active sexual behaviour ('heat') every fourth day. Electrolytic lesions in the ventral noradrenergic bundle similar to those made in the first experiment did not prevent the postoperative occurrence of normal 4-day vaginal oestrous cycles, although these took longer to be re-established after operation than in the sham-operated

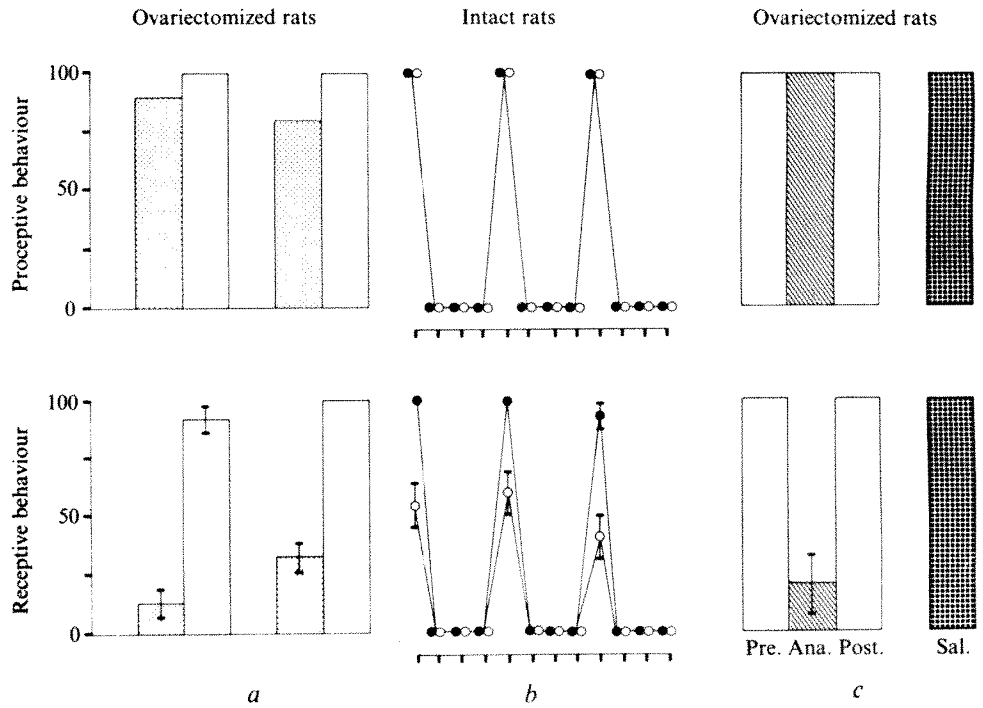

Fig. 1 The effects of ventral noradrenergic bundle (VNAB) lesions or procaine on the receptivity and proceptivity of female rats. *a*, Electrolytic lesions (1.5 mA, 10 s, insulated platinum electrode 0.4 mm o.d., columns 1 and 2) or 6-hydroxydopamine lesions (2 μg base in 0.5 μl 0.9% NaCl with 0.2% absorbic acid injected over 5 min through a cannula 0.3 mm o.d., columns 3 and 4) of the VNAB in ovariectomized rats treated with oestradiol and progesterone. Lesioned females are represented by cross-hatched columns, the receptive behaviour of lesioned females was significantly lower than controls ($P < 0.05$, Mann–Whitney *U*-test) in both cases. Coordinates for lesions were AP −0.5; L ±0.6; V −6.5 according to Konig and Klippel[15]. *b*, VNAB lesions in intact females, showing behavioural effects during three consecutive oestrous cycles (time scale on abcissa in days). Lesioned rats showed impaired lordosis responses (receptivity) during each period of oestrus ($P < 0.05$) while proceptivity was unaffected. Each female had her vagina covered to prevent intromissions. *c*, In ovariectomized oestrogen and progesterone treated rats, procaine-induced anaesthesia of the perineum (Ana.) significantly reduced ($P < 0.05$) receptivity when compared with pre- or post-anaesthesia scores or injection of normal saline (Sal.) at the same sites in the same volume as procaine. Proceptive behaviour was unaffected.

0028-0836/80/280152—03$01.00

controls (26.2 ± 2.4 days compared with 17.2 ± 1.3 days, $P<0.05$). However, Fig. 1*b* shows that the behavioural consequences which followed this procedure in intact animals were very similar to those seen in ovariectomized, oestrogen-treated ones described above. Both lesioned and control animals showed proceptive behaviours every fourth day on the night preceding the presumed time of ovulation. Only the controls showed high levels of receptivity while lesioned rats responded to attempted mounts by only infrequent lordosis. Thus, ventral noradrenergic bundle lesions produced the same behavioural syndrome in animals responding to their own hormones as was observed in ovariectomized animals given oestrogen and progesterone exogenously.

One interpretation of these results is that somatosensory information received from the male during mounting was not gaining access to the neural mechanism responsible for initiating lordosis (receptive) postures in the female rat. We therefore compared these results to those from a third experiment in which we studied behaviour after anaesthetizing the skin in the female's perineal region, to which the male applies tactile stimuli during mounting. Procaine was injected at four sites (0.25 ml per site as a 2% solution) around the perivaginal area as described previously[3]. Figure 1*c* shows that this procedure produced behavioural effects remarkably similar to those following ventral noradrenergic bundle lesions, rats showing marked deficiencies in receptivity but not in proceptivity.

Although these experiments showed, in a behavioural context, that the ventral noradrenergic bundle was clearly important in the transmission of tactile information generated during sexual interaction, we wanted to know whether this system of neurones could function similarly in any other neuroendocrine context. Tactile stimulation of the uterine cervix during copulation in the rat results in daily surges of prolactin which, by extending the lifespan of the corpus luteum, induces pseudopregnancy[7]. This stimulus can be mimicked by gently stimulating the cervix with a glass rod for 40 s during proestrus[8]. In a fourth experiment we found that 8 out of 11 unlesioned females so treated (73%) became pseudopregnant judging by the occurrence of persistent basal cells in their vaginal smears which were taken daily for about a week following stimulation. However, a similar procedure applied to 9 rats with lesions of the ventral noradrenergic bundle resulted in only 2 (22%) becoming pseudopregnant, the remainder continuing to show vaginal cycles after stimulation (Fisher's exact probability test $P=0.032$). This experiment suggests that the ventral noradrenergic pathway is concerned with somatosensory information important in neuroendocrine contexts other than those of regulating behaviour. But whether this only applies to stimuli derived from the genitalia, as explored in the present experiments, or can also extend to other parts of the body and other behavioural or physiological contexts, awaits further study.

It is known that tactile stimuli important in eliciting the receptive posture reach the brain via fibre systems running in the anterolateral columns of the spinal cord[9], and many of these fibres terminate in the vicinity of cell groups which contribute to the ventral noradrenergic bundle, particularly those lying in the ventro-lateral medulla and in the region medial to the superior olivary complex. It has also recently been shown that tritiated oestradiol is taken up into many noradrenergic cell bodies in the brain stem[11], which suggests a more direct relationship may exist between hormones which alter behaviour or pituitary secretion and this part of the noradrenergic pathway.

Table 1 Effects of electrolytic or neurotoxin lesion on the *in vitro* uptake of ^{3}H-noradrenaline by hypothalamic synaptosomes and slices or cerebral cortex slices

	% Decrease in active uptake of ^{3}H-noradrenaline *in vitro*	
Lesion	Hypothalamus	Cerebral cortex
Electrolytic	59.3%*	8%(NS)
6-Hydroxydopamine	65.8%*	13%(NS)

Incubations were performed in Krebs–Ringer bicarbonate buffer[16] with ^{3}H-noradrenaline at a concentration of 10^{-7} M. Data are expressed as % reductions compared with controls (sham lesions resulted in no significant depletions (<5%). The degree of reduction in active uptake is closely related to the degree of neuronal destruction[17]. NS, Not significant.

* $P<0.01$, comparison of original counts by *t*-test.

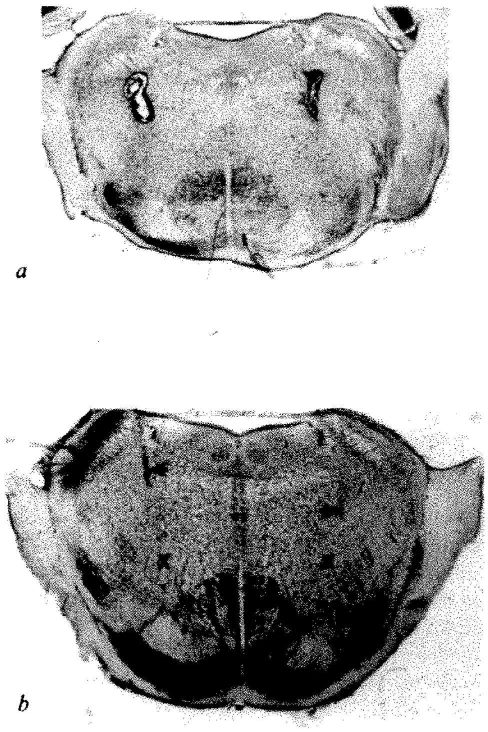

Fig. 2 Representative photomicrographs of electrolytic lesions of the VNAB (*a*) and the site of injection of 6–OHDA (*b*) which resulted in neurotoxic lesion of VNAB. In *a* the maximum dorsal–ventral extent of the lesion is shown, high power examination revealed necrosis and glial infiltration medial to the macroscopic lesion site. In *b* small glial scars can be seen (arrows) which indicate the site of descent of the micro-cannulae through which 6–OHDA was injected at depth *X*. No gross damage around the injection sites can be seen indicating that nonspecific effects of the injection were minimal. The neurochemical consequences of these lesions are shown in Table 1.

We suggest that ascending noradrenergic neurones carried in the ventral noradrenergic bundle and distributed to sub-cortical (hypothalamic and limbic) areas of the brain, may be an important pathway by which tactile information generated during sexual interaction modulates both behaviour and pituitary function. It becomes important to define, therefore, those sites in the brain where noradrenergic neurones exert these effects. Our preliminary evidence suggests that they may depend on the subsequent modulation of dopaminergic mechanisms: thus the switch from active to passive (proceptive to receptive) elements of the female's behaviour may be achieved by a corresponding, somatosensory-induced switch (decrease) in dopaminergic activity[12] mediated by the ventral noradrenergic pathway. Similar mechanisms may also underlie coitus (somatosensory)-induced prolactin secretion, particularly since this hormone (as well as lordosis) is under inhibitory dopaminergic control[13,14]. Furthermore, it is possible that these sub-cortically projecting noradrenaline-containing neurones may be involved in the transmission of somatosensory information in contexts wider than those reported here.

Patients with multiple sclerosis commonly complain of tingling and other sensory disturbances which may occur spontaneously or in response to movement. These symptoms are associated with plaques of demyelination in the corresponding sensory pathways but the physiological abnormalities underlying the symptoms are not understood. We have examined sensory fibres traversing a central demyelinated lesion resembling that of multiple sclerosis for evidence of activity which could account for the symptoms. We present here evidence for the existence of spontaneously and mechanically induced trains of action potentials propagating in both directions from the lesion.

Lesions were induced under anaesthesia (Saffan, Glaxo) in nine cats by the direct microinjection of lysophosphatidylcholine (LPC) into the dorsal column between L_1 and L_3 (ref. 1). The cats were reanaesthetized 7 to 14 days later, given atropine (300 µg) and rigidly held in a stereotactic frame. A laminectomy was performed from T_9 to L_7. Skin flaps were raised to form a recording paraffin pool, maintained at 37 ± 0.5 °C. Dorsal rootlets caudal and rostral to the lesion were isolated and raised on recording electrodes connected via unity gain cathode followers to differential preamplifiers. The data were processed using a small laboratory computer (Biomac 1000; Data Laboratories). The lesions were examined histologically.

Many of the rootlets caudal to the lesion in each of the cats contained spontaneously active units firing with fairly steady frequencies of between 15 and 45 impulses per second (Fig. 1*a*). Some spontaneously active units fired in bursts with, for example groups of about 5 impulses at 110 Hz separated by intervals of approximately 0.1 s (Fig. 1*b*). This pattern of firing bears a striking resemblance to that of the motor discharges associated with myokymia in multiple sclerosis[2].

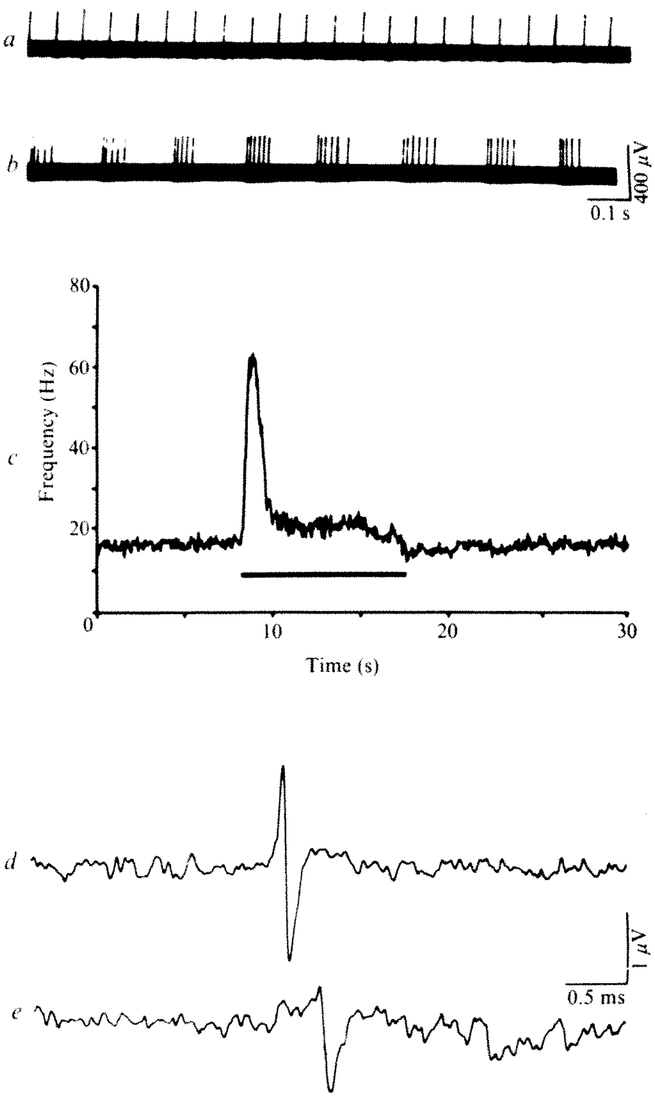

Fig. 1 *a* and *b*, Differential recordings of a steady (*a*) and a bursting (*b*) spontaneously active unit isolated in a teased dorsal root filament, caudal to the lesion, 14 days after LPC injection. *c*, Shows the firing rate of a steadily discharging, mechanosensitive unit recorded from a caudal dorsal root, 8 days after the injection of LPC. The bar marks the duration of a 0.75 mm compression of the lesion with a glass rod. *d* and *e*, Averaged records (n = 4,096) of the same spontaneously active unit, 14 days after LPC injection. Recordings were made 16 mm (*d*) and 6 mm (*e*) rostral to the lesion (conduction velocity = 30 m s^{-1}). The averager was triggered from the antidromic spikes of the unit in a teased dorsal root filament caudal to the lesion. The recordings were made with an imposed delay of 2 ms.

Small deformations (<1 mm) of the dorsal columns with a glass rod at the site of the lesion increased the firing rate of the spontaneously active units (Fig. 1*c*) and frequently recruited firing in units which were previously silent. The firing evoked by sustained deformations typically consisted of a phasic burst of activity followed by a slower, tonic discharge which subsided over about 30 s. Since the resting discharge pattern was not altered by comparable deformations of the dorsal column remote from the lesion, we conclude that the impulses were generated at the lesion in fibres which were unusually mechanosensitive. Tingling sensations, however, are likely to depend on impulses ascending the dorsal columns and it was therefore necessary to establish the existence of abnormal centripetal as well as centrifugal activity. The difficulty of distinguishing abnormal from normal ascending activity in the dorsal columns was overcome by the use of spike-triggered averaging[3] ($n = 128-16{,}284$) and the demonstration that, in some fibres, the descending impulses were time-locked to ascending impulses (see Fig. 1*d*, *e*). The averager was triggered from activity in a single nerve fibre isolated in the central end of a severed dorsal root caudal to the lesion. The input to the averager was connected to an uninsulated platinum wire which was inserted into the dorsal column rostral to the lesion using a micro-manipulator. A delay line (Mullard TDA 1022) was incorporated in the recording circuit when required. Of the 15 fibres examined with this recording arrangement we were able to find three in which there was clear evidence of synchronized trains of action potentials above and below the lesion. Two of the three fibres had quite steady firing frequencies for many hours and the other fibres fired in bursts. The relative latencies of the ascending and descending spontaneous action potentials established that they arose in the lesion. The fibres were also unusually mechanically sensitive at this site. In one fibre it was possible to determine the conduction velocity by recording the ascending action potential at two locations rostral to the lesion (Fig. 1*d*, *e*). From this measurement it was possible to determine the approximate site of origin of the impulses and this fell within the lesion.

The mechanism of origin of the time-locked ascending and descending impulses is uncertain. The simplest explanation is that they arose within the lesion in fibres with intact axons but abnormal myelin sheaths. Ectopic activity is known to occur in congenitally dysmyelinated axons[4]. It is, however, possible that the ascending impulses arose in surviving fibres by ephaptic excitation from spontaneous activity in adjacent severed fibres. Severed fibres exist in the LPC lesion at 14 d[1], as they do in the lesion of multiple sclerosis[5] and are known to generate spontaneous activity whether cut centrally (our unpublished observations) or peripherally[6]. Ephaptic cross-activation has been reported in congenitally dysmyelinated spinal roots of dystrophic mice[4]. Whether demyelinated, but previously normal nerve fibres can be similarly excited remains to be determined.

The present experiments provide clear evidence of spontaneous and mechanically induced trains of action potentials arising in a central demyelinating lesion and propagating in both directions from the lesion. We think it likely that such abnormal activity contributes to some of the sensory symptoms of human disease associated with comparable lesions. For example, many patients with multiple sclerosis or compressive lesions of the cervical spinal cord experience transient paraesthesiae on neck flexion. During this manoeuvre the cervical spine changes in length by several centimetres[7] and we have shown that much smaller deformations (<1 mm) can initiate transient abnormal discharges of a duration similar to that of the paraesthesiae. Length changes also occur in the optic nerve during eye movements and in patients with demyelinating optic neuritis such movements are sometimes associated with the perception of flashes of light[8]. The long-sustained, resting spontaneous discharges similarly provide a sufficient explanation for the continuous paraesthesiae often experienced during acute relapses of multiple sclerosis.

Intrathecal morphine inhibits substance P release from mammalian spinal cord *in vivo*

The central terminals of small diameter primary sensory neurones associated with the transmission of noxious cutaneous stimuli are located predominantly in the superficial dorsal horn of the spinal cord[1-3]. Some of these neurones synthesize substance P (ref. 4) and transport this peptide to their central and peripheral terminals[5-7]. Substance P is released from the dorsal horn *in vitro* following potassium depolarization[8,9]; from spinal cord after electrical stimulation of dorsal roots[10] and from dissociated sensory neurones grown in culture[11]. The iontophoretic application of substance P produces a long-lasting excitation of dorsal horn neurones that are also excited by noxious cutaneous stimuli[12-14]. One population of opiate receptors in the dorsal horn seems to be located on primary afferent terminals[15,16]; the release of substance P from primary sensory neurones is inhibited by opiates *in vitro*[8,11]. At present, however, there is no direct evidence that substance P is released from sensory neurones, *in vivo*, following activation of nociceptive afferents. We report here that substance P-like immunoreactivity is released from the mammalian spinal cord, *in vivo*, following chemical stimulation of sensory neurones with capsaicin and by the activation of high threshold peripheral afferents. Furthermore, release of substance P evoked by high intensity stimuli is completely inhibited by intrathecal morphine.

Experiments were performed on rats and cats, anaesthetized with chloralose–urethane and placed in a stereotaxic frame. A length of PE-10 polyethylene tubing, serving as an inflow cannula, was inserted into the subarachnoid space, via the cisterna magna, to the caudal region of the lumbar enlargement[17]. The spinal cord was superfused at $100\ \mu l\ min^{-1}$ with artificial cerebrospinal fluid (CSF) containing bovine serum albumin ($120\ \mu g\ ml^{-1}$) and bacitracin ($30\ \mu g\ ml^{-1}$ in rats and $300\ \mu g\ ml^{-1}$ in cats). In rats, superfusate was withdrawn with a push-pull syringe pump through a second cannula, placed in the cisterna magna. Superfusate from cat spinal cord was removed with a PE-90 cannula, inserted concentrically over the PE-10 cannula to the rostral region of the lumbar enlargement. Samples were collected at 10-min intervals in rats and 30-min intervals in cats.

After superfusion of the rat spinal cord in the absence of any evoking stimulus, the levels of substance P released were too low for reliable measurement in most experiments (<5 fmol per 10 min). Superfusion of the spinal cord with potassium chloride (40 mM) resulted in the release of 78 ± 9 fmol (mean ± s.e.m.; $n = 4$) substance P during the 10-min collection period. In the fraction following potassium stimulation, release of substance P returned to basal levels. Addition of 2·0 mM cobalt to the superfusing medium prevented the evoked release of substance P.

In the cat it was possible to detect a significant release of substance P from the spinal cord in the absence of any evoking stimulus: 7–15 fmol were measured in each 30-min collection period with very little variation during the course of an experiment (Fig. 1). To examine whether substance P is released from the spinal cord following activation of specific afferent fibre populations, we stimulated the cat sciatic nerve bilaterally, while superfusing segments of the spinal cord receiving sensory input from the sciatic nerve. During stimulation, the compound action potential was monitored to determine the stimulus intensity required to activate Aαβ fibres alone, and that required to recruit Aδ and C fibres. At stimulus intensities sufficient to recruit only low threshold Aαβ afferents, there was no measurable increase in the release of substance P (Fig. 1). The collaterals of large myelinated fibres that are activated by low intensity stimuli terminate with deeper laminae of the dorsal horn. Thus, by superfusing the surface of the spinal cord, we cannot exclude that substance P is actually released from those terminals, but cannot diffuse into the spinal superfusate. Increasing the stimulus intensity to activate Aδ and C fibres produced a 4·9±0·6 fold (mean±s.e.m.; $n=4$) increase in substance P release (Fig. 1). In the fraction following stimulation, the release of substance P returned to pre-stimulation values.

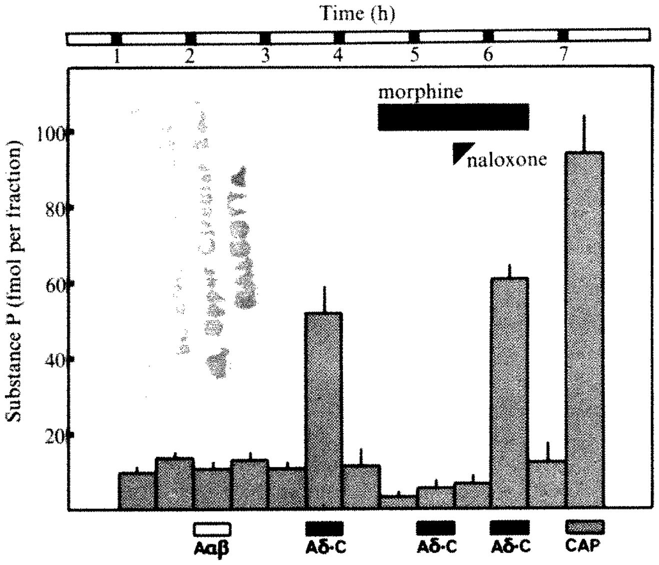

Fig. 1 Release of substance P from superfused cat spinal cord in response to sciatic nerve stimulation and capsaicin. Cats were anaesthetized with chloralose–urethane (100 mg per kg) and prepared with a tracheal tube and jugular and carotid catheters. An incision was made in the cisterna magna and the perfusion cannula was inserted after retraction of the arachnoid layer. The perfusion cannula consisted of a length of polyethylene PE-90 (1.0 mm outer diameter) tubing through which was passed a length of polyethylene PE-10 tubing. The PE-10 served as inflow cannula while the PE-90 was used as collection cannula. Both cannulae were inserted through the retracted incision in the cisterna membrane 37–40 cm down the spinal cord (upper sacral region) and the PE-90 cannula was then retracted 10 cm. Perfusion was therefore localized to the upper sacral and lumbar spinal cord. The position of the inflow and outflow cannulae was determined by X rays after infusion of radio-opaque dye. The sciatic nerve was exposed and prepared for stimulation and recording of the compound action potential. Stimulation of the nerve was performed with rectangular pulses (3–4 V, 0.05 ms, 50 Hz for activation of Aα and Aβ fibres and 40–50 V, 0.05 ms, 50 Hz for recruitment of Aδ and C fibres). Superfusate in all experiments consisted of NaCl, 151.1 mM; KCl, 2.6 mM; $MgSO_4$, 0.9 mM; $CaCl_2$, 1.3 mM; $NaHCO_3$, 21.0 mM; K_2HPO_4; 2.5 mM, gassed with 95% O_2 and 5% CO_2 before perfusion. Perfusion samples (3 ml) were collected into glacial acetic acid (final concentration of 2 N) and immediately frozen and lyophilized. Samples were reconstituted in 1.0 ml assay buffer, neutralized and aliquots of each fraction were used to determine the content of substance P, by radioimmunoassay, using antibody R6P with a sensitivity of 1.5 fmol per assay tube[33]. Serial dilutions of synthetic substance P and immunoreactivity in superfusate samples produced parallel dilution curves. Each value is the mean± s.e.m. from four separate experiments.

We have also examined whether the spinal application of morphine at concentrations known to elicit analgesia[18] can affect substance P release from cat spinal cord *in vivo*. Following superfusion with 5×10^{-4} M morphine sulphate (equivalent to 427.5 μg morphine base superfused over a 30-min period), the resting release of substance P was substantially decreased, in two animals to levels below the sensitivity of the assay (Fig. 1). Furthermore, bilateral stimulation of the sciatic nerve at intensities that clearly caused the release of substance P before the addition of morphine now failed to increase the release of substance P (Fig. 1). Following intraperitoneal injection of naloxone hydrochloride (1 mg per kg), stimulation of the sciatic nerve at the same intensity in the continued presence of intrathecal morphine, fully restored the evoked release of substance P (Fig. 1).

Peripheral application of the homovanillic acid derivative, capsaicin, produces a severe burning pain[19] that reflects the activation of C fibres in sensory nerves[20]. Subcutaneous administration of capsaicin to neonatal rats results in the degeneration of small sensory neurones[21], some of which contain substance P[22].

Capsaicin also depletes substance P from the dorsal horn of adult rats[23,24]. Administration of capsaicin directly onto the spinal cord, *in vitro*, causes a calcium-dependent release of substance P[9,25]. In the present experiments, superfusion of the cat spinal cord with 3×10^{-4} M capsaicin produced a greater than tenfold increase in the release of substance P (5 experiments, Fig. 1). The actions of capsaicin in the spinal cord seem to be restricted to nociceptive primary sensory neurones[23,26]. Thus, the demonstration of a capsaicin-evoked release of substance P from cat spinal cord, *in vivo*, provides further evidence that substance P may be involved in the transmission of noxious peripheral stimuli.

Our results with sciatic nerve stimulation provide direct evidence that substance P is released from mammalian spinal cord *in vivo* by activating nociceptive sensory afferents. The naloxone-reversible inhibition of substance P release by morphine applied directly to the spinal cord at concentrations known to elicit analgesia, may represent one substrate for the direct spinal analgesic actions of the opiates[18]. The opiate inhibition of substance P release reported by Mudge *et al.*[11] is a direct effect on sensory neurones. These authors also found that enkephalin could inhibit calcium influx into cultured sensory neurones by modulating voltage-sensitive channels and suggested that inhibition of substance P release from terminals could be mediated by the same mechanism.

The precise relationship between enkephalin and substance P-containing neuronal elements in the dorsal horn is still unclear. Substance P is highly concentrated within lamina I of the dorsal horn, where primary afferent terminals are rarely postsynaptic in axo-axonal contacts[3]. Furthermore, although there are a variety of enkephalin-containing elements within the superficial dorsal horn[27–29] few of these seem to contribute to axo-axonal contacts with primary afferents[30]. It remains to be seen if other neurotransmitters present in the dorsal horn that can elicit direct spinal analgesia[31,32] also inhibit the release of substance P *in vivo*.

Dopamine receptors in intracerebral motor and endocrine systems[1,2] have been divided into two main types, D-1 and D-2, dependent on the presence or absence of adenylate cyclase linkage[3]. Here we have investigated a number of dopamine agonist and antagonist drugs in man that have different actions on D-1 and D-2 receptors in animals. Motor and endocrine effects in parkinsonian subjects seem to depend on drug interaction with D-2, but not D-1, receptors. These results may have important implications for the design of anti-parkinsonian and antipsychotic agents.

Many dopamine agonists and antagonists have selective actions on D-1 and D-2 systems, as determined by adenylate cyclase stimulation[4-6] and membrane binding studies[7-9], but examination of possible differences in motor, hormonal and other behavioural effects of these compounds in man has proved difficult because of individual variations in drug pharmacokinetics and the response[10]. Despite these problems, we have attempted to establish the magnitude of the motor, growth hormone and prolactin responses to known plasma levels of levodopa and the dopamine-like ergot derivatives, bromocriptine and lisuride[11,12]. Dopamine in low concentration is an agonist at D-2, and in higher concentration at D-1 receptor sites[13], but the ergot derivatives which act as agonists at D-2 receptors in micromolar concentrations have antagonist actions in nanomolar concentrations on striatal D-1 receptors[14,15]. We have also studied the effects of pimozide, a non-selective dopamine receptor antagonist[16], *cis*-flupenthixol, an effective antipsychotic with D-1 antagonist effects on the striatum[8,17], (blockade of adenyl cyclase activity shows a linear relationship with ^{3}H-*cis*-flupenthixol binding in striatal tissue), and the D-2 antagonists metoclopramide, sulpiride, oxiperomide and tiapride[18], on levodopa-stimulated motor and hormonal changes. These drugs were given to subjects with Parkinson's disease, in which dopamine sensitive adenylate cyclase activity is reduced by at least 50% (ref. 19), although the number of D-2 receptor sites in the striatum is increased, as determined by ^{3}H-haloperidol binding[20]. Following levodopa treatment, specific ^{3}H-spiperone binding approaches normal values[21]. Receptor changes and the loss of presynaptic neurones must influence the motor response to levodopa in parkinsonism: for instance, normal subjects do not readily develop levodopa dyskinesias[22]. Pituitary and hypothalamic dopamine receptor assays have not been reported in parkinsonian patients, but prolactin and growth hormone responses to levodopa are similar to those in age- and sex-matched normal controls[23].

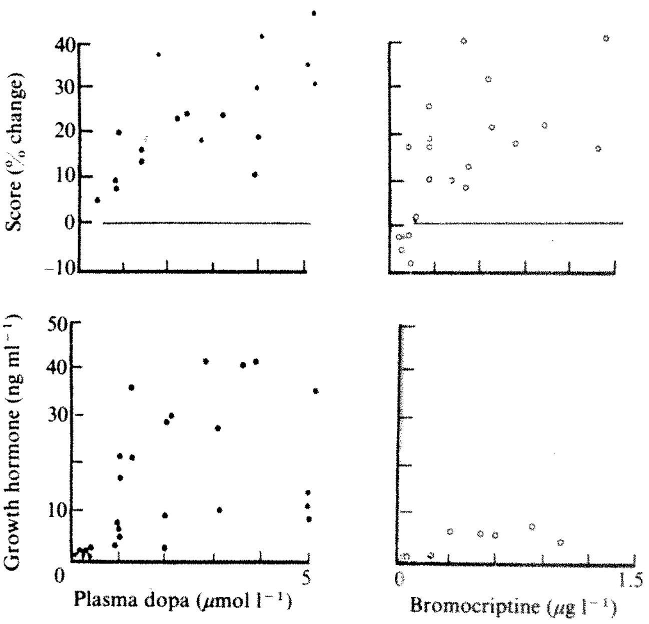

Fig. 1 Peak plasma dopa (μmol l^{-1}) or bromocriptine (μg l^{-1}) level, peak percentage reduction in parkinsonian disability score (score units), and peak elevation of plasma growth hormone level (ng m^{-1}) after single oral doses of levodopa (1 g) or bromocriptine (12.5–100 mg) in subjects with parkinsonism. With dopa, relationship between plasma drug level, motor and growth hormone effect; $r = 0.69$, $P < 0.01$, $n = 18$ and $r = 0{\cdot}50$, $P < 0{\cdot}05$, $n = 27$, respectively; and with bromocriptine, $r = 0.50$, $P < 0.05$, $n = 20$ and $r = 0.10$, not significant, $n = 7$.

Levodopa, bromocriptine and lisuride caused dose-dependent improvement in tremor, akinesia and rigidity, together with dyskinesias, a rise in growth hormone level and a fall in prolactin level in most subjects. Emesis, visual and auditory hallucinosis and delusions occurred with each drug. Bromocriptine and lisuride, but not levodopa, occasionally induced sleep. Systolic and diastolic erect and supine blood pressure fell by 10–20 mm Hg following levodopa, 1 g orally (p.o.), bromocriptine, 100 mg p.o., and lisuride, 0.01 mg intravenously (i.v.). Neither the

Table 1 Timing and duration of response to dopamine agonists

	Peak drug plasma level (min)	Peak therapeutic effect (min)	Peak plasma growth hormone elevation (min)	Peak plasma prolactin depression (min)
Levodopa, 1g p.o.	80	90 (180)	90 (120)	45 (150)
Bromocriptine, 100 mg p.o.	100	130 (480)	170 (120)	60 (480)
Lisuride, 0.15 mg i.v.	—	30 (120)	45 (120)	60 (240)

Values are means after single doses of levodopa, bromocriptine and lisuride in a subject with Parkinson's disease. The total duration of each response is shown in parentheses.

Table 2 Effect of levodopa, bromocriptine and lisuride in Parkinson's disease, and of antipsychotic drugs on levodopa-mediated endocrine changes

	No. of patients	Mean peak plasma levodopa level (μmol l^{-1})	Parkinsonism reduction in disability score	Dyskinesia mean dyskinesia score	Growth hormone rise in plasma level (ng ml^{-1})	Prolactin fall in plasma level (%)
Levodopa, 1 g p.o.	(18)	4.5 ± 1	31 ± 4	4 ± 2	20 ± 3	41 ± 10
Bromocriptine 100 mg p.o.	(4)	—	37 ± 8	7 ± 2	6 ± 4*	41 ± 11
Lisuride, 0.15 mg i.v.	(4)	—	25 ± 5	1 ± 1	22 ± 8	43 ± 11
Levodopa, 1 g and pretreatment with antagonists at stated intervals:						
Metoclopramide, 60 mg p.o. 1 h	(14)	5.1 ± 1	21 ± 5	2 ± 1	6 ± 1†	48 ± 15
Pimozide, 6 mg p.o., 1 h	(11)	4.4 ± 1	13 ± 4†	1 ± 1	15 ± 5	
Tiapride, 200 mg p.o., 1 h	(2)	5.2 ± 1	26 ± 4	1 ± 1	16 ± 8	55
Oxiperomide, 10 mg p.o. 1 h	(5)	4.9 ± 2	27 ± 5	1 ± 1	24 ± 5	46 ± 12
cis-flupenthixol, 3 mg p.o. 4 h	(5)	—	17 ± 3	0	20 ± 3	76 ± 6
Sulpiride, 400 mg p.o. 2 h	(5)	—	14 ± 2†	0	2 ± 1‡	50 ± 7
Placebo (sulpiride), p.o. 2 h	(5)	—	31 ± 4	2	18 ± 3	62 ± 12

Mean (±s.e.m.) peak motor and hormonal changes after single doses of dopamine agonists, and after single doses of levodopa, 1 g p.o. preceded at the stated intervals by a range of antipsychotic drugs are shown. Motor responses: peak reduction in parkinsonian disability score and peak dyskinesia score (both King's College Hospital rating scales) are shown. Hormonal responses: peak increase in plasma growth hormone level (ng per ml) and peak reduction in plasma prolactin level (maximum percentage fall from basal level in case of agonists, and from peak stimulated level in case of antagonists) are shown. All observations are over a 4-h period.

* Rise after bromocriptine less than after levodopa or lisuride ($P < 0.05$ in each case, Student's *t*-test).

† Reduction in anti-parkinsonian effect after pimozide, and in growth hormone peak after metoclopramide, compared with levodopa alone ($P < 0.01$ in each case, Student's *t*-test).

‡ Reduction in anti-parkinsonian effect and growth hormone peak after sulpiride compared with levodopa and placebo ($P < 0.025$, Wilcoxon's signed rank test).

motor nor the hormonal responses were biphasic, that is, deterioration in parkinsonism did not precede improvement, and elevation of prolactin level or depression of growth hormone level did not precede the opposite effect. Peak motor and hormonal responses were simultaneous with peak plasma levels of each drug, although each compound had a different pharmacokinetic profile (Table 1). In equipotent anti-parkinsonian doses, the peak rise in plasma growth hormone level with levodopa (20 ± 3 ng ml^{-1}) and lisuride (22 ± 6 ng ml^{-1}) was greater than with bromocriptine (6 ± 3 mg ml^{-1}); $P < 0.05$ in each case.

The dopamine antagonist drugs had comparable motor and hormonal effects (Table 2). Sulpiride (400 mg) and pimozide (6 mg) were most active, and tiapride (200 mg) and oxiperomide (10 mg) were least active in producing antagonism of levodopa-induced motor and hormonal responses. All antagonists caused hyperprolactinaemia, and prolactin levels subsequently fell following levodopa (1 g). All antagonists reduced the severity of levodopa-induced dyskinesias, but also reduced the therapeutic effect of levodopa, with the exception of tiapride (200 mg) and oxiperomide (10 mg). No antagonist prevented the hypotensive action of levodopa.

The motor, endocrine and behavioural effects of levodopa, bromocriptine and lisuride in Parkinson's disease are thus very similar despite the different effects of these drugs on D-1 and D-2 receptors in animal models. The low peak plasma growth hormone response to bromocriptine compared to equipotent anti-parkinsonian doses of levodopa or lisuride may be due to the action of bromocriptine as a weak noradrenergic antagonist[23]. However, lisuride has similar adrenergic effects to bromocriptine[12].

In animal tissues, bromocriptine has dose-dependent antagonist or agonist effects on D-1 receptors, and in behavioural studies causes reduced exploratory activity before motor activation[24]. These changes have been attributed to separate pre- and post synaptic effects of bromocriptine[25], but a dual response with motor and hormonal inhibition at low plasma levels, and stimulation at high levels, is not evident in Parkinson's disease. However, bromocriptine may act as a partial rather than a complete agonist in the motor system, as clinical improvement with very high plasma bromocriptine levels is not always as great as that accompanying lower levels[10].

As with dopamine agonists, there are no distinctions between the actions of selective D-2 and non-selective D-1 and D-2 receptor antagonists in parkinsonism, apart from differences in potency. Metoclopramide and pimozide are both competitive antagonists to the anti-parkinsonian and growth hormone-elevating actions of levodopa, despite different effects on striatal D-1 and D-2 systems, and the other D-2 antagonists also block these responses. Oxiperomide and tiapride prevent levodopa-induced stereotypies but not motor hyperactivity in rodents[26], and in critical dosage have specific antidyskinetic effect in parkinsonism without impairing the therapeutic action of levodopa[27], although the apparent selectivity of these drugs has not been satisfactorily explained.

The motor and endocrine effects of levodopa, bromocriptine, lisuride and also of different dopamine antagonists in parkinsonism can be attributed to the effects of these drugs on D-2 non-adenylate cyclase linked receptors. The physiological significance of the dopamine-sensitive adenylate cyclase is obscure. Phosphodiesterase inhibitors—including caffeine and oxpentifylline—given to retard the breakdown of cyclic AMP have little or no therapeutic effect in parkinsonism[28]. Hormonal responses to dopamine in peripheral tissues, as shown for example by the release of parathormone from the parathyroid, are mediated by dopamine-stimulated increase in intracellular cyclic AMP[29] and cyclic AMP can mimic the hyperpolarizing effect of dopamine when applied directly to ganglionic neurones[30]. However, prolactin suppression by dopamine in pituitary cells does not involve adenylate cyclase mechanisms[15]. The presence of this enzyme in striatal neurones may be more important in determining the intracellular rather than the electrophysiologically significant membrane response to dopamine.

We thank Janssen, Sandoz, Schering and SESIF for gifts of drugs and Mrs P. Asselman for technical assistance.

α-Adrenergic receptors modulate β-receptor affinity in rat kidney membranes

Elizabeth A. Woodcock & Colin I. Johnston

Monash University, Department of Medicine, Prince Henry's Hospital,
Melbourne, Australia

Adrenergic receptors were first classified into two classes—α and β—on the basis of the relative pharmacological potencies of agonist compounds[1], and this classification has been supported by subsequent studies. In some tissues, such as the heart and liver[2,3], they exert similar physiological responses, and in other tissues, such as the uterus and vasculature, they have opposing roles[4,5]. The occurrence of both classes of receptor in the same tissue leads to the problem of what determines whether the overall response observed is α-type or β-type, as adrenaline and noradrenaline bind to both receptor classes. Furthermore, direct binding studies have demonstrated that the two receptor classes are distinct and separate entities[6]. We show here that stimulation of α-receptors in renal membranes causes a specific decrease in the affinity of the agonist compound isoprenaline for β-receptors in the same membranes. This demonstrates that interactions occur between renal α- and β-adrenergic receptors. Such interactions may modulate the response of the kidney to sympathetic stimulation.

Adult Sprague–Dawley rats were killed by cervical dislocation. Kidneys were removed immediately and homogenized in 0.25 M sucrose in buffer (50 mM Tris-HCl, *p*H 8.1, 10 mM $MgSO_4$). The homogenate was centrifuged twice at 2,000*g* for 5 min and the final supernatant was centrifuged at 30,000*g* for 15 min. The pellet was washed three times with buffer and finally resuspended in buffer at a protein concentration of 5–10 mg ml^{-1}. Binding studies were carried out as described in detail elsewhere[7]. Renal membranes (0.1 ml) were incubated with 5 nM ^3H-dihydroalprenolol (^3H-DHA, Searle Nucleonics) in a final volume of 0.5 ml in 50 mM Tris-HCl, *p*H 8.1, 10 mM $MgSO_4$, 10^{-4} M pyrocatechol and 0.1% ascorbic acid. Incubation was carried out at 37 °C for 10 min and was terminated by filtration through Whatman GF/C glass fibre filters. The filters were washed with 10 ml ice-cold buffer. Specific binding was defined as binding displaceable by 10^{-5} M isoprenaline and constituted 60–70% of the total binding at 5 nM ^3H-DHA. The characteristics of ^3H-DHA binding sites in these conditions were those expected of β-receptor binding and have been described in detail elsewhere[7]. The relative potencies of adrenergic agonists in competing for binding were isoprenaline > (−)adrenaline ≥ noradrenaline ≫ (+)adrenaline = dopamine. (−)Propranolol was 100 times more potent than (+)propranolol. The α-adrenergic agents phenylephrine and phentolamine competed for binding only at concentrations greater than 10^{-5} M. No competition for ^3H-DHA binding by clonidine was observed at concentrations up to 10^{-4} M. Renal membranes contained 33 ± 3 (s.e.m.) fmol per mg of β-receptors, measured by ^3H-DHA binding. The affinity of the receptors for ^3H-DHA was 1.5 ± 0.4 nM ($n = 6$). Receptor concentration and affinity were calculated by Scatchard analysis[8].

The affinity of the β-adrenergic agonist isoprenaline for renal β-receptors measured in competition experiments with ^3H-DHA was decreased in the presence of 10^{-6} M clonidine from 72 ± 4 nM to 185 ± 20 nM (average of 10 experiments; $P < 0.005$) (Fig. 1). This effect of clonidine was specific for agonists as clonidine had no effect on the affinity of the antagonist propranolol for the same membrane receptors (Fig. 1). Similarly, clonidine had no effect on ^3H-DHA binding in the absence of isoprenaline. ^3H-DHA bound in the presence of 10^{-6} M clonidine was 96% ± 4.4 of controls containing no clonidine. The addition of clonidine also caused a change in the Hill coefficient calculated from the isoprenaline displacement curves. In the presence of 10^{-6} M clonidine, the Hill coefficient increased from 0.75 ± 0.05 to 1.04 ± 0.05 (average of 10 experiments; $P < 0.005$). A Hill coefficient of less than one indicates either multiple classes of binding sites or negative cooperativity. K_I values measured in such conditions represent the average isoprenaline affinity at 50% of maximum isoprenaline binding.

The reduction of β-adrenergic agonist affinity was found to be a specific α-adrenergic receptor-mediated effect. The effect of clonidine was concentration dependent and was maximal at 10^{-8}–10^{-7} M. A decreased isoprenaline affinity was observed with clonidine concentrations as low as 10^{-9} M (Table 1). Moreover, the effect was due to the α-adrenergic agonist action of clonidine, as a similar reduction in isoprenaline affinity occurred with another α-agonist compound, phenylephrine. The α-adrenergic antagonist phentolamine antagonized the effect of clonidine (Table 1). Phentolamine alone had no effect on isoprenaline affinity.

In many different tissue preparations, the affinities of β-receptors for agonist compounds are decreased in the presence

Table 1 Modulation of isoprenaline affinity for renal β-adrenergic receptors

Additions	K_I isoprenaline (nM)	No. of experiments
None	72 ± 4	10
10^{-6}M Clonidine	185 ± 20*	10
10^{-7}M Clonidine	176 ± 31†	4
10^{-8}M Clonidine	172 ± 11‡	4
10^{-9}M Clonidine	112 ± 15†	4
10^{-5}M Phenylephrine	210 ± 42‡	4
10^{-6}M Clonidine plus 10^{-5}M phentolamine	105 ± 8§	4
10^{-4}M GTP	245 ± 12‡	4
10^{-4}M GTP plus 10^{-6}M clonidine	215 ± 31§	4

Values are mean ±s.e.m. *P* values were calculated using a paired *t*-test. K_I values were calculated using the formula: $K_I = I_{50}(I + L/K_L)$, where I_{50} is the concentration of the drug causing 50% inhibition of binding. L and K_L are, respectively, the concentration and the dissociation constant of the ^3H-DHA.

* $P < 0.005$ relative to controls; † $P < 0.025$ relative to controls; ‡ $P < 0.01$ relative to controls; § $P < 0.05$ relative to 10^{-6}M clonidine; § NS relative to 10^{-4}M GTP.

0028–0836/80/280159—02$01.00

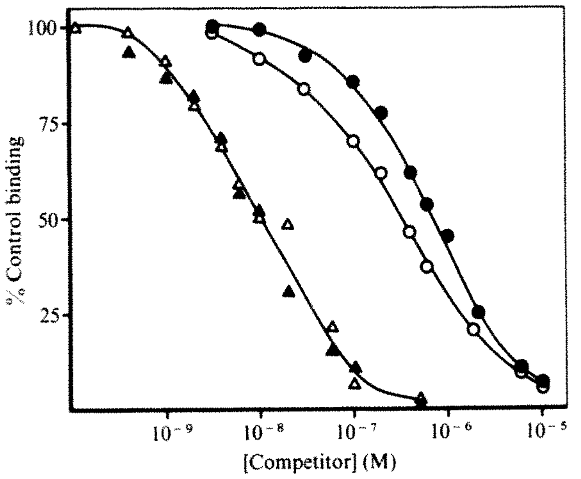

Fig. 1 Effect of clonidine on the affinities of isoprenaline and propranolol for rat kidney β-receptors. ^{3}H-Dihydroalprenolol (5 nM) was incubated with renal membranes in the presence of increasing concentrations of isoprenaline or propranolol and the percentage of control specific binding was determined. A typical experiment is shown. Average values of isoprenaline affinity (K_I) in the presence and absence of clonidine in 10 experiments are given in Table 1. ○, Isoprenaline; ●, isoprenaline and 10^{-6}M clonidine; △, propranolol; ▲, propranolol and 10^{-6}M clonidine.

of GTP and certain GTP analogues[9]. In rat kidney membranes isoprenaline affinity was reduced by 10^{-4} M GTP. The effects of clonidine and GTP were not additive, for in the presence of 10^{-4} GTP, clonidine (10^{-6} M) did not further reduce isoprenaline affinity (Table 1).

There are marked differences in the characteristics of agonist and antagonist binding[10,11]. Receptor affinity for antagonists remains remarkably constant and the Hill coefficient for antagonist binding is generally close to 1.0, indicating a single class of non-interacting binding sites. The Hill coefficient for agonist binding is generally less than 1.0. Also, agonist affinity can be modulated by a variety of agents including guanyl nucleotides[9], Mg^{2+}ion[12] and cholinergic agonists[13]. In general, these factors are thought to influence the apparent binding affinity of agonists through a primary effect on adenylate cyclase or the coupling mechanism between receptor and cyclase[14]; renal α-adrenergic receptors inhibit adenylate cyclase[15]. It is likely that the observed reduction of β-adrenergic agonist affinity in renal membranes by α-adrenergic agonists is also related to an effect on adenylate cyclase.

The kidney contains a functionally heterogeneous population of β-receptors. Although there is little direct evidence, both α- and β-receptors are thought to be present in the renal vasculature[16] on the juxtaglomerular cells[17,18] and β-receptors have been demonstrated on renal tubules[19]. The observed interaction between α- and β-receptors in renal membranes probably occurs in only one of these functional groups. This may explain why the observed shift in isoprenaline affinity is small compared with that caused by GTP in other tissues[9,12]. However, the lack of any additive effect of clonidine and GTP suggests that these two agents influence the same receptor population. This interaction between α- and β-receptors seems to be specific to the kidney, as we have been unable to demonstrate any effect of clonidine on isoprenaline affinity in cardiac membranes.

Cleavage of endorphins to des-Tyr endorphins by homogeneous bovine brain aminopeptidase

Louis B. Hersh*, Thomas E. Smith*
& Jeffrey F. McKelvy†

*Department of Biochemistry, The University of Texas Health Science Center at Dallas, Dallas, Texas 75235
†Departments of Psychiatry and Biochemistry, The University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania 15261

Attention has recently focused on the possible biological roles of peptides related to β-lipotropin (β-LPH)[1,2]. In particular, observations suggest that certain peptide fragments derivable from β-LPH, including γ-endorphin (β-LPH_{61-77}) and α-endorphin (β-LPH_{61-76}), may be involved in various modes of behavioural adaptation[2,3]. Structure–activity studies on behavioural actions of γ-endorphin, an opioid peptide, revealed that the omission of N-terminal tyrosine resulted in a non-opioid peptide, des-Tyr-γ-endorphin, which exhibited greater behavioural activity than γ-endorphin[3]. Subsequent biochemical studies provided evidence for the association with brain synaptic plasma membranes of peptidase activities which could produce γ- and α-endorphins and their des-Tyr derivatives from exogenous β-endorphin[4]. This and earlier observations[4–6] suggest that regulatory physiological events are focused on the N-terminal tyrosine residue; enzymatic reactions exerted at this residue are thus of great interest. We recently purified to homogeneity an aminopeptidase from bovine brain which catalyses the hydrolysis of Met[5]- or Leu[5]-enkephalin by sequential release of amino acids from the amino terminus of the enkephalin molecule[7]. The ability of this enzyme, purified from bovine[7], monkey[8] or rat[9] brain, to use endorphins as substrates has not been previously examined. We now present quantitative studies which show that homogeneous bovine brain enkephalin aminopeptidase catalyses the hydrolysis of the N-terminal tyrosine from γ-, α- and β-endorphins with substantial turnover numbers and yields only the des-Tyr derivatives. These results suggest that this enzyme may be involved in regulating the concentrations of opioid- and opioid-derived biologically active peptides in the brain.

We incubated homogeneous bovine brain aminopeptidase, previously shown to catalyse the hydrolysis of Met^5- and Leu^5-enkephalins[7] ($K_m = 22$ µM, $V_{max} = 20$ µmol per min per mg enzyme for the Tyr^1-Gly^2 bond), with synthetic α-, β- and γ-endorphins, and compared their hydrolysis with that of Met^5-enkephalin in the same experimental conditions by subjecting aliquots of the incubation mixtures to amino acid analysis at various times of incubation. All the commercial synthetic peptides were tested before use by HPLC and amino acid analysis and judged to be pure. The enzymatic digestions were carried out in incubation conditions in which linear rates of

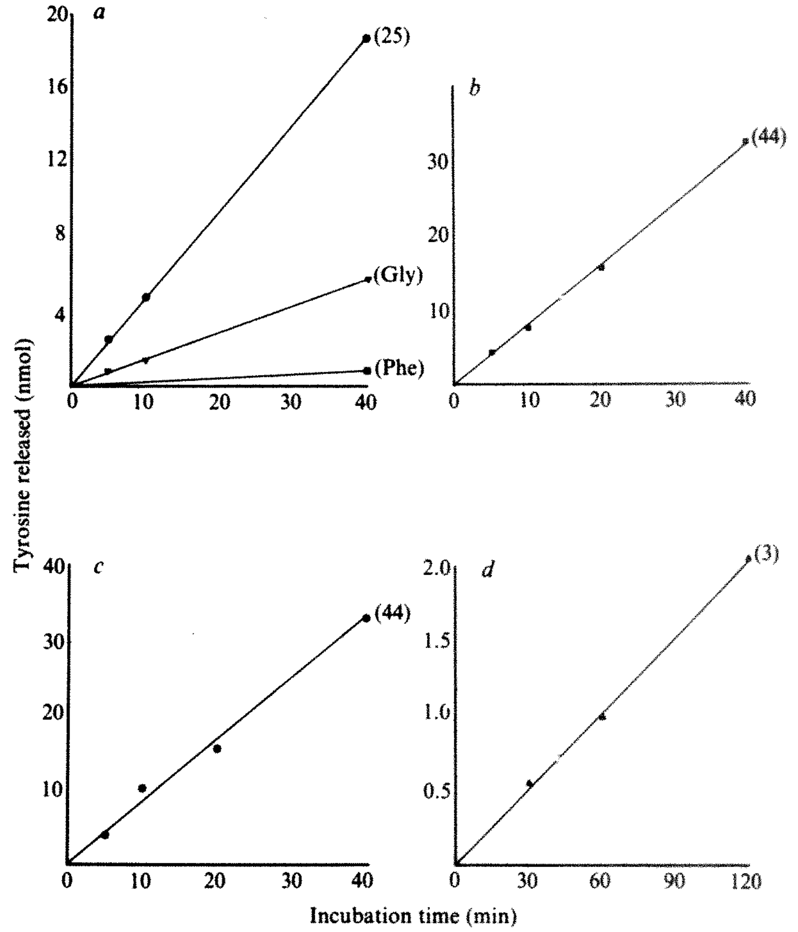

Fig. 1 Release of tyrosine from Met^5-enkephalin and α-, β-, and γ-endorphin catalysed by bovine brain aminopeptidase. Reaction mixtures containing 50 mM Tris-HCl buffer, *p*H 7.4, 0.5 mM substrate (Peninsula) and bovine brain aminopeptidase in a total volume of 150 μl were incubated at 37 °C. At the time points indicated, a 35-μl aliquot was withdrawn, diluted to 0.5 ml with water and boiled for 1 min. The boiled solution was filtered through a 0.45-μm Millipore filter, washed with 1.5 ml of water and the combined effluents lyophilized. The lyophilized samples were dissolved in 100 μl of sodium formate buffer (0.2 M in sodium ion) at *p*H 2.21 and applied directly to an amino acid analyser microbore single column system containing DC-4A cation exchange resin (Pierce). The amino acids were eluted using a three-buffer programme: 0.2 M sodium formate *p*H 3.28, 0.2 M sodium formate *p*H 4.38, and 0.2 M sodium borate *p*H 10.2. The amino acids were identified and quantified by comparison with standards run at various intervals between samples. Analyses were carried out on an Aminco Aminolyzer fluorometric liquid chromatography system equipped with a Shimadzu digital integrator. The fluorogenic reagent used was a *o*-phthalaldehyde. *a*, Tyrosine and glycine release from Met^5-enkephalin using 23 ng of enzyme; *b*, tyrosine release from α-endorphin using 115 ng of enzyme; *c*, tyrosine release from γ-endorphin using 115 ng of enzyme; *d*, tyrosine release from β-endorphin using 172 ng of enzyme. The values in parentheses represent the percentage of the substrate degraded.

hydrolysis were measured. Control incubations in which enzyme and substrate, respectively, were omitted, or in which boiled enzyme was used, revealed that no free amino acids were generated by non-enzymatic breakdown of substrate or by enzyme autolysis.

As shown in Fig. 1, homogeneous bovine brain aminopeptidase catalyses the release of the N-terminal tyrosine residue from Met^5-enkephalin and from α-, γ- and β-endorphins. As shown in Table 1, the rate of hydrolysis of α- and γ-endorphins was approximately 30% that of Met^5-enkephalin whereas β-endorphin was hydrolysed at a much lower rate—0.5% relative to Met^5-enkephalin. It is interesting that whereas glycine was also released from Met^5-enkephalin at about one-third the rate of tyrosine, no glycine was liberated from α- or γ-endorphin, even in conditions in which over 40% of the tyrosine was released. These results suggest that, unlike des-Tyr-Met^5-enkephalin, des-Tyr-α- and des-Tyr-γ-endorphins adopt a conformation resistant to further degradation by the aminopeptidase. This resistance could contribute to the metabolic stability of these peptides and thus to their biological activity. Note also that the homogeneous bovine brain aminopeptidase exhibited substantial turnover numbers for the hydrolysis of the N-terminal tyrosine of α- and γ-endorphins, 689 and 634 min^{-1} relative to 2,040 min^{-1} for Met^5-enkephalin (Table 1). This rapid rate of reaction with these endorphins raises the possibility of an *in vivo* role for the aminopeptidase in partitioning peptide fragments derived from β-endorphin between opioid and non-opioid pathways in response to functional demands. The rate of release of N-terminal tyrosine from β-endorphin was much lower than that for the other endorphins; although the extent of cleavage was relatively small in the conditions used, the enzyme seemed to produce only the des-Tyr fragment of β-endorphin. Whether this reaction, which would produce a non-opioid derivative of β-endorphin, is of physiological significance, for example, by being modulable by regulatory agents, is a subject for further study.

Our results provide new biochemical evidence in support of the hypothesis that des-Tyr α- and des-Tyr-γ-endorphins may have a role in brain function, as we have observed that a homogeneous brain aminopeptidase catalyses the cleavage of the N-terminal tyrosine residue from α- and γ-endorphins at a rapid rate to yield the des-Tyr derivatives with no further cleavage of the peptide. The relationship between this activity and the production of des-Tyr-α- and des-Tyr-γ-endorphins from β-endorphin by a rat brain "synaptic plasma membrane" (SPM) fraction observed by Burbach *et al.*[4], is not known. However, in the latter study, marker enzyme data were not presented to aid in understanding to what extent the vesiculation known to accompany the preparation of such membranes may have resulted in the inclusion of synaptoplasmic elements, possibly including the soluble aminopeptidase which we have described. It will be interesting to compare the properties of the SPM-associated production of des-Tyr α- and des-Tyr-γ-endorphins with those tabulated for our homogeneous enzyme preparation in terms of sensitivity to mercurials, puromycin and chelators. On the other hand, it may be that these are separate

Table 1 Rate of tyrosine release from Met^5-enkephalin and α-, β- and γ-endorphin by bovine brain aminopeptidase

Substrate	Rate of tyrosine release (μmol per min per mg enzyme)	Turnover number (min^{-1})
Met^5-enkephalin	20.4 (6.1)	2,040
α-Endorphin	6.5	634
γ-Endorphin	6.9	689
β-Endorphin	0.10	10

The data from Fig. 1 were used to calculate the rate of tyrosine release. The value in parentheses is the rate of glycine release.

*For hydrolysis of the Tyr^1–Gly^2 bond; molecular weight of the enzyme, 100,000 (ref. 7).

activities, and that the soluble aminopeptidase acts on a different metabolic pool of endorphins. *A priori*, based on our lack of knowledge of the modes of action of peptides in intercellular communication in the nervous system, there is no reason to assume that soluble enzymes metabolizing peptides could not be importantly involved in the use of peptides as primary output signals. In addition, many enzymes formerly considered to be soluble on the basis of extractability properties are now known to exhibit transient associations with subcellular organelles, such as hexokinase with mitochondria[10] and choline-acetyltransferase with synaptic vesicles[11], and are solubilized from such organelles by metabolites as part of regulatory intracellular processes. It will be of interest to investigate brain peptidase activities from this perspective.

Identification of a tetrodotoxin-sensitive Na^+ channel in a variety of fibroblast lines

J. Pouysségur, Y. Jacques & M. Lazdunski

Centre de Biochimie, Faculté des Sciences, Parc Valrose, 06034 Nice, France

The action potential Na^+ ionophore of excitable cells can be activated either by alkaloid compounds such as veratridine, or by small polypeptide toxins extracted from scorpion venom or sea anemone[1,2]. One of the main features of this Na^+ channel is that it is blocked by tetrodotoxin (TTX). However, we report here that during analysis of Na^+ influx in resting fibroblasts, we found that a variety of fibroblast lines also possess a TTX receptor. Veratridine and sea anemone toxin act synergistically to stimulate Na^+ influx 7 to 10-fold in hamster and rat fibroblasts. As in excitable cells, this toxin-stimulated Na^+ influx is blocked by TTX. Addition of serum to hamster fibroblasts arrested in G_0 stimulates Na^+ influx three-fold. Observations that TTX does not prevent serum-activated Na^+ influx, initiation of DNA synthesis and cell proliferation suggest that the fast Na^- channel which we have identified in fibroblasts is not involved in growth control.

The gating system of the Na^+ channel in excitable cell systems such as nerve, skeletal muscle, cardiac cell and neuroblastoma is altered by veratridine and sea anemone toxin II[3–5]. These toxins also reveal 'silent' channels[6]. Figure 1 shows that the well known action of these toxins on excitable membranes is also observed in fibroblasts. The kinetics of $^{22}Na^+$ uptake in the Chinese hamster lung fibroblast line CC139 (ATCC) are shown in Fig. 1*a*. Veratridine at 100 µM or sea anemone toxin at 10 µM have no effect on $^{22}Na^+$ influx. However, when added together, these toxins effect a 5–10-fold stimulation in the 5-min Na^+ uptake in these fibroblasts (Fig. 1, Table 1). The toxin-activated influx is completely inhibited by TTX. Half-maximal inhibition is observed at 20–40 nM TTX. The apparent affinity of TTX for the fibroblast Na^+ channel is identical to that found in similar studies with spiking neuroblastoma cells[5]. Also, the number of Na^+ channel receptors might be even higher in CC139 than in neuroblastoma cells, as suggested by comparison of the toxin-stimulated Na^+ fluxes of these two cell lines (Table 1).

When Na^+ efflux through the $(Na^+ + K^+)$ATPase system is inhibited with ouabain, the addition of veratridine (100 µM) and sea anemone toxin (10 µM) to CC139 cells leads to rapid lysis (Fig. 2), which is due to an increase in cell osmotic pressure caused by massive Na^+ entry. Cell lysis is prevented when TTX is added before the other toxins, when ouabain is omitted (Na^+ escapes from the cells) or when external Na^+ is replaced by choline$^+$.

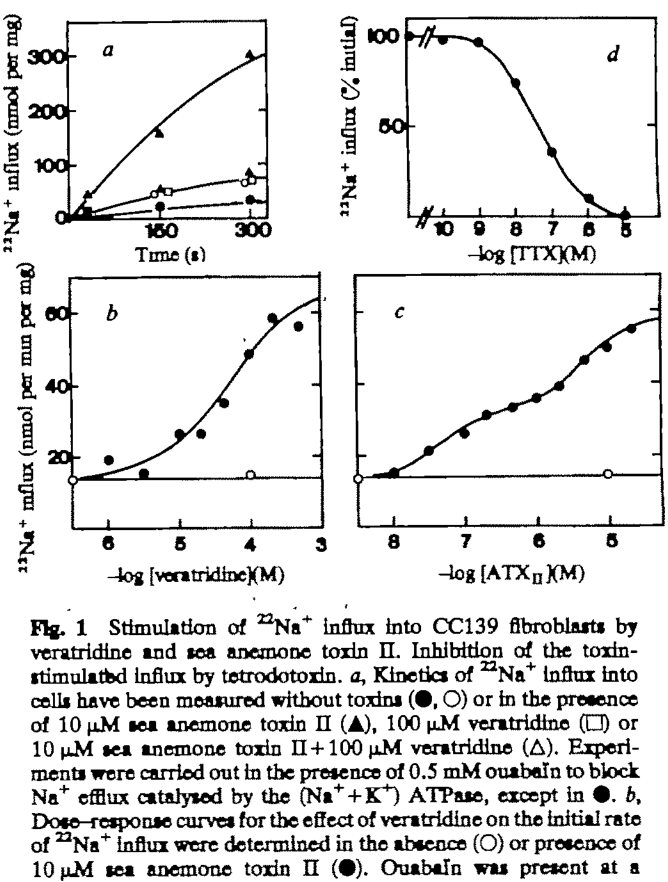

Fig. 1 Stimulation of $^{22}Na^+$ influx into CC139 fibroblasts by veratridine and sea anemone toxin II. Inhibition of the toxin-stimulated influx by tetrodotoxin. *a*, Kinetics of $^{22}Na^+$ influx into cells have been measured without toxins (●, ○) or in the presence of 10 µM sea anemone toxin II (▲), 100 µM veratridine (□) or 10 µM sea anemone toxin II + 100 µM veratridine (△). Experiments were carried out in the presence of 0.5 mM ouabain to block Na^+ efflux catalysed by the $(Na^+ + K^+)$ ATPase, except in ●. *b*, Dose–response curves for the effect of veratridine on the initial rate of $^{22}Na^+$ influx were determined in the absence (○) or presence of 10 µM sea anemone toxin II (●). Ouabain was present at a concentration of 0.5 mM. *c*, Dose–response curves for the effect of sea anemone toxin II (ATX$_{II}$) determined in the absence (○) or presence of veratridine (100 µM) (●). Ouabain was present at a concentration of 0.5 mM. *d*, Inhibition by TTX of the stimulating effect induced by the mixture of sea anemone toxin II (10 µM) and veratridine (100 µM) on the initial rate of $^{22}Na^+$ influx in the presence of 0.5 mM ouabain. $^{22}Na^+$ influx into confluent monolayers of CC139 cells was determined at 37 °C essentially as described previously for neuroblastoma cells[5]: culture medium of 35-mm dishes was first replaced by 1 ml of a saline solution buffered with 25 mM HEPES-Tris (*p*H 7.4) and containing 140 mM NaCl, 5.4 mM KCl, 1.8 mM $CaCl_2$, 0.8 mM Mg SO_4, 5 mM glucose and 0.1 mg ml^{-1} bovine serum albumin. After a 5-min preincubation of cells in this medium, $^{22}Na^+$ influx was then initiated by replacing the preincubation medium by 1 ml of the same saline solution isotopically labelled with $^{22}NaCl$ (2 µCi ml^{-1}). Ouabain (0.5 mM) and toxins were present in this uptake medium except when indicated. $^{22}Na^+$ influx was stopped 5 min later by removing the radioactive medium and washing the cells three times with 1 ml of a Na^+- and K^+-free saline solution at room temperature. In these conditions less than 5% of intracellular $^{22}Na^+$ is lost during the 15 s of the washing procedure. After solubilization of cells in 1 ml of NaOH (0.1 M), radioactivity was determined by scintillation counting and the initial rate of $^{22}Na^+$ influx calculated from the amount of $^{22}Na^+$ taken up in 5 min assuming linear kinetics. The time points of *a* were determined as described for the 5-min uptake points.

0028–0836/80/280162—03$01 00

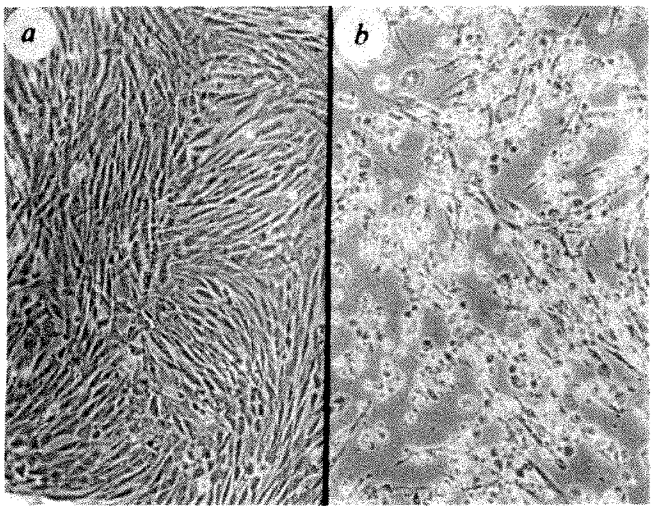

Fig. 2 Veratridine and sea anemone toxin-induced cell lysis in CC139 fibroblasts. Cells cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum were incubated with no drug (*a*) or with 100 μM veratridine + 10 μM sea anemone toxin and 0.5 mM ouabaïn (*b*). Phase contrast micrographs were taken 12 h after drug addition. Cell swelling is seen only after at least 30 min and 1 h before cell lysis (few cells) is detected. However, 2–3 h are required to see massive cell lysis. Incubation of the cells with ouabaïn alone or with the toxin mixture in the absence of ouabaïn over 24 h does not induce cell lysis (not shown).

Although CC139 cells have the morphology of fibroblasts, form fibrosarcoma tumours and do not generate action potentials, the origin of this established cell line cannot be known definitively. We therefore looked for fast Na^+ channels in two other fibroblast lines of Chinese hamster (CHO and CHL-V79), in a rat Fisher fibroblast line[7] and its polyoma virus-transformed derivative, and in chick embryo fibroblasts. Interestingly, all the cells possess a Na^+ channel stimulated by the mixture of veratridine and sea anemone toxins (Table 1). Although the stimulation effected by these toxins varied from 1.5- to 10-fold depending on the cell line, 30–50 nM TTX elicited half-maximal inhibition of Na^+ influx in all the cells tested. These results demonstrate the ubiquity of the fast Na^+ channel in fibroblasts from different origins.

It has been proposed that an increase in Na^+ influx might be the initial mitogenic signal in many cell systems[8]. Therefore, we have investigated whether the fast Na^+ channel of CC139 fibroblasts has any role in controlling their division. These cells can be arrested in G_0 by serum depletion. Figure 3 shows that reinitiation of DNA synthesis by 10% fetal calf serum is preceded by a very early threefold stimulation of Na^+ influx. The influx in these conditions is not blocked by TTX. This result, together with the observations that TTX does not affect the Na^+ uptake of growing fibroblasts, prevent reinitiation of DNA synthesis or alter cell division (not shown), strongly suggests that the TTX-sensitive Na^+ channel of fibroblasts is not involved in growth control.

Accordingly, these fibroblasts, like excitable cells, have receptors for veratridine, sea anemone toxin and TTX. The dose–response curves for the association of the different toxins with their respective receptors occur in a range of toxin concentrations which is similar for fibroblasts (Fig. 1*b*, *c*, *d*) and for excitable cells such as neuroblastoma[5]. Veratridine or sea anemone toxin alone significantly stimulate $^{22}Na^+$ entry through the TTX-sensitive Na^+ channel of neuroblastoma cells, and the two toxins act in synergy. In contrast, neither toxin alone stimulates $^{22}Na^+$ entry into fibroblasts (Fig. 1*a*); the mixture of the two toxins is essential for activation of the TTX-sensitive Na^+ channel. Electrophysiological studies are under way in an attempt to understand the differences between TTX-sensitive Na^+ channels in fibroblasts and those in excitable cells like neuroblastoma cells. Also, we hope to use the toxin-activable Na^+ channel of CC139 fibroblasts as a Na^+ microinjection device with which to

Table 1 Effect of veratridine and sea anemone toxin II on Na^+ influx in various fibroblast cell types

Cell type	Origin	5 min $^{22}Na^+$ uptake (nmol per mg protein) Basal	 Veratridine + sea anemone toxin	Stimulation (fold)
CC139	Chinese hamster lung fibroblast (ATCC)	72	570	7.9
CHL-V79	Chinese hamster lung fibroblast (ATCC)	88	95	1.1(2.1)
CHO	Chinese hamster ovary (Toronto's strain)	67	190	2.8(4.7)
FR-3T3	Rat Fisher fibroblasts[7]	16	154	9.6
3T3-PY	Rat Fisher-polyoma transformed	67	132	2
CEF	Secondary chick embryo fibroblast	67	93	1.4
NIE-115	Neuroblastoma	46	320	7

$^{22}Na^+$ uptake was measured as described in Fig. 1 legend, in the presence of 0.5 mM ouabaïn (basal) or 100 μM veratridine + 10 μM sea anemone toxin II for the toxin-stimulated influx. Values in parentheses represent the toxin-stimulation factor when cells were arrested by serum deprivation (serum deprivation reduces basal Na^+ influx, see Fig. 3). All values represent the average of duplicate experiments (less than 10% difference was observed in duplicate determinations).

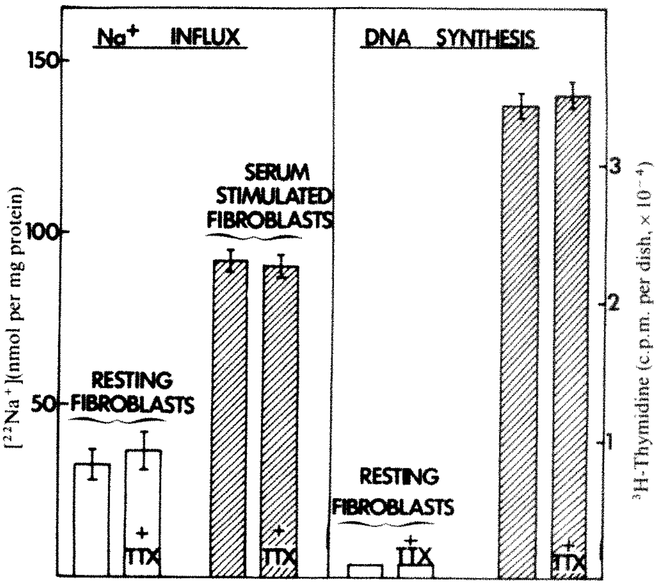

Fig. 3 Serum induced Na^+ influx and DNA synthesis in quiescent fibroblasts. Confluent CC139 fibroblasts were arrested in G_0/G_1 by incubating the cells in serum-free medium for 30 h. Na^+ influx was measured in the presence of 0.5 mM ouabaïn. Values represent 5 min $^{22}Na^+$ uptake in resting fibroblasts or in cells stimulated for 5 min with 10% fetal calf serum (hatched bar). For measurements of DNA synthesis, serum-deprived cells were incubated for 24 h in the presence of 0.5 μCi ^3H-thymidine without (empty bar) or with (hatched bar) 10% fetal calf serum. Where indicated +TTX, tetrodotoxin was added at 10^{-5} M during Na^+ uptake studies or during the 24 h of thymidine incorporation.

analyse the possible role of increased Na^+ influx in mitogenicity. These cells respond well to purified growth factors[9]. Finally, the toxin-effected cell lysis shown in Fig. 2 provides a powerful selection procedure for developing the genetics of Na^+ gating membrane components in a diploid and rapidly growing cell line.

We thank Mrs A. Franchi for technical assistance and Dr M. Murphy for reading the manuscript.

Loss of immune competence with age may be due to auto-anti-idiotypic antibody regulation

Myron R. Szewczuk & Rita J. Campbell

The Host Resistance Program, Department of Pathology, McMaster University Medical Centre, Hamilton, Ontario, Canada L8N 3Z5

The decline in immune function with ageing involves both a loss of B-cell function[1,2] and a decline in T-cell function[3-5]. This picture has been complicated by the recent observation that normal old mice produce more B-cell mitogen-induced autoantibodies to syngeneic erythrocytes than do young animals[6]. They also produce elevated levels of IgM and IgA anti-IgG autoantibodies[7] and increased suppressor-cell activites[8-10]. It is therefore difficult to explain the relationships between autoantibody production, increased suppressor-cell activities and the loss of immune competence in old animals. Recently, auto-anti-idiotypic antibody regulation has been proposed to explain a rapid decline in the antibody-forming cell response to antigen during a normal immune response in young adult mice[11]. Schrater *et al.*[12] have suggested that this antibody, produced during the immune response, combines with B-cell-surface antigen receptors and thus inhibits antibody secretion. If the number of B cells is normal in old animals[13], but their function is impaired, it may be that the decline in immune competence with age is due to auto-anti-idiotypic antibody regulation, perhaps affecting the B-cell-surface antigen receptors and preventing the cell from responding normally to exogenous antigens. We have therefore investigated whether auto-anti-idiotypic antibody could be detected in immune splenic B cells from old and young mice of the same strain. We report here that auto-anti-idiotypic antibody regulation seems to have a role in the loss of B-cell function with age.

We first immunized various aged C57BL/6J male mice intraperitoneally (i.p.) with a highly thymic-dependent antigen, trinitrophenylated bovine γ-globulin (TNP-BGG) in complete Freund's adjuvant (CFA). Splenic anti-TNP plaque-forming cell (PFC) responses were assayed 2 weeks after immunization. As shown in Table 1, 4-month-old mice produced high numbers of IgM, IgG and IgA anti-TNP PFCs whereas the 1- and 2-month-old mice produced relatively low numbers. However, mice of 8 months or older showed a significant decline in the number of anti-TNP PFCs in the three isotypes studied as compared with the PFC responses of the 4-month-old group. Thus, aged ani-

Male mice received 500 μg TNP-BGG in CFA i.p. Splenic anti-TNP PFCs per 10^8 nucleated cells were assayed 2 weeks after immunization. Data presented are the geometric means of pooled spleens from three to five animals from three to six independent experiments. The data from the 11- and 24-month groups are geometric means from individual spleens. The data from the 15-month group are from pooled spleens from five animals from one experiment. The value in parentheses is the natural logarithm of s.d. obtained from natural log-transformed data. The *t*-test was used to evaluate the statistical significance of differences on natural long-transformed data. NS, Not significantly different. Anti-TNP PFCs were determined by the method of Jerne *et al.*[21] as modified for a slide assay by Dresser and Greaves[22]. Rabbit anti-mouse IgG and rabbit anti-mouse IgA were used at predetermined optimal dilution (1:300), to develop indirect IgG and IgA plaques, respectively. The IgA-developing serum was prepared in rabbits by using pure mouse myeloma MOPC 315 (IgAλ2). The antiserum was depleted of anti-light-chain activity by passage through a pure mouse IgG-Sepharose 4-B immunoadsorbent column. The IgG-developing serum was prepared in rabbits by using purified mouse IgG (Miles, Lot 51). The antisera showed only a single line against normal mouse sera and pure IgG on Ouchterlony analysis. Pure mouse IgA or IgG when added to the PFC assay inhibited the development of only IgA or IgG PFCs, respectively, when the respective developing sera were added. Before developing indirect plaques, goat anti-μ was used to inhibit >95% IgM plaques during the first incubation period. The anti-μ antiserum was prepared in goats by using pure mouse MOPC 104E (IgMλ1) (Bionetics, Lot AJ110). It was passaged through a pure mouse IgG–Sepharose 4-B immunoadsorbent column to deplete anti-light-chain activity.

Table 2 Effect of age on the heterogeneity of affinity of splenic anti-TNP PFC responses in C57BL/6J mice

		Heterogeneity index		
Age (months)	No. of mice	For IgM PFCs	For IgG PFCs	For IgA PFCs

Male mice received 500 μg TNP-BGG in CFA i.p. Splenic anti-TNP PFCs were assayed 2 weeks after immunization. The Shannon heterogeneity index[15] was used to describe the degree of heterogeneity of affinity of the IgM, IgG and IgA anti-TNP PFC population of pooled spleens from three to five mice. The values presented are the means ± s.d. from three or four independent experiments. The values from the 15-month group were obtained from a single pool of five mice from one experiment. The values from the 24-month group were obtained from individual spleens and presented as means ± s.d. from two animals. The larger the index, the greater the heterogeneity. The *t*-test was used to evaluate the statistical significance in the heterogeneity indices as compared with the 4-month-old group.

Table 3 Effect of age on the appearance of anti-idiotype-blocked hapten-augmentable, anti-TNP PFCs during the normal immune response to TNP-BGG in C57BL/6J mice

Age (months)	No. of mice	TNP-EACA	Splenic anti-TNP PFCs per 10^8 cells					
			IgM PFCs	(% aug PFCs)	IgG PFCs	(% aug PFCs)	IgA PFCs	(% aug PFCs)
2	15	–	2,154		2,035		1,838	
		+	2,283	6%	2,340	15%	2,022	10%
4	10	–	2,084		1,350		2,394	
		+	2,272	9% (NS)	1,755	30% ($P<0.005$)	2,729	14% (NS)
8	15	–	3,818		1,856		2,196	
		+	5,765	51% ($P<0.001$)	3,972	114% ($P<0.001$)	4,085	86% ($P<0.001$)
15	5	–	707		987		833	
		+	1,308	85%	2,240	127%	1,974	137%
24	2	–	351		337		456	
		+	1,127	221%	896	166%	880	43%

Male mice received 500 μg TNP-BGG in CFA i.p. Splenic anti-TNP PFCs per 10^8 nucleated cells were assayed 2 weeks after immunization. Data presented are the geometric means of 10–15 animals from two or three independent experiments. Spleen tissues were assayed as a single pool from five animals in each experiment. Spleen tissues from the 15-month-old group were assayed as a single pool from five mice in one experiment. Spleen tissues from the 24-month group were assayed as individual spleens and geometric means of two animals from one experiment are presented. Percentage augmentation of PFCs by optimal hapten concentration ($1\times10^{-9}-1\times10^{-7}$ M TNP-EACA) is calculated as: 100×(PFCs in presence of hapten – PFCs in absence of hapten)/PFC in absence of hapten. The *t*-test was used to evaluate the statistical significance of differences on natural log-transformed data as compared with the 2-month group.

mals exhibited a loss of IgM, IgG and IgA PFCs in their primary immune response to TNP-BGG. These results are consistent with other data reported for this strain, with a loss of IgM anti-sheep red blood cell (SRBC) PFCs *in vitro* in mice over 4 months of age[14].

We then investigated the heterogeneity of the PFC response during ageing. The distribution of PFCs with regard to avidity was determined by hapten inhibition of plaque formation in mice of different ages and can be quantitated using the Shannon function[15] as heterogeneity index, thereby permitting a simple statistical evaluation of the data. This index is expressed as a $\log_2$ term and increases with increasing heterogeneity of the PFC distribution. The heterogeneity indices calculated from these data (distributions not shown) show a significant decrease in heterogeneity of splenic PFCs with age (Table 2). Thus, IgM, IgG and IgA PFCs from 8-month-old animals are significantly ($P<0.001$) less heterogeneous than PFCs from 4-month-old animals. The affinities of IgM and IgG PFCs from the 24-month-old animals are completely restricted but the IgA PFCs still retain some heterogeneity, although this is significantly ($P<0.001$) less than that in the 4-month-old group. Thus, with ageing, there is a progressive decrease in heterogeneity, characterized by a loss of high-avidity PFC subpopulations in older animals.

Auto-anti-idiotypic antibodies have been shown to be responsible for a decline in the number of PFCs, a reduction in the heterogeneity of avidity of PFCs and the occurrence of hapten-augmentable PFCs (anti-idiotype blocked)[12]. We therefore investigated the effect of age on the appearance of anti-idiotype-blocked, hapten-augmentable anti-TNP PFCs. As shown in Table 3, 8-month-old mice, during the primary immune response to TNP-BGG, produced a significantly ($P<0.001$) high percentage of hapten-augmentable PFC responses in the IgM (51%), IgG (114%) and IgA (86%) isotypes studied as compared with the 2-month-old group, which did not show any appreciable (6–15%) hapten-augmentable PFCs. Older mice also produced a high percentage of hapten-augmentable PFC responses, ranging from 85% to 221% in the three isotypes. These data support the hypothesis that auto-anti-idiotypic antibody de-regulation of splenic anti-TNP PFC responses of old mice is responsible for the age-associated decline in the number and heterogeneity of avidity of the PFCs in the three isotypes studied.

Other studies[16] describe an assay for anti-idiotypic antibody that makes use of the ability of such antibody in the immune sera to inhibit plaque formation by idiotype-producing cells. This inhibition was reversible by the hapten, TNP-ε-amino-*n*-caproic acid (EACA). Results in Table 4 show that pools of immune sera from 8-month or older mice immunized 14 days previously with TNP-BGG in CFA caused a hapten-reversible block of plaque formation by spleen cells from TNP-BGG immune 2-month-old mice. In contrast, immune sera from 2-month-old mice failed to inhibit the PFC response.

Table 4 Anti-idiotypic antibody activity in immune sera from ageing C57BL/6J mice as assayed by hapten-reversible plaque inhibition

Serum source	Anti-TNP titre (reciprocal)	% Of control response					
		PFCs from spleen 1			PFCs from spleen 2		
		IgM PFCs	IgG PFCs	IgA PFCs	IgM PFCs	IgG PFCs	IgA PFCs
NMS	<2	100	100	100	100	100	100
Immune 2-month-old	80	100	110	99	78	83	95
Immune 4-month-old	80	78	52	96	72	75	96
Immune 8-month-old	160	42	23	73	31	57	71
Immune 11-month-old	80	62	33	88	53	39	50
Immune 15-month-old	160	47	40	88	52	37	60
Immune 24-month-old	160	42	23	45	ND	ND	ND

Immune spleen cells were obtained from individual 2-month-old C57BL/6J male mice that had been immunized i.p. with 500 μg TNP-BGG in CFA 14 days before assay. The control values (PFCs determined in the presence of normal mouse serum [NMS]) ranged for 1,667 IgM, 5,451 IgG and 3,608 IgA anti-TNP PFCs per 10^8 nucleated cells from spleen 1 and 2,073 IgM, 2,439 IgG and 10,829 IgA PFC's from spleen 2. Immune cells at $3\text{–}5\times10^7$ cells per ml were incubated with immune sera or NMS at a 1:10 final dilution for 5 min at 4°C. The cells were washed once, resuspended to the original volume, and plated. The inhibition of plaque formation was completely reversible by addition of hapten. The data illustrated are from one representative experiment out of six independent experiments. Anti-TNP titre was determined by passive hemagglutination. ND, Not determined.

The NMS pool was obtained from 10 C57BL/6J male mice at 10 weeks of age. Pools of immune sera were obtained from groups of 3–10 C57BL/6J male mice at various indicated ages, which had been immunized with 500 μg TNP-BGG in CFA i.p. 14 days before collection of sera.

The above findings suggest that the loss of immune competence in the splenic B-cell population may be due to auto-anti-idiotypic antibody regulation. The nature of the stimulus for the production of auto-anti-idiotypic antibody with age is unknown. However, the reported[13] increased appearance of new or altered antigenic determinants on the surface membrane of lymphoid cells from old mice or possibly alterations in I-region products with age[17], may serve as an attractive model to explain the increased appearance of auto-anti-idiotypic reactive B-cell clones. Also, auto-anti-idiotypic antibody may contribute to the increased suppressor cell activities in old animals. This is supported by the findings that anti-idiotypic antibody can induce the activation of suppressor T cells in normal young adult mice [18–20]. This type of observation has not been demonstrated in old animals. Furthermore, the relationship between auto-anti-idiotypic antibody regulation in old animals and auto-immune disease remains unclear.

Phenotypic changes of phytohaemagglutinin-stimulated hairy cells

Paul Guglielmi, Jean-Louis Preud'homme & Georges Flandrin

Laboratory of Immunochemistry and Immunopathology (INSERM U 108 and Laboratory of Oncology and Immunopathology of CNRS) and Laboratory of Cytology, Research Institute on Blood Diseases, Hôpital Saint-Louis, Paris, France

Hairy cell leukaemia (leukaemic reticuloendotheliosis) appears to be a homogeneous and well defined disease on the basis of clinical presentation, light and electron microscopic features and cytochemical characteristics[1], but the study of immunological markers of hairy cells (HC) from many patients reveals apparent heterogeneity. The most common phenotype associates B-cell and monocytic properties: HC usually express monoclonal surface (and in certain cases cytoplasmic) immunoglobulins, receptors for IgM and IgG Fc, and mouse erythrocytes, and Ia-like antigens. Additionally, they are capable of phagocytosis, glass adherence, lysozyme and peroxidase synthesis[2–18]. However, most of these features are not constant and cases have been reported in which HC fail to express one or more of these properties. In certain cases HC even display a T-cell phenotype, while, in others, features of both T and B cells are expressed[16,19–22]. Moreover, in two recently studied patients, the phenotype of HC in the blood differed from that in the spleen (B+T in the blood and B in the spleen)[16]. These surprising discrepancies led us to hypothesize that HC from the same individual might be able to express different phenotypes following an appropriate stimulus. We therefore studied immunological parameters of HC stimulated by mitogens and the results indeed showed that after stimulation by phytohaemagglutinin (PHA) the cells switched from B to T or B+T phenotypes.

The three patients studied were affected with clinically and morphologically typical HC leukaemia. They had not previously received specific therapy. In patient Go., HC were obtained twice (3 months apart) from leukaemic blood. On both occasions, cell suspensions resulting from Ficoll centrifugation contained 10% lymphocytes and 90% HC as shown by cytological and cytochemical examination. Cells obtained from the spleen (splenectomy) were almost all HC in patient Cha. and 95% HC in patient Que. Cells from both blood and spleen were studied for lymphocyte markers and cultured with or without PHA; cultured cells were serially examined for cell number, tritiated thymidine incorporation, cytology and lymphocyte markers (see legend to Table 1).

Table 1 Immunological markers of fresh and cultured hairy cells (% positive cells)

Patients	Cells studied	SIg	cIg	γFcR	E rosettes	Anti-T serum
Go.	Fresh cells	77$\delta\lambda$	0	89	8	ND
	Day 4 cultured cells					
	Control	90$\delta\lambda$	56$\mu\lambda$	67	8	20*
	PHA	0	0	12	69	61*
Go. Expt 2	Fresh cells	71$\delta\lambda$	82$\mu\lambda$	73	37	25
	Day 3 cultured cells					
	Control	69$\delta\lambda$	82$\mu\lambda$	69	10	12
	PHA	0	0	2	80	82
Cha.	Fresh cells	38$\gamma\kappa(\mu\delta)$	0	1	1·5	1
	Day 14 cultured cells					
	Control	90$\gamma\kappa(\mu(\delta)$	0	51	4	5
	PHA	0·5	0	0	83	92
Que.	Fresh cells	95$\delta\lambda(\mu)$	67$\mu\lambda$	90	6	5
	Day 14 cultured cells					
	Control	83$\delta\lambda(\mu)$	57$\mu\lambda$	99	1	3
	PHA	2	50$\mu\lambda$	96	88	90

The cells obtained from blood or spleen were studied for cytological (Giemsa staining and tartrate-resistant acid phosphatase activity) and immunological parameters, then cultured at 1×10^6 cells ml^{-1} in RPMI 1640 medium containing 10% fetal calf serum (Gibco) either with or without PHA (PHA M, Gibco, final concentration 0.6%). Cultured cells were repeatedly studied for cytology, cytochemistry, cell numeration, thymidine incorporation and immunological features. Surface and cytoplasmic immunoglobulins (SIg and cIg) were assessed by direct immunofluorescence with rhodamine-conjugated rabbit F(ab')2 fragments prepared in our laboratory as previously described[23]. Conjugates polyvalent for human Ig and monospecific for μ, γ, σ, α, κ and λ chains were used. Ig Fc receptors (γ Fc R) were detected by immunofluorescence with immune complexes in conditions in which the positive cells are predominantly B cells[24]. E-rosette forming cells were enumerated according to a classical method[25]. Human T-lymphocyte specific antigens were studied by indirect immunofluorescence with a rabbit antiserum raised against peripheral T cells and a rhodamine-coupled sheep F(ab')2 fragment anti-rabbit IgG (ref. 26). ND, Not determined.

* Performed on day 7, when the control and PHA-stimulated cultures contained 26% and 81% E-rosetting cells respectively.

In the first study of cells from patient Go., the fresh HC displayed a B-lymphocyte phenotype with $\delta\lambda$ monotypic SIg (5–20% of the cells also stained for μ, γ and κ, which probably

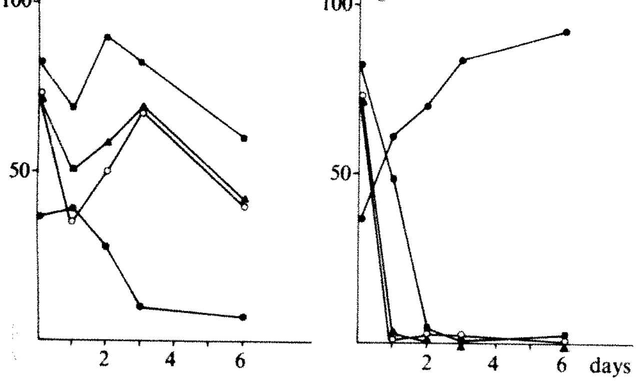
0028–0836/80/280166—03$01.00

corresponded to exogenous Ig bound to Fc receptors since only δ and λ chains were subsequently found on cultured cells), γFcR and no T-cell markers (Table 1). PHA-stimulated cells were not examined before day 4 of culture. At this time, more than 90% of the cells in both PHA-stimulated and control cultures were typical HC on morphological grounds. In the control culture, the B phenotype remained stable except that monotypic cIg (IgM λ) became detectable. On the contrary, PHA-stimulated HC had lost SIg and γFcR, formed E rosettes and were strongly stained by anti-T serum, thus displaying a T-lymphocyte phenotype. The immunological phenotype in both control and PHA-stimulated cultures remained the same for the 5 following days, then most PHA-stimulated cells died. During this period, the appearance of PHA-stimulated cells changed: 50% of cells on day 5 and 60–70% the following days were large blast cells showing a strong acid phosphatase positivity which was tartrate-sensitive. Cell numbers were relatively stable and roughly similar in control and stimulated cultures. Relatively low levels of thymidine incorporation were found with stimulation indices of 18.6 and 3.0 on days 4 and 6 after PHA-stimulation (similar observations were made in patients Cha. and Que. with stimulation indices varying between 7.5 and 9.7 in PHA-stimulated cultures on days 4 and 6). These data and the rapidity (24 h) of morphological changes suggest that the T-blast cells may be derived from the PHA-stimulated HC.

When studied again 3 months later, fresh HC from patient Go.'s blood showed two features different from those found at first examination: most HC contained cytoplasmic μ and λ chains and a fair number had T-cell markers. Since 90% of the cells were HC, the obvious overlap of figures for T and B markers (Table 1) indicates that some HC had a mixed B+T phenotype. This mixed phenotype was lost in the control cultures (Table 1 and Fig. 1*a*) where HC retained B-cell characteristics only (the cells staining with the anti-T serum on days 3 and 6 were small lymphocytes by phase contrast microscopy). Daily study of PHA-stimulated cells showed a rapid loss of B-cell markers and the acquirement of T markers (Fig. 1*b* and Table 1). Morphological changes similar to those initially found were observed; the cells had a typical HC appearance till day 4 and were large blast cells on the following days.

Only 38% of fresh HC in patient Cha.'s spleen had monotypic SIg(γκ). Between 6 and 10% of the cells also stained for μ and δ, respectively. All these Ig chains were probably synthesized by the cells since they were found in control cultures at repeated examinations over 3 weeks. In non-stimulated cultures, we observed a progressive increase in the number of SIg-bearing cells (up to 90% on day 14) and the appearance of γFcR which was not detectable on fresh cells (Table 1). The changes occurring after PHA-stimulation had a slower kinetics than in patient Go. On day 5, the cells had lost SIg expression but only 10% formed E rosettes. These cells were virtually all HC by morphological criteria. Then, the percentage of E-rosetting cells increased. After day 12, most cells displayed T-cell features (Table 1). However, these cells were blast cells lacking cytological and cytochemical characteristics of HC. PHA-stimulated cells could not be studied after day 15 due to cell death.

Fig. 1 B and T cell markers of patient Go.'s blood cells cultured *a*, without or *b*, with PHA (second experiment). ●, E rosettes; ▲, SIg; ■, cIg; ○, γFcR. The number of cells staining with the anti-T serum paralleled that of E rosettes (not shown).



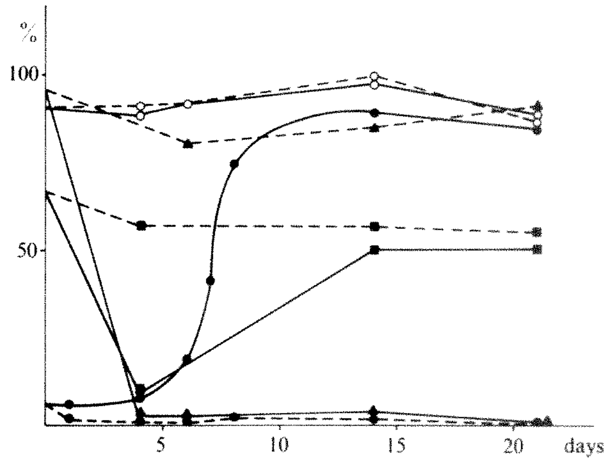


Fig. 2 B- and T-cell markers of patient Que.'s spleen cells in control (dotted lines) and PHA-stimulated (solid lines) cultures. ●, E rosettes; ▲, SIg; ■, cIg; ○, γFcR.

Study of patient Que.'s fresh spleen HC showed a B phenotype with SIg (δλ on most cells and also μ on some), cIg(μλ) and γFcR (Table 1). A faint surface staining and a globular cytoplasmic staining for γ, μ, κ and λ was additionally found and it was shown to be due to adsorption and pinocytosis of exogenous Ig. The B-cell phenotype remained stable in the control culture (Table 1 and Fig. 2, dotted lines). After PHA-stimulation, SIg rapidly disappeared whereas the number of cells with γFcR was constant. After an initial drop, the number of cells containing cytoplasmic μ and λ chains returned to pre-culture levels. The number of cells forming E rosettes and staining with anti-T serum sharply increased from day 4 to day 8 and then the phenotype of PHA-stimulated cells was unchanged until day 21 (Table 1 and Fig. 2, solid lines). Further study was not possible due to cell death. During these phenotypic changes and in contrast with the first cases, stimulated HC retained their typical morphological features. Therefore, the origin of these cells with a mixed T–B phenotype from the HC in this patient was supported by morphology and by the retention of some of the original B-cell markers (especially monoclonal cytoplasmic μ and λ chains).

This study provides three major findings: (1) when HC from the same patient were studied twice, their properties were not the same; (2) spontaneous variations were observed in control cultures: acquirement of cIg or of γFcR, switch from a B+T to a B phenotype. These data are in agreement with the finding of a different phenotype in the spleen and the blood from two patients[16]. Moreover, sequential studies of immunological markers in the same patients showed clear-cut fluctuations, as reported very recently[27]; (3) the most striking finding in our study is that PHA stimulation induced a switch from a B (patients Go. and Cha.) or a B+T (patient Go.) phenotype to a T phenotype, or from a B to a B+T phenotype (patient Que.). The two T-cell markers found on these cells were distinct since we were unable to inhibit E-rosette formation by preincubation with anti-T serum. Cells binding sheep erythrocytes were actual E rosettes and not immune rosettes which could have resulted from secretion or surface expression of Ig with anti-sheep red cell activity, as sometimes observed in CLL[28]. Indeed, rosetting was obtained only in the thermal and incubation conditions needed for T cells; it was not inhibited by incubation with anti-Ig sera and the cells did not form plaques with sheep erythrocytes. It must be stressed that these E rosettes were centered by lymphoid cells (as shown by phase contrast microscopy and

Giemsa staining of cytocentrifuge slides) and were not just clumps of red cells due to PHA in the medium (which was indeed a problem during the 2 or 3 first days of culture although HC were washed several times before rosette assay).

In two cases, there is no doubt that the cells which showed T-cell properties after PHA-stimulation did not result from the expansion of normal T cells and were derived from the original HC since: (1) These cells were still typical HC by morphological and cytochemical criteria. (2) In patient Que., they continued to express γFcR and the same intracytoplasmic Ig chains as the fresh cells. (3) In patient Go., the changes were too rapid (already clear-cut after 1 day of culture) to have been accountable by the growth of normal T cells. (4) Low levels of mitogenic stimulation and roughly stable or slightly decreased cell numbers similarly negate this hypothesis. In patient Cha., the cells with T-cell markers on day 12 of culture which could not be identified as HC upon morphological grounds were nevertheless probably derived from HC. Indeed, day 5 PHA-stimulated cultures from this patient's cells contain exclusively typical HC which had lost SIg while 10% of them had become E positive. The morphological changes subsequently observed are probably similar to those observed in patient Go., in whom typical HC with T-cell properties were replaced by blast cells probably derived from them (since this morphological change was observed within 24 h).

Since HC have peculiar surface properties, one could hypothesize that T-cell markers in PHA-stimulated cultures may not be endogenous but result from adsorption of membrane molecules released in the culture medium by PHA-stimulated normal T cells. This hypothesis may be ruled out for the following reasons: (1) cells from control cultures were incubated for 1 h, 3 h and overnight at 37 °C in supernatant media of PHA-stimulated cultures containing mostly cells with T markers. This incubation did not result in any change of the phenotype of these cells. (2) On several occasions, in patient Go., control and pokeweed-mitogen stimulated cultures contained a fair number of T cells (10–30%, with a similar percentage of large blast cells on Giemsa-stained smears) whereas HC in these cultures had no T-cell markers; (3) This hypothesis may hardly explain the loss of B cell features.

It is therefore clear that PHA actually induces major phenotypic changes of HC. This phenomenon is reversible since, when cultured cells with newly acquired T cell features were washed several times to remove the bulk of PHA and incubated in fresh medium without PHA, they lost T-cell characteristics and expressed the same B-cell properties as before culture within 2 days. Preliminary results of studies performed with other mitogens showed that concanavalin A induced changes similar to those observed with PHA, whereas we observed a plasmacytic differentiation after stimulation with the mitogen from nocardia opaca. If similar changes occur *in vivo*, our observation conciliates the published discrepancies in immunological phenotypes and HC may be considered as very remarkable cells capable of expressing different properties after an appropriate stimulation.

We thank Dr Larry B. Vogler for reviewing the English form of this manuscript, and A. Dimitriu for performing some of the tests. This work was supported by DGRST (grant no. 80.7.220).

The immunoglobulin μ constant region gene is expressed in mouse thymocytes

David J. Kemp, Anne Wilson, Alan W. Harris & Ken Shortman

The Walter and Eliza Hall Institute of Medical Research, Post Office, Royal Melbourne Hospital, Victoria 3050, Australia

It has been a matter of controversy whether the functional capacity of T cells to discriminate between antigens is mediated via immunoglobulin, an immunoglobulin-like molecule, or by the product(s) of unrelated genes. The progenitors of immunoglobulin-secreting cells, B cells, express membrane-bound immunoglobulin as the antigen-specific receptor on their surface[1]. For T cells, although products of immunoglobulin heavy chain variable region genes are implicated as receptor components[2–4], there has been no compelling immunochemical evidence for participation of either immunoglobulin light chains or heavy chain constant regions (see refs 2–6 for the disparate views). Recently, using cloned immunoglobulin DNA sequences as hybridization probes, we have demonstrated that the immunoglobulin C_μ gene, but not the C_κ gene, is expressed as polyadenylated RNA in some T cell tumour (T lymphoma) cell lines[7]. Individual T lymphoma lines yielded up to three discrete μ RNA species of different sizes (1.9, 2.2 and 3.0 kilobases), each species being different in size from the major μ RNA species present in B lymphoma cells (2.4 and 2.7 kilobases)[7,8]. We show here that cells from the normal mouse thymus contain μ RNA species, indistinguishable in size from those in T lymphoma cells, but contain little if any κ RNA.

To detect μ and κ RNAs in T- and B-cell RNA preparations, we used as probes DNA fragments[7] derived from plasmids bearing cDNA copies of a μ (ref. 9) and a κ (ref. 10) mRNA. Polyadenylated RNA from the cells was fractionated by agarose gel electrophoresis, blotted from the gel onto diazobenzyloxymethyl paper and hybridized with the ^{32}P-DNA probes[11]. RNA species which hybridized were detected by autoradiography. Thymocytes were prepared[12] from 5–6-week-old male CBA mice with care to exclude parathymic lymph nodes. They were found to be contaminated by 0.2–0.3% of surface immunoglobulin-positive cells, presumably B cells. The contaminating B cells were depleted at least threefold by treatment of the thymocytes with antiserum against Ia^k followed by rabbit complement[13]. To evaluate further whether contaminating B cells might contribute to immunoglobulin RNA in thymocyte RNA preparations, we characterized RNA obtained from three sources of B cells: normal spleen, spleen cells from

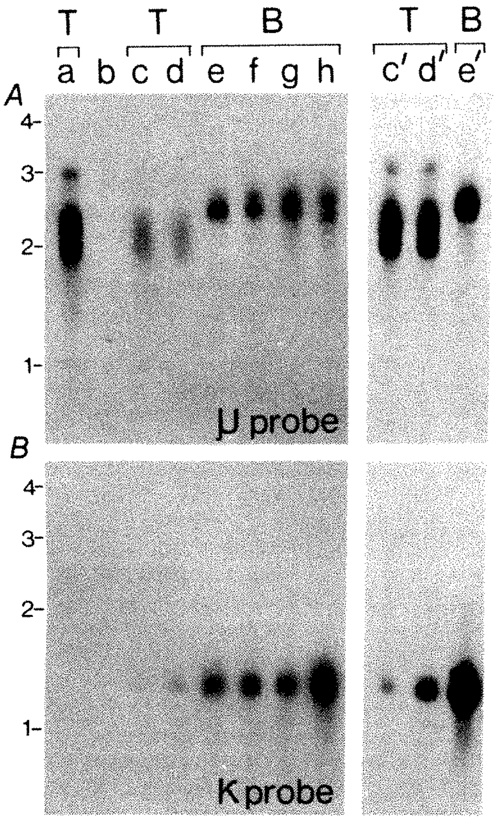

Fig. 1 Detection of *A*, μ RNA; and *B*, κ RNA in T and B cells. Polyadenylated RNA isolated from the cells indicated was denatured, fractionated by agarose gel electrophoresis, transferred to diazobenzyloxymethyl paper[11], hybridized with ^{32}P-DNA from cloned μ (ref. 9) and κ (ref. 10) cDNAs and autoradiographed for 3 days (tracks a–h) or 10 days (tracks c', d', e'), all as described previously[7]. Polyadenylated RNA (5 μg) was loaded onto tracks a–d and 0.5 μg onto tracks e–h. The sizes (in kilobases) are indicated on the left. The cells used for RNA preparation were: lane a, STRij-4-2.2 T lymphoma cells[7]; lane b, EMT6 sarcoma cells[7]; lanes c, d, c' and d', thymus cells prepared from 5–6 week old male CBA/CaHWehi mice. The cells used for the RNA preparation in lanes c and c' had been treated[13] with antiserum against Ia^k (prepared in the congeneic A.TH anti-A.TL combination) followed by rabbit complement treatment and removal of damaged cells[12]. Anti-Ia^k/complement treatment reduced the number of surface immunoglobulin-positive cells (determined by immunofluorescence) from 0.2% to <0.06% and lowered the level of functional B cells detected in a limit dilution assay[13] by at least 10-fold; lanes e, e', spleen cells, prepared from CBA.nu mice; lanes f and g, spleen cells, prepared from DBA/2 mice. The spleen cells used for lane f had been treated with anti-Thy-1 plus complement followed by damaged-cell removal, a procedure which removed 29% of the cells and all detectable T cells; lane h, W231.1 B lymphoma cells.

athymic nude mice and spleen cells treated with anti-Thy 1 plus complement to remove T cells.

Autoradiographs revealing species of RNA hybridizing with radioactive μ and κ probes are shown in Fig. 1. Relative contents of μ and κ RNA estimated from densitometric measurements on the autoradiographs are listed in Table 1.

In thymocyte RNA we detected μ RNA species of 1.9, 2.2 and 3.0 kilobases (Fig. 1*a*, tracks c, d, c' and d'). They were of the same size and relative abundance as μ RNA species from STRij-4 T lymphoma cells (track a). In contrast, each of the three different types of B cell preparations tested contained μ RNA species of 2.4 and 2.7 kilobases, analogous to the two species from WEHI-231 B lymphoma cells (tracks e–h and e'). As expected[7], the control RNA from the sarcoma cell line EMT6 (track b) contained no detectable μ RNA. In comparing the intensity of the μ RNA signals in the various tracks shown in Fig. 1, note that 10 times more RNA from thymocytes and STRij-4 T lymphoma cells than from splenic B cells and WEHI-231 B lymphoma cells was loaded on to the gel, as the μ RNA content of thymocytes was 10- to 20-fold lower than that of B cells.

It is crucial to know whether the μ RNA species are authentic products of the C_μ gene as, for example, hybridization of an RNA species distantly related to the C_κ gene has been observed in a T lymphoma[14]. The results shown in Fig. 1*A* were obtained using a probe representing only domains 1 and 2 of the C_μ gene[7]. When a cloned segment containing only C_μ domains 3 and 4 (ref. 7) was used as the probe, μ RNA species identical to those shown in Fig. 1*A* were detected in anti-Ia^k purified thymocytes (data not shown). Hence the thymocyte μ RNA species must each contain sequences from both the 5' and 3' halves of the C_μ gene, as is the case with T lymphoma μ RNAs[7]. We have also examined the thermal stability of hybrids formed with thymocyte RNA and the probe for domains 3 and 4. The hybrids formed with each thymocyte μ RNA species were stable to incubation at 65 °C in 0.036 M Na$^+$. In these conditions, this DNA probe forms stable hybrids only with the C_μ gene[15], not with any other sequence in the mouse genome. Thus the thymocyte μ RNAs are authentic products of the C_μ gene.

As κ chains comprise about 95% of the known immunoglobin light chains in the mouse, we expected that κ RNA would be readily detectable in B cells and this was borne out (Fig. 1*B*, tracks e–g). κ RNA was also detectable in RNA from crude thymocyte preparations (Fig. 1*B*, track d), but in lower amounts than in any of the B cell preparations (Table 1). We think most of the κ RNA comes from cells of the B lineage, because it was lowered by about threefold by depletion of B cells and plasma cells from the thymocyte population (Fig. 1*B*, track c); the resultant molar ratio of κ RNA to μ RNA was only one tenth of that found in purified B cells (Table 1). To delineate further the cellular origins of both μ and κ RNA in thymocyte preparations, we fractionated CBA mouse thymocytes on the basis of their buoyant density by centrifugation on continuous albumin gradients. The procedure used produces a marked separation of the minor, immunologically active, low Thy-1, cortisone-resistant, medullary subset (concentrated in fraction 2, Table 1) from the major subset (mostly found in fractions 3–4)[16]. The few contaminating activated B cells and immunoglobulin-secreting plasma cells are concentrated in the least dense fraction[17]. While μ RNA of the characteristic T lymphoma size classes was found

Table 1 Relative μ and κ RNA contents of T and B cells

Cells	Purification	κ RNA / μ RNA*
Expt 1		
STRij-4-2.2	Cloned cell line	<0.01
Thymus	None	0.25
Thymus	Anti-Ia^k	0.085
Spleen	None	0.90
Spleen	Anti-Thy-1	1.00
Spleen	From athymic nude mouse	0.72
WEHI-231.1	Cloned cell line	1.83
Expt 2		
Thymus	None	0.065
Thymus	Fraction 1 (ρ = 1.0630–1.0730)	0.28
Thymus	Fraction 2 (ρ = 1.0730–1.0752)	0.024
Thymus	Fraction 3 (ρ = 1.0752–1.0798)	0.014
Thymus	Fraction 4 (ρ = 1.0798–1.0824)	<0.02
Thymus	Fraction 5 (ρ = 1.0824–1.0910)	<0.02
Spleen	Anti-Thy-1	1.00

*The relative amounts of μ (or κ) RNA in each sample were determined by quantitative densitometry on autoradiographs prepared as described in Fig. 1 legend. These values were normalized to the values obtained for T cell-depleted spleen cells, assuming the latter value to be 1.0 mol κ RNA per mol μ RNA.

in all density fractions with little evidence for selective concentration in any fraction, the molar ratio of $\kappa : \mu$ RNA decreased to ≤ 0.024 in fractions 2–5 (Table 1). More than 90% of the total κ RNA was concentrated in the least dense fraction, which contained only 12% of the thymocytes. We conclude that the κ RNA originates from contaminating plasma cells or activated B cells. Since plasma cells (as evidenced by plasmacytomas) contain about 100–1,000 times more immunoglobulin mRNA than do B cells[7,8], they would contain at least 40,000 times as much κ RNA as our purified thymocytes (present data). Plasma cell contamination at a level of 1 in 40,000 could be present in thymocytes and might be the origin of immunoglobulin κ chains which others have found to be synthesized by thymocyte suspensions[18]. Our results certainly do not confirm earlier reports[19,20] suggesting the presence of similar amounts of κ RNA in spleen and thymus cells.

The average μ RNA content of about 5–10 molecules per thymocyte is similar to that found in some T lymphoma cell lines that we have studied[7]. We do not know, however, what proportion of thymocytes contain μ RNA. Expression of the μ but not the κ gene in thymocytes suggests a close parallel with pre-B cells[21] and this analogy is extended by the recently reported presence in an immature B cell lymphoma line[8] of μ RNA species with sizes (2.1 to 3.0 kilobases), similar to those in T lymphoma lines.

Our demonstration here of C_μ gene expression in normal thymocytes complements our results with cloned T lymphoid cell lines[7]. Together they constitute a strong case that the C_H locus functions in at least some cells of the T lineage, perhaps to encode a component of the T cell antigen receptor.

We thank Sue Kyne and Angela Apa for technical assistance, Jerry Adams and Suzanne Cory for helpful discussions and Judy Layton for determining immunofluorescence. This work was supported by grants from the National Health and Medical Research Council (Australia) and the National Cancer Institute (USA).

Israel Schechter

Department of Chemical Immunology, The Weizmann Institute of
Science, Rehovot, Israel

Immunoglobulin light chain genes of the mouse are composed in germ-line DNA of four separate segments, the leader, V (variable), J (joining) and C (constant) segments. In immunocompetent cells a V and a J gene segment are joined by a site-specific recombination event[1,2]. In variants of the mouse myeloma MPC11 a so-called kappa (κ) light chain fragment is expressed[3] which consists of the MOPC321 leader peptide, joined to the κ constant region peptide[4,5]. Using the Southern blotting technique[6] we found that the gene coding for the light chain fragment has apparently been generated by an aberrant translocation of a V gene segment identical or very similar to the MOPC321 V gene segment into the large intervening sequence between the J and the C gene segments. The resulting deletion of the splice signals of the J segments could be the reason for the observed splicing between leader and C region sequences, a phenomenon which may be of general interest for the understanding of the splicing mechanism.

Two variants of myeloma MPC11 were investigated. In one only the κ light chain fragment is found; in the other one in addition an intact κ light chain with MPC11 leader and variable region peptides is expressed. The variants are called MPC11 (Lf) and MPC11 (L+Lf), respectively. High molecular weight DNA isolated from mouse liver and the two MPC11 variants was digested with various restriction nucleases and fractionated on agarose gels. Liver DNA has been shown to contain the C gene segment in an arrangement very similar if not identical to the one found in germ-line DNA[7]. After denaturation the DNA fragments were transferred to nitrocellulose filters[6] and hybridized with a nick-translated plasmid probe specific for the C gene segment plus about 2,000 base pairs of surrounding genomic DNA sequences. Figure 1 shows the autoradiograms obtained after digestion of the three DNAs with *Eco*RI, *Sst*I, *Bam*HI, and *Eco*RI plus *Hpa*I. The chain length of fragments observed in these and other digestion experiments are compiled in Table 1. In the *Eco*RI digests of both, MPC11 (L+Lf) and MPC11 (Lf) DNA a 19 kilobase band was identified while liver DNA (not shown) yielded the known[7,9,11] 15 kilobase fragment. The 19 kilobase band of MPC11 (L+Lf) is composed of two fragments of similar length as could be shown by digestion with for example *Bam*HI. Two fragments were formed, the smaller of which was also found in digests of MPC11 (Lf) DNA (Fig. 1). The *Bam*HI fragment of liver DNA differs from the two fragments of MPC11 DNA. A pattern of corresponding and non-corresponding fragments was also obtained in the analysis of the C region specific fragments with *Hpa*I (Fig. 2). The *Bam*HI and *Hpa*I fragment patterns already indicate the existence of two differently rearranged κ light chain genes in MPC11 (L+Lf) DNA. Only one of the rearranged κ genes is preserved in MPC11 (Lf) DNA which must be the one responsible for the synthesis of the L chain fragment.

According to the known amino acid sequence[10] of the MPC11 L chain and the nucleotide sequence of the five J gene segments[8,9] either J1 or J2 should be the target of the site-specific recombination process which leads to the formation of the complete MPC11 L chain gene. Restriction nucleases which cleave in the large intervening sequence between J2 and the C gene segment should then generate the same fragment from MPC11 (L+Lf) and liver DNA (compare Fig. 2). This was the case in *Bgl*II, *Xba*I, and *Sst*I digests (Figs 1, 2). The additional fragments in MPC11 (L+Lf) DNA digests correspond to the

0028-0836/80/280170—04$01.00

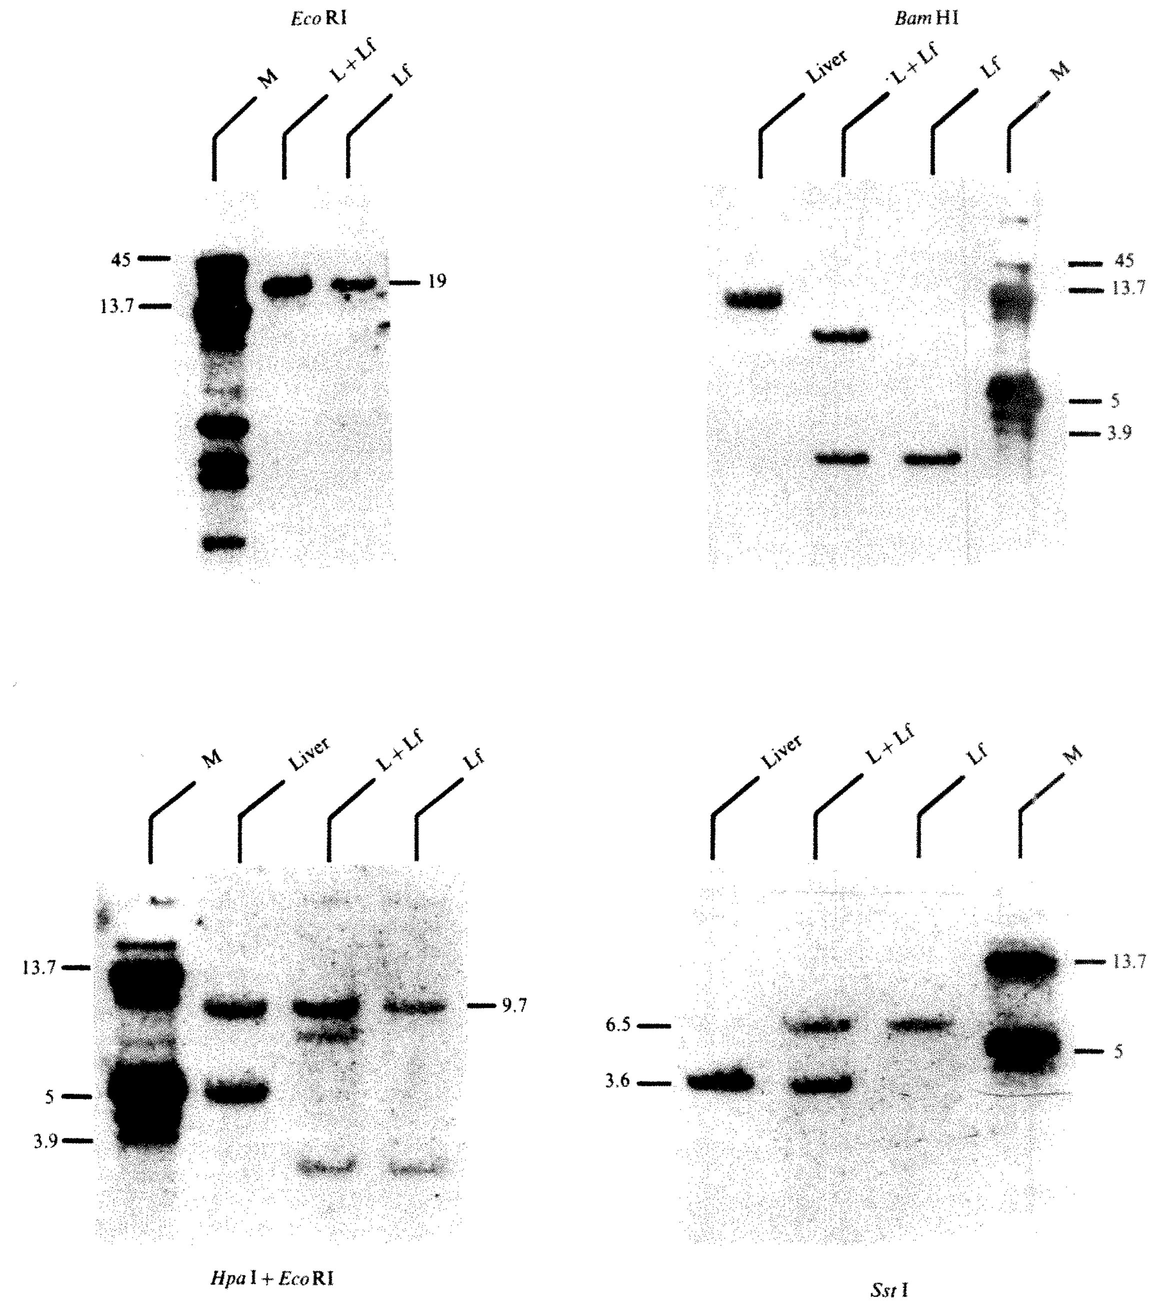

Fig. 1 Identification of DNA fragments containing the κ C gene segment in restriction endonuclease digests of mouse liver, MPC11 (L + Lf) and MPC11 (Lf) DNA. Clone 66.2 (ref. 3) designated MPC11 (L + Lf) and clone NP-2 (ref. 3) designated MPC11 (Lf), originally provided by R. Laskov (Hebrew University, Jerusalem), were maintained as solid tumours by subcutaneous transplantation in inbred BALB/c mice. DNAs were prepared according to ref. 13. Samples of 10 µg of DNA were digested with 10 units of *Eco*RI, *Bam*HI, *Sst*I (Bethesda) or *Hpa*I (Boehringer Mannheim) plus *Eco*RI for 3 h at 37 °C in volumes of 150–200 µl. Plasmid DNA when mixed with mouse DNA was completely digested. DNA digests were electrophoresed on a 0.7% or 0.5% (*Eco*RI digest) agarose gel in Tris-EDTA-phosphate buffer[14] containing 1 µg ml^{-1} ethidium bromide at 1.4 V cm^{-1} overnight. The gels were then exposed to 254 nm light for 5–10 min[15] and submitted to the transfer procedure[6]. The hybridization probe had been constructed by subcloning in pBR322 the 2.8 *Hin*dIII-*Bam*HI fragment containing the C gene segment of the 14 kilobase *Eco*Ri fragment from myeloma DNA[7]. The subcloned fragment is identical to the corresponding fragment from liver DNA (ref. 7, Fig. 2). Nick-translation[16,17] of the plasmid DNA with [α-^{32}P]dATP and [α-^{32}P]dCTP led to 2×10^{8} c.p.m. per µg DNA. Filters which had been baked for 2 h at 80 °C *in vacuo* were preincubated in 3 × SSC, 10 × Denhardt's solution[18] for 3 h at 68 °C and subsequently in 2 × SSC, 6.6× Denhardt's solution, 50 µg ml^{-1} sheared and heat-denatured salmon sperm DNA, 0.1% SDS for 1 h at 68 °C. The filters were then incubated in a graduate in a volume of 2.5 ml of the latter solution supplemented with 40 ng ml^{-1} heat-denatured nick-translated probe for 15 h at 68 °C under constant rotation. After this hybridization filters were washed six times for 5–10 min each in 2 × SSC, 6.6× Denhardt's solution, 0.1% SDS at 68 °C and twice in 1 × SSC, 0.1% SDS at 65 °C 15 min each. Some of the filters were further washed in 0.1 × SSC, 0.1% SDS at 65 °C, which did not alter the band pattern shown. Dry filters were exposed to Kodak X-Omat R film for 2 d at −80 °C with a SE6 intensifying screen from Cawo (Schrobenhausen, West Germany). The slots contain the following: liver, L + Lf, Lf, restriction fragments of mouse liver DNA, MPC11 (L + Lf) and MPC11 (Lf) DNA, respectively. The hybridization marker (M) consisted of 100 pg each of a *Pst*I, *Hin*dIII, *Bam*HI, and *Hpa*I digest of the genomic clone Ch4A 173/1 (ref. 7) and 100 pg of a *Hin*dIII plus *Pst*I digest of a pBR322 subclone[12] containing the 2.7 kilobase *Bgl*II fragment with the C gene segment from liver DNA (compare Fig. 2). Fragment sizes are given in kilobases.

fragments in MPC11 (Lf) DNA digests, indicating that the recombination in the MPC11 (Lf) genome has occurred to the right of the *Sst*I cleavage site in the large intervening sequence.

The previous conclusions are based on the assumption that the C gene segment itself and its 3′ flanking sequence has not been altered. This is made likely by the occurrence of identical fragments in the digests of the three DNAs (12 kilobases in the

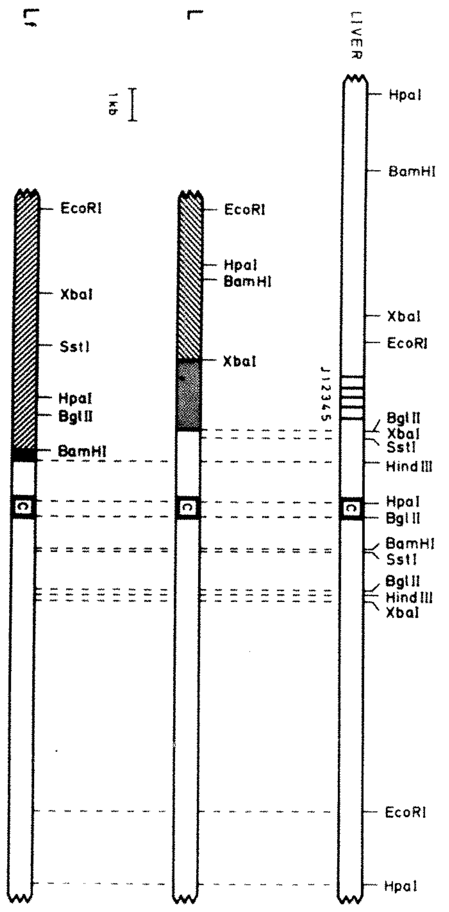

Fig. 2 Organization of the κ C gene segment in mouse liver, MPC11 (L+Lf) and MPC11 (Lf) DNA. Only those restriction endonuclease cleavage sites which were identified by Southern gel blotting experiments are shown. J (positions according to refs. 8, 9) and C gene segments are indicated by bars and boxes. Regions on the MPC11 DNA which differ from each other and from those on the liver DNA are shown as hatched boxes. DNA segments carrying the recombination site are indicated as stippled boxes.

*Hpa*I and 2.3 kilobases in *Bgl*II digests) and is further supported by double digestion experiments with pairs of restriction nucleases which cleave in the C gene segment and the 3′ flanking sequence and therefore should lead to the identification of the same DNA fragment in all three genomes. In *Hpa*I plus *Eco*RI digests of the three DNAs the expected 9.7 kilobase fragment was found (Fig. 1). Also, *Hpa*I plus *Xba*I, *Bgl*II plus *Sst*I, and *Bgl*II plus *Bam*HI digests yielded fragments which were common to the three DNAs (Table 1). The other fragments in the double digestion experiments are obviously derived from the 5′ flanking sequences of the C gene segment.

To show directly that the recombination process leading to the formation of the Lf genome gave rise to a deletion of the J gene segments *Eco*RI and *Xba*I digests of the MPC11 DNAs were hybridized with the *Eco*RI-*Bgl*II fragment from liver DNA containing the J gene segments (Fig. 2; compare also refs 8, 9) which had been subcloned[12] in pBR322. No hybridization band could be detected in digests of MPC11 (Lf) DNA whereas a 19 kilobase *Eco*RI resp. a 2.2 kilobase *Xba*I fragment (Table 1), obviously derived from the chromosome containing L chain gene, was identified in digests of MPC11 (L+Lf) DNA (not shown).

The mapping data on the MPC11 L and Lf genes are summarized in Fig. 2 and compared to the arrangement of the J and C gene segments in liver DNA. From our data the region where the recombination has occurred can be confined to the *Xba*I-*Bgl*II fragment for the MPC11 L chain gene (in agreement with the sequence data in refs 8–10) and to the *Bam*HI-*Hin*dIII fragment for the Lf gene (stippled boxes in Fig. 2). The *Hin*dIII sites to the left of the C gene segment have been found at the same positions on all three mouse DNAs. The localization of the recombination site involved in the formation of the Lf gene was supported by the results of *Hin*fI digestions of MPC11 (Lf) DNA (data not shown) although the interpretation of the blots was complicated, probably due to methylation of some of the restriction sites.

Since the Lf mRNA of MPC11 contains the MOPC321 light chain leader sequence it was of interest to search near the C gene segment of the MPC11 DNA for this sequence and also for MOPC321 V gene sequences. The hybridization probes we had available for these experiments were a *Pst*I subclone of MOPC321 cDNA comprising the leader sequence and a small part of the MOPC321 V gene segment as well as a *Bam*HI subclone containing only V region sequences (Fig. 3 legend). In *Eco*RI digested liver DNA we identified with either probe all DNA fragments which are known[11] to contain MOPC321 V region related sequences (in addition two small DNA fragments

DNA fragments were identified by hybridization with a subclone containing the C gene segment (Fig. 1 legend), except for the last two digests where a subclone containing the J gene segments (see text) had been used. 'Common' fragments were found in all three digests and 'shared' ones only in the liver and the MPC11 (L+Lf) DNA digests; 'unique' fragments are derived exclusively from the liver, the L, or the Lf genome. Appropriate sizes are given for the fragments as they are obtained in Southern blot analysis while for the markers (Fig. 1) the more exact values are used which were determined by mapping of cloned fragments.

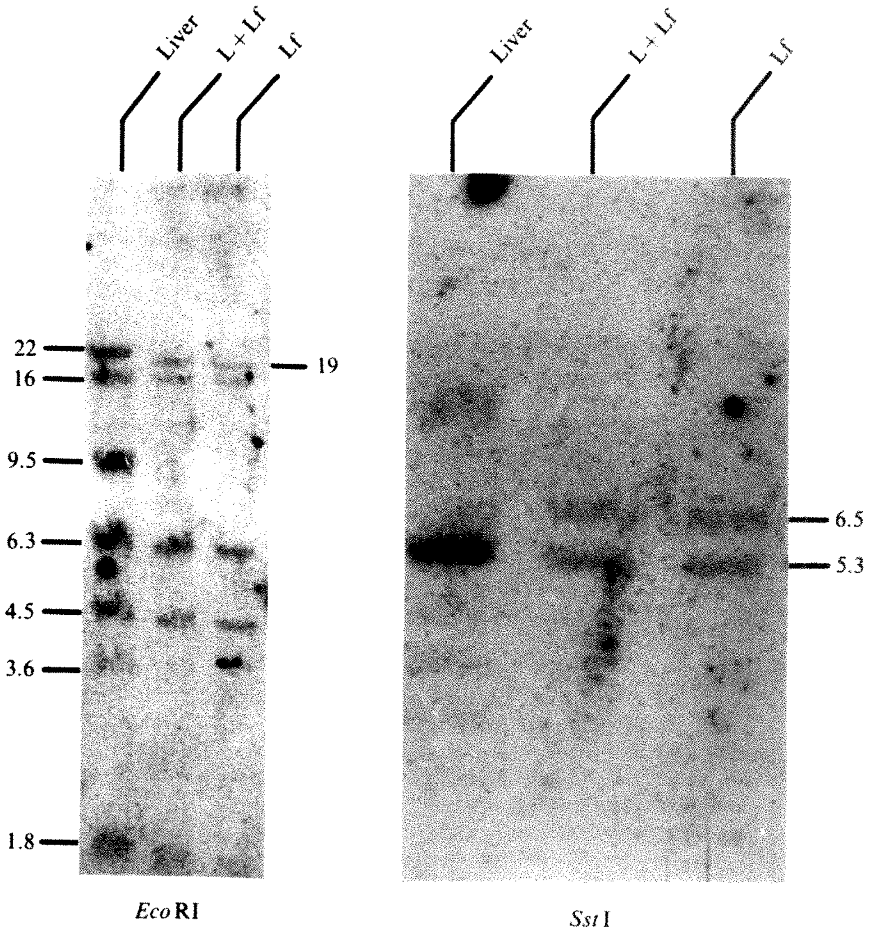

Fig. 3 Identification of restriction nuclease fragments in mouse liver, MPC11 (L+Lf) and MPC11 (Lf) DNA which hybridize to MOPC321 V region probe. Nuclease digestions, electrophoresis, markers, blotting, and hybridizations were as in Fig. 1, with the following exceptions: electrophoretic separation of the *Eco*RI digested DNA was for 3 d at 1 V cm^{-1} in the cold room; preincubation of the filters was in 6 × SSC and hybridization in 4 × SSC instead of 3 × SSC and 2 × SSC, respectively; after hybridization the filters were washed with 1 × SSC and autoradiographed for 9 d with a SE6 intensifying screen. As hybridization probes for the *Eco*RI and *Sst*I blots subcloned *Pst*I-*Pst*I and *Bam*HI-*Bam*HI fragments were used, respectively, which had been derived from a MOPC321 cDNA clone[20,21]. The *Pst*I fragment of ~160 base pairs contains a short GC-tail, 13 base pairs of the MOPC321 5′ untranslated region and the entire leader sequence plus the V region DNA sequence up to the codon for ^{23}Cys (I. Schechter and A. Bothwell, in preparation). The ~100 base pair *Bam*HI fragment contains part of the MOPC321 V region DNA sequence from a Gly codon at position 57, 64, or 66 to the ^{93}Gln codon[20,21]. Very similar or identical patterns were obtained when the *Bam*HI probe was used for the *Eco*RI digest and the *Pst*I probe for the *Sst*I digest.

could be identified which are not shown in Fig. 1 of ref. 11). In the *Eco*RI digests of both MPC11 DNAs three of these fragments (22, 9.5 and 3.6 kilobases) were absent while a 19 kilobase fragment not found in the liver DNA digest was seen (Fig. 3). The absence of germ-line V gene fragments and the appearance of a new fragment indicate that MOPC321 leader and V region segments have been arranged. In the *Eco*RI, *Sst*I, and the *Xba*I digests of both MPC11 DNAs the new fragments are identical in size to the fragments detected with the C region probe in the Lf genome (Table 1); this refers to the fragments of 19 kilobases (Fig. 3), 6.5 kilobases (Fig. 3), and 9.7 kilobases (not shown), respectively. It is of particular interest that very similar or identical hybridization patterns were found with the leader and the V gene probes (Fig. 3 legend). The results are best interpreted by assuming that in the MPC11 Lf genome the V gene segment of MOPC321 or a segment with a closely related V gene has been translocated into an aberrant position inside the large intervening sequence. It is not known yet whether the sequences at this recombination point bear similarity to the ones at or near the known J gene segments. Probably the whole region comprising the MOPC321 leader and V gene segments or a large part of this region has been translocated. Since apparently the J region with its splice points is deleted in the MPC11 (Lf) genome (see above; Fig. 2) the mRNA coding for the light chain fragment has to be formed by a splicing event (or events) in the pre-mRNA between the leader and C region. Further work is needed to establish whether the translocation of the MOPC321 gene segments into the large intervening sequence occurs directly or through a V–J joining and subsequent deletion of part of the intervening sequence including the splice signal.

We thank Ms F. Kantor for preparing the *Pst*I subclone of MOPC321 cDNA clone, E. Zeelon for preparing myeloma DNA, R. E. Streeck for samples of *Hin*dIII, *Bgl*II, *Xba*I, and T. Igo-Kemenes for *Bam*HI. The work was supported by Bundesministerium für Forschung und Technologie and Fonds der Chemischen Industrie.

Secretion requires a cytoplasmically disposed sulphydryl of the RER membrane

Robert C. Jackson*, Peter Walter & Günter Blobel

Laboratory of Cell Biology, The Rockefeller University,
New York, New York 10021

The capacity of the rough endoplasmic reticulum (RER) membrane of eukaryotic cells to translocate nascent presecretory proteins from the cytosol to the intracisternal space is preserved on cell fractionation and can be assayed *in vitro*[1]. Two attempts to characterize this translocation activity have been reported. Warren and Dobberstein[2] reported that microsomal membranes can be depleted of their translocation activity by extraction with a solution of high ionic strength (500 mM KCl) and that activity can be restored to the depleted membranes by re-addition of the salt extract. On the other hand, Walter *et al.*[3] reported that KCl extraction of the microsomal membrane does not result in complete depletion of its translocation activity. However, mild trypsinization of the microsomal membrane released a tryptic fragment(s) from the membrane which, when recombined with a tryptically inactivated membrane fraction, restored translocation activity[3]. We now show that both the trypsin and the KCl extracted factors, but not the membrane-integrated remainder of the translocation apparatus, contain at least one sulphydryl group that is essential for activity.

Our assay for the translocation activity of microsomal membranes takes advantage of the obligate coupling of translocation to proteolytic processing of nascent presecretory proteins[3-5]; hence, the ratio of 'processed' prolactin to 'unprocessed' preprolactin is a readily quantifiable measure of the translocation activity of the microsomal membrane.

It was previously noted[6] that *N*-ethylmaleimide, a sulphydryl-modifying reagent, inhibited translocation. Our data here confirm this observation. Preincubation of ribosome-stripped microsomal vesicles with 1.5 mM *N*-ethylmaleimide completely inhibited translocation, as virtually no processed prolactin was synthesized (Figs 1, 2, compare lanes 2 and 3).

A quantitative analysis of this inhibition by various concentrations of *N*-ethylmaleimide and other sulphydryl-modifying reagents (TLCK, a trypsin inhibitor, is mildly reactive with sulphydryl groups[7]) is shown in Fig. 3. We also analysed duplicate aliquots of these same modified samples by the signal peptidase-independent translocation assay described by Warren and Dobberstein[2]. In this, translocation activity is determined from the ability of the microsomal membrane to protect translocated polypeptides from proteolytic digestion, as quantitated by an increase in trichloracetic acid-precipitable radioactivity. Values comparable to those presented in Fig. 3 (data not shown) were obtained. *N*-Ethylmaleimide was the most effective inhibitor of translocation. At a concentration of less than 1.0 mM, *N*-ethylmaleimide completely inhibited translocation (Fig. 3*a*, *b*). Although the other sulphydryl-modifying reagents tested were also effective, concentrations in excess of 1.0 mM were required to achieve complete inhibition of translocation in the given conditions. Interestingly, the bound ribosomes of 'native' rough microsomes do not protect the sensitive sulphydryl group(s) from *N*-ethylmaleimide modification. As shown in Fig. 3*b*, *N*-ethylmaleimide-modified rough microsomes, when stripped of ribosomes by EDTA extraction and subsequently assayed for translocation activity, are inhibited to the same extent as an equivalent amount of microsomes which had been stripped of ribsomes before *N*-ethylmaleimide modification.

To rule out the possibility that the observed inhibition of the synthesis of processed prolactin could have resulted from an inactivation of signal peptidase rather than an impairment of translocation, *N*-ethylmaleimide-modified stripped microsomes were dissociated with sodium deoxycholate and assayed for signal peptidase activity in a post-translational assay[8,9]. The results (Fig. 4) demonstrate that signal peptidase is not inactivated by *N*-ethylmaleimide modification.

The fact that the translocation apparatus can be separated into soluble and membrane-associated fragments enabled us to localize the sensitive sulphydryl group(s) to either of these fragments. Soluble fragments were prepared as previously described[3], by subjecting EDTA-stripped and KCl-extracted microsomal vesicles to low concentrations of trypsin (7 μg ml^{-1}). Although such a mild treatment does not completely separate the membrane from the soluble portion of the translocation apparatus, it avoids the rapid inactivation of the solubilized fragments observed at higher concentrations of trypsin[3]. Centrifugation yielded a supernatant fraction that was further incubated in the absence or presence of *N*-ethylmaleimide. These fractions are referred to as t_7-sup or t_7n-sup, respectively.

Membrane-associated fragments, on the other hand, were prepared by digestion of EDTA-stripped, salt-extracted microsomal vesicles with a high concentration of trypsin (60 μg ml^{-1}). This harsher treatment generates a membrane fraction that is completely translocation inactive by itself (see Figs 1, 2, lane 7)

Fig. 1 The sulphydryl group required for translocation is located on a cytoplasmically disposed, trypsin-sensitive domain of the translocation apparatus. Supernatant (sup) and membrane (mb) fractions were prepared from mildly (7 μg ml^{-1}) and extensively (60 μg ml^{-1}) trypsin-digested samples of EDTA and KCl-stripped rough microsomes (k-mb) as previously described[3]. Aliquots of these fractions were reacted with 1.5 mM *N*-ethylmaleimide for 30 min at 25 °C, then quenched with a 10 fold molar excess of dithiothreitol (DTT). Both modified and unmodified fractions were assayed for their ability to support and/or reconstitute the translocation of preprolactin across the microsomal membrane. Samples of the indicated fractions were added to a wheat-germ *in vitro* translation system[10] programmed with bovine pituitary RNA and supplemented with human placental ribonuclease inhibitor[11] at a final concentration of $0.006A_{280}$ units ml^{-1}. In assaying for the reconstitution of translocation by the t-sup fractions, 3 μl of the indicated supernatant fraction were added to a typical 25-μl translation mixture. (3 μl of t-sup are derived from $0.126A_{280}$ units of stripped microsomes.) Where indicated, membranes were present at a final concentration of 2.3 A_{280} units ml^{-1}. Translation products were separated by polyacrylamide gel electrophoresis in SDS_4 and detected by autoradiography. Translocation capacity is assessed from the ability of the added fractions to process preprolactin (pPL) to prolactin (PL). The membrane fractions are: k-mb, KCl and EDTA-stripped rough microsomes; kn-mb, *N*-ethylmaleimide-modified k-mb; t_{60}-mb, extensively (60 μg ml^{-1}) trypsinized k-mb; t_{60}n-mb, *N*-ethylmaleimide-modified t_{60}-mb. The supernatant fractions are: t_7-sup, supernatant from mildly (7 μg ml^{-1}) trypsinized k-mb; t_7n-sup, *N*-ethylmaleimide-modified t_7-sup.

Fig. 2 A factor removed from EDTA-stripped rough microsomes by extraction with 0.5 M KCl also contains an essential sulphydryl moiety. EDTA-stripped rough microsomes were extracted with 0.5 M KCl, as described by Warren and Dobberstein[2]. Aliquots of the KCl extract (k-sup) and membrane (k-mb) fractions were modified with 1.5 mM *N*-ethylmaleimide as described in Fig. 1 legend. Samples of the modified and unmodified supernatant and membrane fractions were assessed for their ability to support and/or reconstitute translocation activity as indicated by their ability to process preprolactin to prolactin. In assaying for the reconstitution of translocation by the t-sup and k-sup fractions, 3 μl of these supernatant fractions were added to a typical 25-μl translation mixture. (3 μl of k-sup are derived from 0.154A_{280} units of EDTA-stripped microsomes.) Where indicated, membranes were present at a final concentration of 2.3 A_{280} units ml^{-1}. The abbreviations used are: k-sup, 0.5 M KCl extract of EDTA-stripped rough microsomes; kn-sup, *N*-ethylmaleimide-modified k-sup; other abbreviations are as in Fig. 1.

but retains its competence to serve as acceptor for the solubilized fragment(s) and thereby to restore translocation activity (Fig. 1, lane 9). Before assaying for translocation activity, the trypsinized membrane fraction was further incubated in the absence or presence of *N*-ethylmaleimide. The resulting fractions are referred to as t_{60}-mb or t_{60}n-mb, respectively.

The effects of *N*-ethylmaleimide treatment of these various fractions as well as some essential controls are shown in Fig. 1. Two conclusions can be drawn from the data. First, *N*-ethylmaleimide inactivated only the trypsin-solubilized fragments, but not the membrane-integrated remainder of the translocation apparatus (compare lanes 11, 12 with 9, 10). Thus, the important sulphydryl group(s) is located in the cytosol-exposed, trypsin-sensitive domain of the translocation apparatus. Furthermore, as *N*-ethylmaleimide readily permeates membranes, and as reconstitution of translocation is not affected by *N*-ethylmaleimide modification of t_{60}-mb (Fig. 1, lane 10), the residual t_{60}-mb cannot contain any sulphydryl groups essential for translocation, that is, the essential sulphydryl is located exclusively on the cytosol-exposed domain of the translocation apparatus. Second, non-trypsinized control membranes (k-mb) must contain membrane-integrated fragments comparable to those that are experimentally generated by trypsinization (t_{60}-mb fraction). This was previously suggested by the finding that the translocation activity of trypsin-inactivated membranes could be increased to levels greater than those of untrypsinized membranes by the addition of saturating concentrations of the trypsin-solubilized supernatant factor[3]. Here it is indicated by the finding that a non-trypsinized, but *N*-ethylmaleimide-modified membrane fraction (kn-mb) which is translocation inactive (see Fig. 1, lane 3) can be partially reactivated by a t_7-sup fraction (lane 4). In other words, the control,

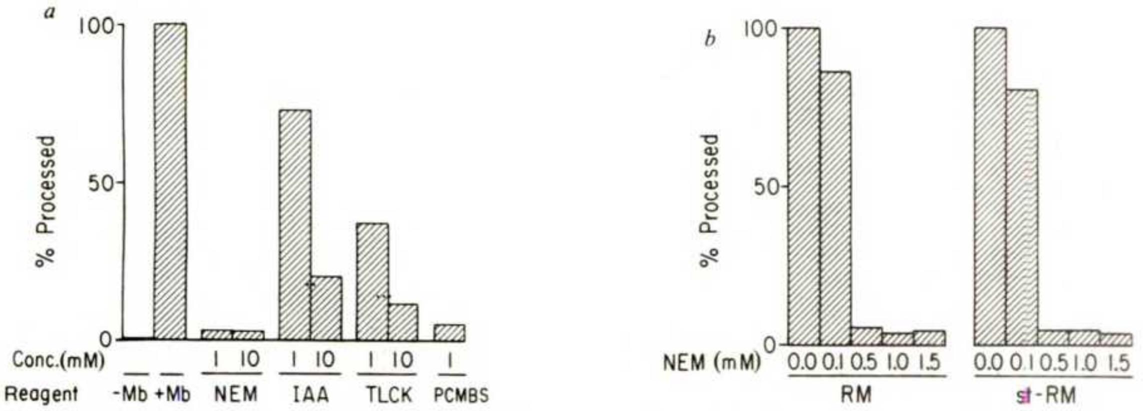

Fig. 3 *a*, Inhibition of precursor processing (and translocation) by sulphydryl-modifying reagents. Stripped rough microsomes (st-RM) were prepared as previously described[3,12] with the exception that DTT was excluded from all buffers. Modification reactions (50 μl) contained stripped microsomes at a final concentration of 46.5 A_{280} units (determined in 5% SDS), 1% Trasylol, 0.2 M sucrose, 100 mM triethanolamine-HCl (TEA-HCl), *p*H 7.5, 40 mM KCl, 0.8 mM $MgCl_2$ and the indicated concentration of freshly prepared sulphydryl-modifying reagent. Reactions were quenched after 30 min at 25 °C by the addition of at least a 10-fold molar excess of DTT. The DTT-inactivated sulphydryl-modifying reagents were removed from the modified stripped microsomes by centrifugation in a Beckman cellulose nitrate airfuge tube containing a sucrose step gradient comprised of 80 μl of 0.5 M sucrose, 10 mM TEA-HCl, *p*H 7.5, 1 mM DTT and 25 μl of 2.0 M sucrose in the same buffer. After centrifugation (5 min, at 30 lb per sq. inch, 100,000g_{av}) the microsomes were removed from the 2.0–0.5 M sucrose interface with a Hamilton syringe, brought to a total volume of 20 μl with 10 mM TEA-HCl, *p*H 7.5, and 1 mM DTT, and assayed for their ability to support translocation (see text) and processing of preprolactin to prolactin. Translocation assays were carried out in a final volume of 50 μl in a wheat-germ translation system[10] supplemented with human placental ribonuclease inhibitor[11] at a final concentration of 0.006 A_{280} units ml^{-1}. The wheat-germ system was programmed with pituitary RNA and supplemented with the appropriately modified membranes at a final concentration of 2.3 A_{280} units ml^{-1}. The ^{35}S-Met-labelled products were separated by gel electrophoresis in SDS, detected by autoradiography of the dried gel and quantitated by excising and counting the portion of the gel containing the ^{35}S-Met-labelled preprolactin and prolactin products[3,12]. Processing is expressed as per cent of control, unmodified membranes (+mb). In this particular experiment, the absolute amount of preprolactin processed by the unmodified membranes was 35.0% of the total preprolactin synthesized. The abbreviations used are: *N*-ethylmaleimide, NEM; iodoacetamide, IAA; *p*-chloromercuribenzene sulphonic acid, PCMBS; *N*-α-*p*-tosyl-L-lysine chloromethyl ketone, TLCK; sodium dodecyl sulphate, SDS. *b*, The processing (and translocation) activity of both rough and stripped rough microsomes is inhibited by *N*-ethylmaleimide modification. A rough microsomal fraction (RM), 107 A_{280} units ml^{-1}, was divided into two samples. Ribosomes were removed from the microsomes of one of these samples by mixing the sample with one volume of a ribosome-stripping solution containing 0.25 M sucrose, 40 mM EDTA and 50 mM TEA-HCl, *p*H 7.5. The stripped microsomes (st-RM) were separated from EDTA by centrifugation. Aliquots of both the stripped and the unstripped microsomes were modified with the indicated concentration of *N*-ethylmaleimide (NEM) as described in *a*. After inactivation of residual *N*-ethylmaleimide with DTT, ribosomes were removed from the rough microsomal fractions by EDTA extraction, as described above. The modified, stripped microsomes were separated from inactivated *N*-ethylmaleimide and EDTA by centrifugation and assayed for translocation activity (see *a*). In this particular experiment, the absolute amount of preprolactin processed by the unmodified stripped microsomes was 74.5% of the total preprolactin synthesized.

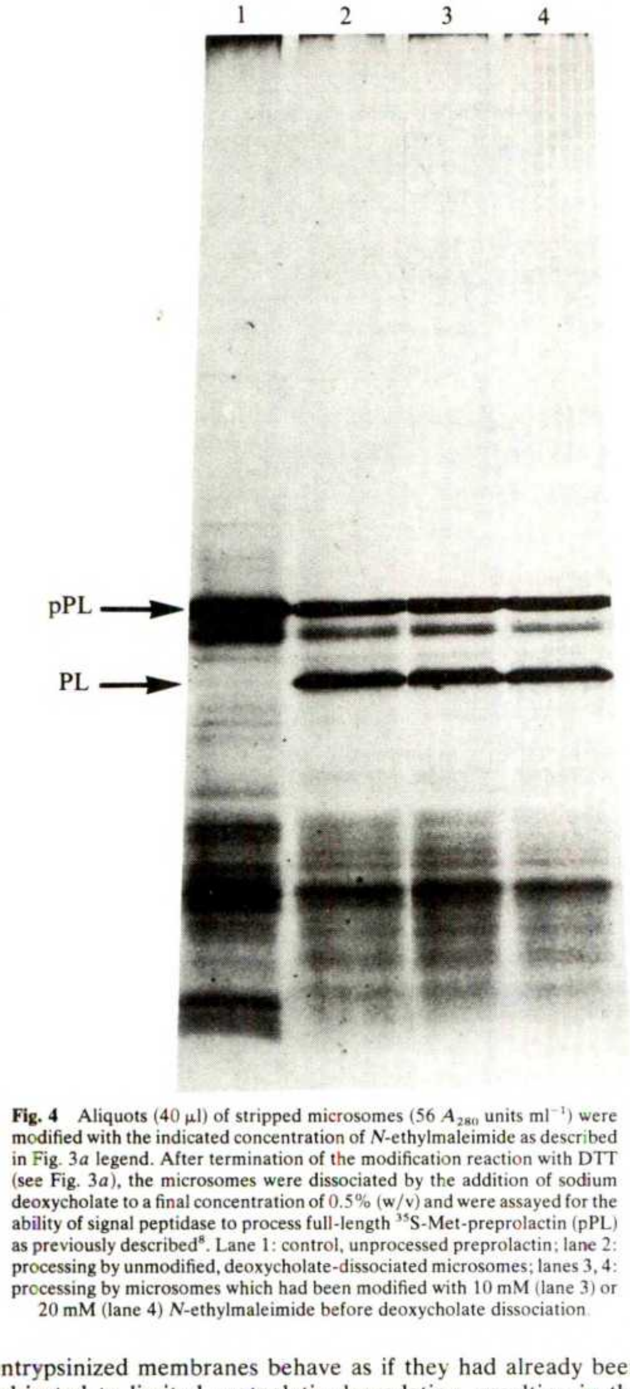

Fig. 4 Aliquots (40 μl) of stripped microsomes (56 A_{280} units ml^{-1}) were modified with the indicated concentration of *N*-ethylmaleimide as described in Fig. 3*a* legend. After termination of the modification reaction with DTT (see Fig. 3*a*), the microsomes were dissociated by the addition of sodium deoxycholate to a final concentration of 0.5% (w/v) and were assayed for the ability of signal peptidase to process full-length ^{35}S-Met-preprolactin (pPL) as previously described[8]. Lane 1: control, unprocessed preprolactin; lane 2: processing by unmodified, deoxycholate-dissociated microsomes; lanes 3, 4: processing by microsomes which had been modified with 10 mM (lane 3) or 20 mM (lane 4) *N*-ethylmaleimide before deoxycholate dissociation.

untrypsinized membranes behave as if they had already been subjected to limited proteolytic degradation, resulting in the production of some nonfunctional but reactivatable translocation sites. As expected, the observed reactivation of the kn-mb fraction is eliminated when a t_7n-sup fraction (Fig. 1, lane 5) is substituted for the t_7-sup fraction.

In the controls in Fig. 1, we show that neither the t_7-sup (lane 13) nor the t_7n-sup (lane 14) fractions are themselves capable of supporting translocation in the absence of added membrane. An additional control (lane 6) demonstrates that the t_7n-sup fraction does not inactivate translocation by added k-mb, indicating that our procedures (see Fig. 3*a*) for quenching *N*-ethylmaleimide are effective and that the observed effects of the *N*-ethylmaleimide-modified fractions are not due to a carryover of residual *N*-ethylmaleimide.

The presence of nonfunctional, but reactivatable translocation sites in untrypsinized k-mb suggested that the 'salt factor' of Warren and Dobberstein[2] is in reality a salt-extractable, proteolytic fragment of the translocation apparatus, comparable to that experimentally generated by trypsin. Therefore, one would expect that the salt factor, like the trypsin-generated soluble fragment(s), might also contain a sulphydryl group(s) that is essential for activity. These expectations were indeed borne out by data shown in Fig. 2. Although in our hands KCl extraction does not result in a complete loss of translocation activity, our KCl extract (k-sup) fraction does contain a salt factor which is able to restore translocation activity to trypsin-inactivated microsomes (Fig. 2, lane 9), to *N*-ethylmaleimide inactivated microsomes (Fig. 2, lane 10) and to microsomes inactivated by both trypsin and *N*-ethylmaleimide (Fig. 2, lane 4). In fact, the ability of the KCl extract to restore translocation is quantitatively superior to that of the tryptic extract (compare Figs 1 and 2, lanes 4, 9, 10). Although this difference in activity may reflect a genuine difference in the absolute reactivation capacity of the KCl and tryptic factors, other explanations (particularly tryptic inactivation of a substantial portion of the trypsin-solubilized factor) are also likely. Nevertheless, like its trypsin-generated counterpart, the salt factor is readily inactivated by *N*-ethylmaleimide (Fig. 2, compare lanes 5, 11, 12 with lanes 4, 9, 10). The control (Fig. 2, lane 6) demonstrates that the *N*-ethylmaleimide-inactivated salt factor does not affect translocation of EDTA-stripped, KCl-extracted membranes (Fig. 2, compare lane 6 with lane 3), indicating that the observed effects of the *N*-ethylmaleimide-modified fractions are not due to a carryover of residual *N*-ethylmaleimide.

From these experiments, we conclude that the translocation-reactivating factors present in k-sup and t_7-sup are functionally and structurally similar, in that both restore translocation activity to *N*-ethylmaleimide- or trypsin-inactivated test membranes, and both contain an essential sulphydryl group(s). Although both these factors are probably derived from the same parent molecule, differences in their extractability (the trypsin factor is released in the absence of salt) suggest that tryptic digestion removes a smaller fragment of the parent translocator protein than is generated by the endogenous tissue protease(s) which produces the salt factor. Presumably, it is this additional domain of the salt factor which is responsible for the differential salt extractability of the salt and tryptic factors. In any case, the observation that the cytoplasmically disposed domain of the translocation apparatus contains an essential sulphydryl which can be readily modified provides us with a tool which should be extremely useful in the purification and characterization of the polypeptides responsible for translocation of nascent secretory and membrane proteins across the membrane of the rough endoplasmic reticulum.

Efficiency of the adaptive response of *Escherichia coli* to alkylating agents

John Cairns

Imperial Cancer Research Fund, Burtonhole Lane,
London NW7 1AD, UK

When cultures of *Escherichia coli* are exposed to a low level of the alkylating agent *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) they accumulate mutations for about 20 min and then

0028–0836/80/280176—03$01.00

become resistant to further mutagenesis by that level of MNNG[1]. This 'adaptive response,[2] has been shown to be due, at least in part, to induction of the rapid repair of O^6-alkylguanine[3–5] which appears to be the main mutagenic and carcinogenic lesion produced by simple alkylating agents[6,7]. A similar kind of repair has been demonstrated in the livers of rats exposed to nitrosamines[8], and this presumably helps to protect animals against carcinogenesis by the various alkylating agents that are widespread in our environment. It seemed important, therefore, to find out just how effectively such adaptive responses can control mutation rates.

The very efficiency of the response of *E. coli* to MNNG imposed certain constraints on the experiment to measure residual mutation rates. To prepare cultures of adapted bacteria which are free from the mutants that initially arose when adaptation was being induced, it is necessary to start each culture with only a few thousand adapted bacteria. But measurement of the subsequent very low mutation rate of bacteria growing in the presence of the level of MNNG to which they are adapted requires samples of at least 10^7 bacteria. It was therefore necessary to prepare a low *p*H, low phosphate[9] growth medium in which MNNG was sufficiently stable to survive for more than 12 bacterial generations (10–15 h). In practice, the stability of MNNG in such a medium is best checked by observing the distribution of mutant clone sizes in replicate cultures; for, if its concentration is effectively unchanged for the course of the experiment and the mutation rate (m) per cell per generation is therefore constant, the proportion of cultures of N bacteria that contain x or more mutants will follow the distribution of clone sizes, described by Luria[10] for mutations that arise at random in an exponentially increasing population: namely

$$x \sum_{i=x}^{i=N} P_i \rightarrow 2mN, \quad \text{as} \quad \frac{2mN}{x} \rightarrow 0 \qquad (1)$$

and the proportion of cultures that contain one or more mutants will be

$$\sum_{i=1}^{i=N} P_i = 1 - \exp(-2mN) \qquad (2)$$

[In the present instance, it is not necessary to consider the time of duplication of different genes in the cell cycle, because the experiments are solely concerned with comparisons between mutation rates at a single locus and furthermore do not deal with fractional generation times.]

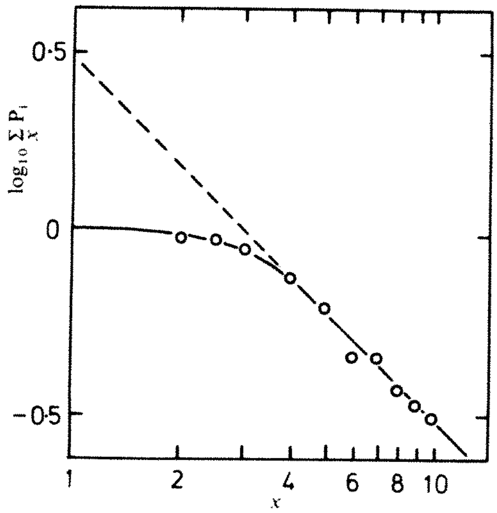

Fig. 1 The distribution of arg^+ revertant clone sizes in cultures of *E. coli* AB 1157 growing in the presence of 0.5 μg ml^{-1} MNNG. If the mutation rate is constant, the proportion of such cultures that contain x or more revertants will approach $2mN/x$ (equation (1)), and the best estimate of mN can be obtained by fitting a line of slope −1 to a plot of the logarithm of these proportions against log x and then measuring the intercept at $x = 1$. Here, the intercept gives log (2 mN) equal to 0.48, or 2 mN equal to 3. As N equalled 4×10^7, m equals 4×10^{-8}.

From either of these equations it is possible to measure the spontaneous mutation rate of unadapted bacteria growing in the absence of MNNG and the overall mutation rate (provoked plus spontaneous) of adapted bacteria growing in the presence of the concentration of MNNG to which they have been adapted. What the MNNG-provoked mutation rate would have been, in the absence of the adaptive response, can be determined simply by exposing a strain that cannot induce the response[11] to the medium in which the adapted bacteria had been growing; after a period of one generation these non-adapting bacteria will contain mN mutants.

The results of such an experiment are shown in Table 1 and Fig. 1. Most mutant clones in the adapted cultures are small (that is, of recent origin) and have the expected distribution (Fig. 1). The extra mutation rate in the MNNG-adapted cultures was 3.5×10^{-8} arg^+ per generation, but the medium in which these bacteria were growing produced $20{,}000 \times 10^{-8}$ arg^+ per generation in an adaptation-deficient strain. In these particular conditions, therefore, the adaptive response was lowering the mutation rate about 6,000-fold. This is a surprising result. Each DNA base in *E. coli* serves as template once every 2,500 s. For adaptation to lower 6,000-fold the probability that an altered base serves as a source of mutation, the adaptive response may have to render each premutational lesion such as O^6-methylguanine harmless within 0.5 s: (of course, the process would not have to be completed so quickly if the enzymes for post-replication mismatch repair can recognize and correct structures such as O^6-methylguanine·thymine base pairs). Conceivably, the reaction succeeds in being rapid because the catalytic reactant restores the normal base-pairing properties of the guanine

Table 1 Measurement of the mutation rate produced by 0.5 μg ml^{-1} MNNG in bacteria that are either adapted or unable to adapt

	Cells plated	arg^+ revertants	Mutation rate per generation $\times 10^8$
AB 1157	4×10^7	0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 2, 2, 5	0.5*
AB 1157 in 0.5 μg ml^{-1} MNNG	4×10^7	0, 2, 2, 3, 3, 3, 3, 3, 4, 4, 4, 4, 5, 5, 5, 5, 5, 7, 7, 7, 8, 9, 13, 19, 23, 42, 55, 89, 239, ~2,000	4.0†
AB 1157 *ada* 5	6×10^7	0, 0, 0, 0, 1, 1, 1, 1	~0.4*
AB 1157 *ada* 5 1 hr in supernates of MNNG cultures	1×10^6	174, 181, 192, 196, 204, 204, 211, 231	20,000

A culture of *E. coli* AB 1157 (*arg, his, leu, pro, thr, thi*) was grown in a low *p*H, low phosphate medium containing 0.1 M NaCl, 0.04 M KCl, 0.02 M NH_4Cl, 1 mM $MgCl_2$, 0.5 mM KH_2PO_4, 0.2 mM Na_2SO_4, 0.1 mM $CaCl_2$, 0.01 mM $FeCl_3$, 0.025 M Tricine (Sigma) *p*H 6.1, plus required amino acids (20 μg ml^{-1}) and vitamins (0.1 μg ml^{-1}) and 0.6% glucose. When the bacterial concentration had reached 10^7 per ml, MNNG was added to give a level of 0.1 μg ml^{-1} for one generation and 0.5 μg ml^{-1} for a further generation. At this point the culture was diluted to 2,000 bacteria per ml, and 32 3-ml aliquots were prepared in the absence of MNNG and 32 in the presence of 0.5 μg ml^{-1} MNNG. After 18 h incubation (when the cultures contained, by microscope count, 2×10^7 bacteria per ml), each aliquot was centrifuged, resuspended in 0.5 ml minimal medium and plated on minimal plates lacking arginine, to give the number of arg^+ revertants. These two sets of cultures therefore provided estimates of the spontaneous reversion rate and the sum of spontaneous and MNNG-provoked mutation rate to arg^+. At the same time, the supernatant medium from the MNNG-containing cultures was used to suspend similar cultures of the adaptation-defective strain AB 1157 *ada* 5 (ref. 11). After exposure for 1 h (roughly one generation) these cultures were centrifuged and similarly plated on arginine-deficient plates.

* Mutation rate determined by equation (2).

† Mutation rate determined by equation (1) (see Fig. 1).

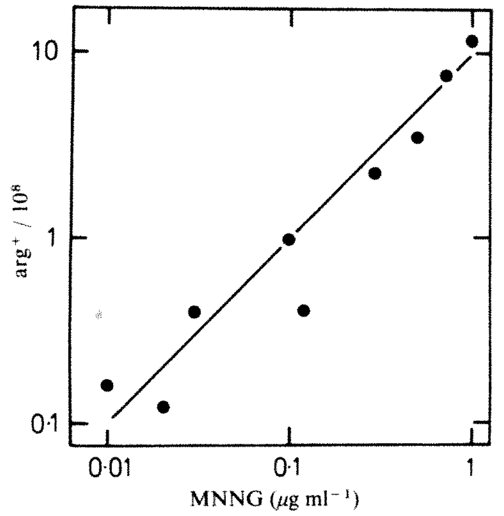

Fig. 2 The extra mutation rate of *E. coli* AB 1157 growing in the presence of various concentrations of MNNG. The mutation rate (*arg*$^+$ revertants per generation) was determined as described in Table 1 and Fig. 1; the spontaneous rate (1.2×10^{-9}) has been subtracted.

in one step by providing an alternate site of attachment for the alkyl group[5], and this is why each reactant molecule apparently can act only once[4]. Whatever the mechanism, it is interesting that the adaptive response succeeds in being at least as efficient as the 'error-free' repair of pyrimidine dimers produced by ultraviolet light[12,13] even though dimers are presumably much less of a threat because, unlike alkylated bases, they cannot be copied and so are not an immediate source of mutation.

The above calculation was based on the assumption that the low residual mutation rate in adapted bacteria is due to the very rare occasions when an O^6-methylguanine happens to be copied before it is repaired; and if that is correct, the mutation rate in adapted cultures should be directly proportional to the rate of production of alkylated bases (that is, proportional to mutagen concentration). However, more complex relationships between dose and response are imaginable. For example, the adaptive response could be 100% efficient once induced, but a small proportion of the cells might fail to undergo induction; in this case, very low levels of mutagen might be more mutagenic than higher levels. Such questions are of practical importance in assessing the likely risks from low levels of carcinogens, and so these experiments with bacteria were extended to cover a range of MNNG concentrations.

As Fig. 2 shows, adapted cultures of *E. coli* growing in the presence of MNNG have an increase in mutation rate that is approximately proportional to MNNG concentration. Interestingly, a similar result has been seen when rats are continuously exposed to dimethyl or diethyl nitrosamine in their drinking water (R. Peto, personal communication). Doses below 1 p.p.m. (that is, below about 0.1 mg per kg per day) produced an incidence of liver cancer that was roughly proportional to dose; but between 1 and 10 p.p.m. the age-specific incidence increased about 1,000-fold. For these alkylating agents it seems clear, therefore, that brief exposures are much more mutagenic for certain bacteria and high dose rates are much more carcinogenic for certain animals than might be expected from the response to continuous low dose rates.

Virus-specific effects of interferon in embryonal carcinoma cells

Timothy W. Nilsen, Debra L. Wood & Corrado Baglioni

Department of Biological Sciences, State University of New York
at Albany, Albany, New York 12222

Embryonal carcinoma (EC) cells are susceptible to infection by a variety of viruses[1], but do not become resistant to infection by Semliki Forest virus[2] or vesicular stomatitis virus[3] (VSV) on treatment with interferon. These observations have led to the conclusion that interferon does not induce an antiviral state in EC cells[2,3]. We report here, however, that EC cells treated with interferon become resistant to infection by two picornaviruses and two *ts* mutants of VSV, whereas they remain sensitive to wild-type VSV, Sindbis and influenza virus infection. These results suggest that a partial antiviral state is induced in EC cells by interferon and that the induced antiviral protein(s) interferes with the replication of specific viruses. A significant common feature of these viruses is their replication through structures containing double-stranded RNA (dsRNA)[4].

Interferon induces in human and mouse cells the synthesis of a few proteins that are detected by gel electrophoresis[5,6]. Among these are two enzymes, an oligonucleotide polymerase and a protein kinase (see ref. 7 for refs), which are activated by dsRNA in extracts of interferon-treated cells. The polymerase converts ATP into a series of oligonucleotides characterized by 2'5'-phosphodiester bonds and designated 2-5A (ref. 8). The 2-5A activates an endoribonuclease that degrades RNA[9,10]. The protein kinase (PK_{ds}) inhibits protein synthesis by phosphorylating the α subunit of initiation factor eIF-2 (ref. 7). Wood and Hovanessian[3] assayed these enzymatic activities in extracts of interferon-treated EC cells and observed an increase in 2-5A polymerase activity comparable to that in mouse L cells, whereas the PK_{ds} was not significantly increased in EC cells. As these cells did not become resistant to VSV infection[3], the induction of 2-5A polymerase could not be correlated with an antiviral state. In a different cell system, however, the induction of 2-5A polymerase is closely correlated with the inhibition of replication of a picornavirus, encephalomyocarditis virus

Table 1 Effect of interferon on virus yield and induction of 2'5'-oligo(A) polymerase and protein kinase

Cells	PCC4		L	
Interferon treatment	–	+	–	+
EMCV yield	8	3	8	4
VSV yield	8	8	8	4
2'5'-oligo(A) synthesis	10	680	10	2,440
Protein kinase	2	2	2	30

Cultures of control and interferon-treated cells (100 units ml^{-1} for 20 h) were infected for 48 h as described in Fig. 1 legend. The cultures were frozen and thawed three times and centrifuged for 10 min at 30,000*g*. The virus yield was measured by end-point dilution of the supernatant and quantification of the cytopathic effect on L-cell monolayers. Virus samples of known titre were assayed in parallel; virus yield is expressed as the $\log_{10}$ of the titre in plaque-forming units per ml. Cytoplasmic extracts were prepared from control and interferon-treated cells grown in 75-cm^2 flasks. The cells were washed with saline and homogenized as described elsewhere[16], with the addition of 0.5% Triton X-100 to the homogenization buffer. The S30 fraction obtained by centrifugation for 5 min at 30,000*g* was assayed for 2-5A synthesis with poly(I) · poly(C)-paper as described by Stark *et al.*[26]. The synthesis of 2-5A obtained with 100 µl of S30 in 16 h is expressed in pmol of ATP converted into oligonucleotides out of an input of 250 nmol of ATP per 50-µl reaction. The protein kinase activity was assayed by measuring the phosphorylation of a 67,000 molecular weight polypeptide as described elsewhere[27]. The S30 was centrifuged for 90 min at 150,000*g* and the pellet obtained resuspended and incubated with [^{32}P]ATP and 1 µg ml^{-1} of poly(I) · poly(C); the phosphorylated proteins were resolved by gel electrophoresis, detected by autoradiography and quantified by scanning the autoradiographs as described elsewhere[27]. The protein kinase activity is expressed in units of peak area, relative to a reference polypeptide present in both L and PCC4 cells.

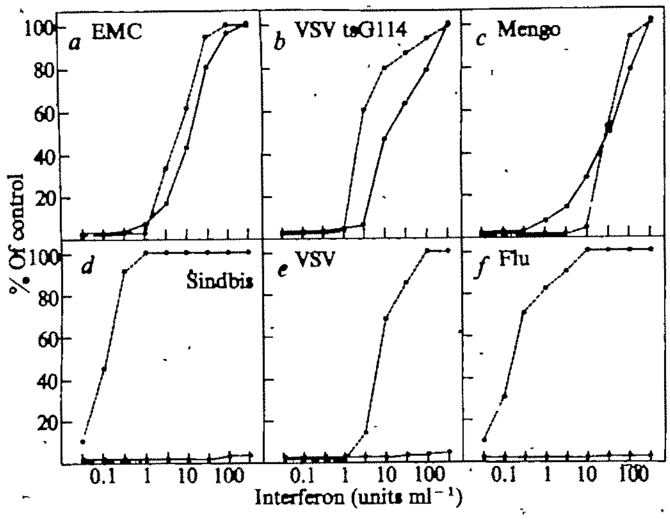

Fig. 1 Antiviral effects of interferon in embryonal carcinoma (●—●) and L cells (○– –○) infected with different viruses. The PCC4AzaR1 and L929 cell lines were maintained in monolayer cultures in Dulbecco modified Eagle's medium containing 10% heat-inactivated calf serum. Before infection the cells were seeded at about 3×10^5 cells per 16-mm well in 24-well cluster plates (Costar). The amount of virus required to produce a complete cytopathic effect in 48 h was determined for both cell types by end-point dilution of concentrated virus stocks. The cytopathic effect was quantified by the viral dye uptake method[15] The L cells were infected by adding 0.2 ml of virus stock diluted in medium minus serum to each well. After 1 h at 37 °C for all viruses except the *ts* mutants of VSV, which were kept at 30 °C, 0 8 ml of medium containing 1% fetal calf serum was added and the infection continued for 48 h. As the PCC4 cells were infected more effectively while the cells were not adhering to the plastic wells, these cells were resuspended by shaking, infected and allowed to re-attach Treatment with the concentration of interferon indicated in the abscissa (NIH reference units) was for 20 h before infection. At the start of the interferon treatment the PCC4 cells were suspended as described above for virus infection The cytopathic effect was quantified after 48 h of infection. In all experiments control infected and non-infected cells were examined in parallel cultures. The A_{540} of the dye taken up by the latter cells was taken as 100%; the A_{540} of the control infected cells represents the 0% value shown in the ordinate. Typical A_{540} values were 2.5 for uninfected cells and 0.15 for untreated infected cells. Mouse interferon was obtained from Ehrlich ascites tumour cells infected with Newcastle disease virus and partially purified to about 10^7 units per mg of protein[13]. The viruses used are indicated Vesicular stomatitis virus (VSV) was the Indiana serotype strain. Identical results were obtained with both VSV *ts* mutants G114 and G11 and therefore the results with tsG114 only are shown. Flu designates the WSN strain of influenza virus

(EMCV)[11]. Moreover, this inhibition is observed even when induction of PK_{ds} is prevented by actinomycin D (ref. 11). In view of these observations, it was of interest to investigate the response of interferon-treated EC cells to picornavirus infection.

The EC cell line PCC4, derived from the transplantable ascitic form of the OTT 50-60 teratocarcinoma[12], and L929 cells were grown in monolayer cultures. These cells were treated with increasing concentrations of mouse interferon prepared from Ehrlich ascites tumour cells[13] and infected with different viruses as described in Fig. 1 legend. The viruses were: EMCV and Mengo, two picornaviruses; VSV and its two mutants tsG11 and tsG114 (ref. 14); Sindbis and influenza virus. All the viruses infected both L and EC cells, as shown by quantification of the cytopathic effect by a viral dye uptake method[15]. Low concentrations of interferon protected L cells from all viruses tested. In contrast, concentrations up to 300 units ml⁻¹ of interferon did not protect EC cells from VSV, Sindbis or influenza virus. Interferon concentrations comparable to those effective for L cells, however, protected EC cells from infection by EMCV, Mengo and the VSV mutants.

To confirm that interferon has a protective effect on EC cells, we also measured virus yield in control and interferon-treated cells infected with EMCV and VSV (Table 1). Treatment with interferon reduced virus yield by four logs in both cells infected with EMCV, but had no effect on the yield of VSV in EC cells. The protective effect of interferon in EC cells, therefore, is clearly virus specific.

In subsequent experiments, we confirmed that only one of the two enzymatic activities induced by interferon is elevated in EC cells, whereas both are increased in L cells (Table 1). The 2-5A polymerase was induced in EC cells by interferon, but the kinase was not. The 2-5A synthesized by EC and L cell extracts was characterized by its elution from DEAE-cellulose with 0.35 M KCl[16] (Table 1) and by its biological activity in an endonuclease activation assay[9]. Oligonucleotides synthesized with extract of interferon-treated PCC4 and L cells activated a HeLa cell endonuclease, whereas corresponding fractions from incubations with extract of control cells did not (data not shown).

These observations suggest a possible correlation between the inhibition of replication of specific viruses in EC cells and the induction of the 'antiviral protein' 2-5A polymerase. Although the precise mechanism of action of this enzyme has not been determined, the following observations suggest that the 2-5A polymerase has some role in preventing replication of picornaviruses: (1) 2-5A is formed in interferon-treated cells infected with EMCV[17]; (2) 2-5A introduced into intact cells inhibits protein synthesis and causes RNA breakdown[18,19]; (3) preferential degradation of viral RNA is observed when the replicative intermediate (RI) of EMCV is incubated with extracts of interferon-treated cells (the RI is the RNA component of the replicative complex)[20]; (4) EMCV replicates by forming base-paired structures. This was shown by isolating cross-linked RI from infected cells treated with aminomethyltrioxalen[4]. This compound intercalates into duplexes and forms covalent bonds on irradiation[21]. Cross-linked RNA could not be detected in cells infected with wild-type VSV, but was detected in cells infected with two *ts* mutants that are sensitive to interferon protection in EC cells[4].

Interferons are glycoproteins that are operationally defined in terms of their antiviral activity against a wide range of viruses. With the recent advances in our understanding of the molecular basis of the antiviral state[7], it has become clear that several defence mechanisms are activated in interferon-treated cells; for example, an inhibitor of viral mRNA methylation[22] and a reduction in the amount of G protein incorporated into VSV[23] have been reported. The fact that interferon does not protect EC cells from VSV infection presumably means that these latter defence mechanisms are not operational in EC cells. In most cells interferon activates a spectrum of antiviral defence mechanisms, whereas in EC cells it elicits a restricted antiviral state, possibly limited to the induction of 2-5A polymerase.

A better understanding of the different antiviral mechanisms and of the replication of different viruses may ultimately provide a satisfactory explanation for the present and previous observations. A genetically determined virus-specific effect of interferon, for example, is due to the *Mx* allele in A2G mice[24]. Haller *et al.*[25] have reported that macrophages of *Mx* mice can be protected from influenza virus by much smaller interferon concentrations than are necessary to protect macrophages of other mice; no difference in protection is observed, however, on infection with EMCV or VSV. These authors speculate that the antiviral state is composed of a multitude of specific antiviral mechanisms and envisage the *Mx* gene as regulating the expression of a component of the antiviral state[25]. Each component may be both genetically and developmentally regulated, as shown by this report and by our observations on embryonal carcinoma cells.

This work was supported by NIH grant AI-16076. The VSV *ts* mutants were obtained from Drs Gail W. Wertz and Philip Marcus, Mengo was obtained from Dr Jean Lucas Lenard and other viruses from Dr James McSharry.

A new papillomavirus associated with alimentary cancer in cattle

M. Saveria Campo[*], Martin H. Moar[*],
William F. H. Jarrett[†] & Helen M. Laird[†]

[*] Department of Zoology, University of Edinburgh, Edinburgh, UK
[†] Department of Veterinary Pathology, University of Glasgow, Glasgow, UK

A high incidence area of carcinoma of the alimentary tract of cattle has been reported[1–4]. The carcinomas are preceded by papillomas which may transform to malignancy. A papillomavirus was isolated from these warts and was shown to occur as a widespread infection of cattle in the UK[2]. In the high cancer area there is a marked increase in the overall incidence of this infection, an increase in the number of papillomas per animal and an increase in the number of specific sites of infection as compared with cattle from adjacent areas where cancers are not found. The papillomas are found in young animals but carcinomas do not develop until the cows are over 7 yr old. There is strong circumstantial evidence[1] that the factor associated with the increased multiplicity of papillomas and the subsequent malignant transformation is the ingestion of bracken fern. This plant is known to possess radiomimetic, mutagenic and carcinogenic activity. Preliminary experimental evidence supports the circumstantial data and we also have preliminary evidence of the presence of viral genome sequences, without production of virus, in the cells of carcinomas. In addition to the alimentary papillomas of the type described above, three more major patterns of bovine papillomatosis are found in the UK[5]—cutaneous fibropapillomatosis, papillomatosis of the skin of the udder and teats, and papilloma of the penis. We have extracted papillomaviruses from all the above tumours, and our results, published in a preliminary form elsewhere[5], indicate that the different lesions are caused by different papillomaviruses. Here we report the partial characterization of the virus involved in alimentary tract tumours and its differentiation from other bovine papillomaviruses. The system seems to present a dissectable model for investigating the mechanistic relationship between the viral infection and the ingestion of an environmental 'carcinogen'.

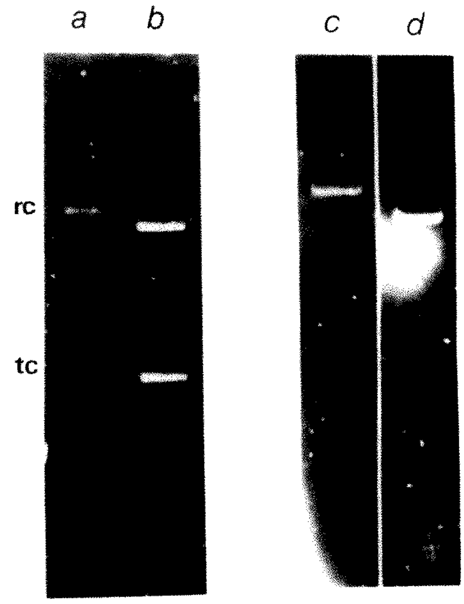

Fig. 1 Comparison between BCPV and BAPV DNA. *a*, Unrestricted BCPV DNA, and *b*, unrestricted BAPV DNA, electrophoresed in a 1% agarose gel. rc, relaxed circles; tc, twisted circles. *c*, *Hin*dIII-restricted BCPV DNA, and *d*, *Bam*HI-restricted BAPV DNA, electrophoresed in a 0.7% agarose gel. The MWs ($\times 10^{-6}$) are shown on the right. The MW of BAPV DNA was calculated by using the known MW of BCPV DNA as reference. Cutaneous and oesophageal papillomas were finely homogenized in TS buffer (10 mM NaCL, 1 mM Tris *p*H 8.0, 1 mM EDTA). The debris was pelleted at 2,000 r.p.m. for 5 min and the supernatant centrifuged at 10,000*g* for 15 min. Virions were pelleted from the 10,000*g* supernatant by centrifugation at 35,000 r.p.m. for 90 min. The virion pellet was resuspended in TS buffer and the virions were banded in a CsCl gradient at 1.36 g ml^{-1}. The band containing the virus was collected and, after dilution with TS buffer, the virions were pelleted at 35,000 r.p.m. for 2.5 h. The final pellet was resuspended in TS buffer and the virions were disrupted by adding SDS to 0.5%. The viral DNA was extracted with phenol, precipitated with alcohol and resuspended in 10 mM Tris, *p*H 7.8, and 1 mM EDTA. Unrestricted DNA was electrophoresed in a 1% agarose gel and restricted DNA in a 0.7% agarose gel in E buffer[16], at 5 V cm^{-1}. The DNA was visualized by staining the gel with ethidium bromide and by photography under UV light. Conditions of restriction are as in Fig. 2 legend.

Virus was isolated from a variety of papillomas by homogenization and density gradient centrifugation on CsCl. The papillomas were of four of the types recognized in cattle in the UK[5]. Alimentary papillomavirus (BAPV) was obtained from oesophageal warts; each isolate was made from a single abattoir animal which had several tumours but no concurrent carcinoma, and no other type of papillomas. DNA was purified from the virus and was present in two forms, twisted circles (form 1) and relaxed circles (form 2) (Fig. 1*b*). In agarose gel electrophoresis, both forms migrated ahead of the corresponding forms of DNA isolated from the virus (BCPV) of cutaneous fibropapillomas (Fig. 1*a*, *b*). This suggested that BAPV has a genome of lower molecular weight (MW) than BCPV. BAPV is cut at one site by *Bam*HI restriction endonuclease and this linear molecule shows a higher electrophoretic mobility than BCPV DNA linearized by *Hin*dIII (Fig. 1*c*, *d*). The MW of DNA of BAPV in the above experiments was calculated as approximately 4.5×10^6, or 10% smaller than the normally quoted MW for papillomavirus DNA[6,7].

We have analysed BAPV DNA with six restriction enzymes and compared it with physical maps generated in a similar fashion which we have made of BCPV DNA, and also with DNA from virus isolated from a group of tumours commonly found on the teats of cows and the penis of bulls that we have designated bovine paragenital papillomavirus (BPPV)[5].

Because of the limited amount of viral DNA obtainable from single alimentary tract papillomas, we found it inconvenient and wasteful to analyse restriction patterns by ethidium bromide fluorescence. We circumvented this problem by labelling some of the virus DNA by nick-translation[8] and by hybridizing the radioactive DNA to Southern blots[9] containing nanogramme amounts of restricted DNA. The results are presented in Fig. 2. *Bam*HI and *Hpa*I produce unit length linear DNA (Figs 1*d*, 2*a*, *h*); therefore, there is only one cleavage site for these enzymes in the DNA. *Eco*RI produces two fragments (Fig. 2*f*), *Hin*dIII three fragments (Fig. 2*d*) and *Hin*dII four fragments (Fig. 2*b*). The viral DNA is not restricted by *Bgl*II (not shown) and therefore has no cleavage site for this enzyme.

The MWs of the restriction fragments are listed in Table 1. The total MW of the viral genome obtained by adding the MWs of individual restriction fragments generated by any one enzyme ranges from 4.43×10^6 to 4.5×10^6, thus confirming our previous estimate.

0028-0836/80/280180—03$01.00

When the DNA is digested with *Eco*RI + *Bam*HI, the *Eco*RI fragment B disappears and two smaller fragments are produced (Fig. 2*g*). The *Bam*HI site therefore maps within *Eco*RI fragment B. Restriction with *Hin*dIII + *Bam*HI produces three detectable fragments (Fig. 2*e*). The first two correspond to *Hin*dIII fragment A and fragment B, respectively, and the third fragment corresponds to *Hin*dIII fragment C minus a low MW fragment that we could not detect in this particular gel. The *Bam*HI site is thus located within *Hin*dIII fragment C. When the DNA is restricted with *Hin*dII + *Bam*HI, five fragments are produced (Fig. 2*c*). Three fragments correspond, respectively, to *Hin*dII fragments, B, C and D. *Hin*dII fragment A is split into a major fragment and a very low MW fragment. This places the *Bam*HI site within *Hin*dII fragment A. Restriction with *Hpa*I + *Bam*HI produces two fragments (Fig. 2*i*). As the recognition sites of *Hpa*I are a subset of those of *Hin*dII[10], the double restriction shows that the single *Hpa*I site coincides with the *Hin*dII site at 0.278 map units (see below and Fig. 3). Restriction with *Eco*RI + *Hin*dIII, and *Eco*RI + *Hin*dII places the two *Eco*RI sites within fragments A and C of both *Hind* enzymes (Table 1). Of the three *Hin*dIII sites, two map within *Hin*dII fragment A and one within *Hin*dII fragment B (Table 1).

The MWs of the fragments obtained in all double digest experiments are listed in Table 1. Arbitrarily assigning the zero map unit to the single *Bam*HI site, and taking into account the fractional length of all the restriction fragments, these can be ordered in a circular map (Fig. 3).

This map differs considerably from the restriction maps of papillomavirus DNA from both the typical cutaneous warts and the paragenital (teat and penis) lesions[5] (M.S.C. *et al.*, in preparation). The differences between the viruses are not confined to the position of the restriction sites along their genomes: in liquid hybridization experiments, carried out in 2 × SSC at 70 °C, BAPV DNA failed to cross-hybridize to the DNA of the other two viruses, whereas the latter cross-reacted with each other to at least 55% as estimated from the S_1 nuclease resistance of the hybrids. Moreover, BAPV DNA did not hybridize to Southern blots of large amounts (up to 0.5 μg) of restricted BCPV DNA or restricted BPPV DNA, and conversely, neither of the latter hybridized to blots of *Hin*dII- and *Hin*dIII-restricted BAPV DNA. These results show that the alimentary tract papillomavirus is not a deletion mutant of the other two viruses, but belongs to a type of its own.

In contrast, the extensive cross-hybridization between the typical BCPV DNA and BPPV DNA and the respective restriction fragments immobilized on nitrocellulose showed that the sequence homology between these two types of virus is not confined to a particular region of the genome, but is spread throughout the whole of it[5]. Similar results have recently been obtained by Law and colleagues[11].

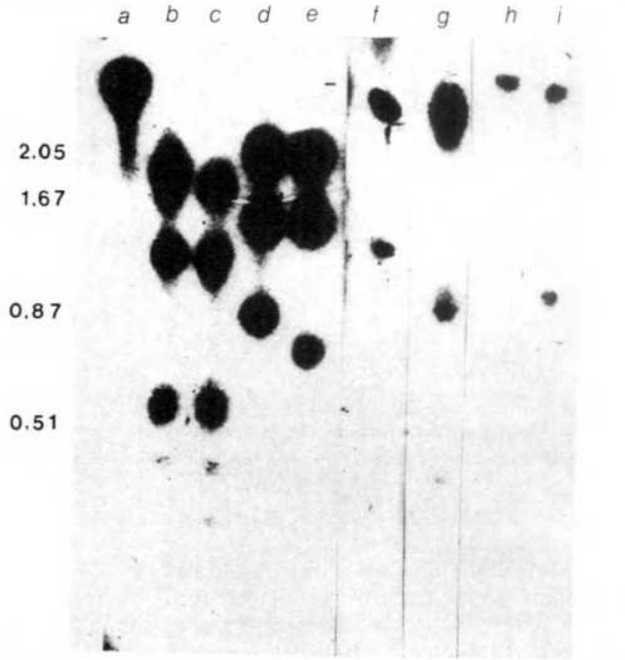

Fig. 2 Restriction fragments of BAPV DNA. *a*, *Bam*HI; *b*, *Hin*dII; *c*, *Hin*dII + *Bam*HI; *d*, *Hin*dIII; *e*, *Hin*dIII + *Bam*HI; *f*, *Eco*RI; *g*, *Eco*RI + *Bam*HI; *h*, *Hpa*I; *i*, *Hpa*I + *Bam*Hi (all Boehringer). The buffers used were as recommended by Boehringer laboratories. Nanogramme amounts of viral DNA were digested and the resulting fragments were electrophoresed in a 1.5% agarose gel as described in Fig. 1 legend. The DNA fragments were transferred to nitrocellulose[9] and hybridized overnight to nick-translated[8] ^{32}P-labelled viral DNA, in Denhart-2 × SSC at 70 °C (ref. 17). The nitrocellulose sheet was extensively washed in 1 × SSC at 70 °C, dried and exposed to a flash-activated X-ray film (Kodak X-Omat H) at −70 °C (ref. 18) for 3 weeks. The *Hin*dII fragments of BCPV DNA, visualized both by ethidium bromide fluorescence and by hybridization to ^{32}P-BCPV DNA, were used as MW markers. The sharpness of the stronger high MW bands has been lost so that the presence of the much fainter low MW bands can be seen.

Marked differences between BAPV on the one hand and BCPV and BPPV on the other were also found at the level of antigenic determinants. Whereas BCPV and BPPV have a major determinant in common, no serological cross-reaction was observed with BAPV[5] (W.F.H.J. *et al.*, in preparation). Thus, BCPV and BPPV seem to belong to the same group and, although distinguishable, are much more closely related to each other than they are to BAPV.

Two types of bovine papillomavirus, BPV 1 and BPV 2, have recently been described[12]. Although the precise body localization of the papillomas from which these viruses were purified is not specified in that work, BPV 1 corresponds to our BPPV and BPV 2 to our BCPV. Also, bovine papillomavirus with a genome of MW 4.5×10^6 has recently been found by Pfister *et*

Table 1 Molecular weights and fractional lengths of the restriction fragments of BAPV DNA

0.26	5.9	4.45				0.43	9.7		
4.36									

The MWs were calculated as in Fig. 2 legend. In two different experiments, the measurement error ranged from 0.01×10^6 to 0.15×10^6 for individual fragments. The fractional lengths were calculated from the percentage of the MW of a single fragment over the total MW. In the case of *Hin*dII + *Eco*RI double digest and of *Hin*dII + *Hin*dIII double digest, where small fragments were missing, presumably because they failed to bind to the nitrocellulose, the fractional length was calculated on the total MW of the single digest.

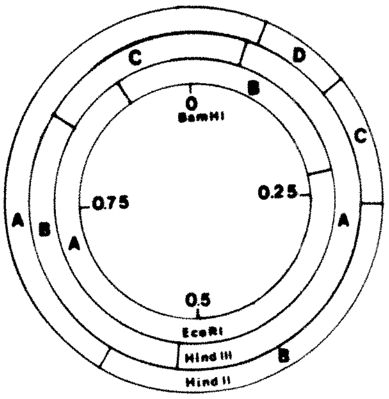

Fig. 3 Restriction map of BAPV DNA. The circular genome has been divided into tenths, and the restriction enzyme sites have been mapped according to the fractional length of the fragments produced by a given enzyme. Zero map unit has been arbitrarily assigned to the single *Bam*HI site. The approximate map positions of the other restriction sites are: *Hpa*I = 0.278; *Eco*RI = 0.220, 0.920; *Hin*dIII = 0.040, 0.514, 0.844; *Hin*dII = 0.057, 0.152, 0.278, 0.587

al.[13] in cutaneous papillomas from Australian cattle, but not in papillomas from German cattle where only the typical cutaneous type was found. Despite the similarity in MW, the DNA restriction map of the Australian virus found by those authors differs from the DNA restriction map of the small virus we have found in alimentary tract papillomas. Experiments in progress suggest that 'rice grain'-type lesions of the teat papillomatosis are caused by yet another type of papillomavirus. This would bring the number of different bovine papillomaviruses to five. We are now investigating the relationship between the several viruses at the molecular, immunological and pathological levels. We injected BAPV into the soft palate of 18 calves and into the skin of the neck of 6. After 2 months, all 18 calves injected in the palate showed marked papillomatosis, whereas no cutaneous papillomas have so far (8 months) been detected in the calves injected subcutaneously. Studies on the infectivity of BAPV are in progress. The viral DNA purified from the experimentally induced alimentary tract papillomas is indistinguishable in MW and restriction pattern from the one used to induce the tumours. In addition, the sera from the tumorous calves failed to cross-react with antisera raised against the other viruses, confirming the uniqueness of BAPV. The finding that BAPV does not induce cutaneous warts complements the finding of Olson and his colleagues[14], who, although able to induce cutaneous warts experimentally in cattle with BCPV, failed to infect the alimentary tract.

Thus, although our analysis of these viruses is incomplete, our initial studies of their epidemiological, pathological, immunological and molecular heterogeneity provide increasing evidence of a close relationship between the type of papillomavirus and the type and site of lesion caused by them. This is particularly interesting in view of the fact that, as far as we know, only BAPV is associated with the only benign papillomas that commonly undergo malignant transformation in cattle. A similar situation is found in humans: epidermodysplasia verruciformis, a papilloma with marked tendency to malignant transformation, is caused by HPV-5 (previously classified as HPV-4), a human papillomavirus differing from the other, more common, viruses associated with ordinary skin warts[15]. In addition, preliminary evidence indicates that bovine alimentary carcinoma cells contain BAPV DNA sequences, but not BCPV or BPPV DNA sequences, thus further suggesting that only the alimentary virus is involved in carcinogenesis.

This work was carried out with the aid of grants from the Agricultural Research Council (AG. 17/112), the NIH (N01 CP 81022), and the Cancer Research Campaign (916/800/2). We thank Mr Brian O'Neil, Mrs Ellen Leighton, Mrs C. Burke and Mrs C. McLay for technical assistance.

A pyrimidine dimer–DNA glycosylase activity associated with the *v* gene product of bacteriophage T4

Eric H. Radany & Errol C. Friedberg

Laboratory of Experimental Oncology, Department of Pathology,
Stanford University, Stanford, California 94305

Mutations in the *v* gene of bacteriophage T4 are associated with a marked increase in sensitivity to killing by UV radiation at 254 nm, but not to a variety of other forms of base damage to DNA[1–4]. Early studies from this laboratory provided evidence for a role of the *v* gene in the excision of pyrimidine dimers (PD) from DNA. Specifically, it was shown that extracts of T4v^+-infected *Esherichia coli* catalyse the formation of single-strand breaks (nicks) and/or alkali-labile sites in UV-irradiated duplex DNA[5]. Comparable hydrolysis of phosphodiester bonds is not observed with extracts of *E. coli* infected with the mutant T4v_1 (ref. 5). The product of the *v* gene has been extensively purified in a number of laboratories[6–9]; however, convincing evidence of purification to physical homogeneity has not yet been presented.

Characterization of the partially purified *v*-gene product yielded results that were consistent with the interpretation that this gene codes for an endonuclease activity (endonuclease V of T4 or T4 UV endonuclease) that directly catalyses the hydrolysis of phosphodiester bonds 5′ to PD in duplex DNA, creating nicks with 3′OH and 5′P termini[6,8,10,11]. The additional observations that the enzyme attacks single-stranded DNA containing PD[6,11] and that no other form of base damage in DNA thus far examined is recognized as substrate[1–4,12], support the notion that the activity coded by the *v* gene recognizes PD in DNA specifically.

Grossman *et al.*[13] and Haseltine *et al.*[14] have recently suggested an alternative mechanism for the incision of DNA containing PD. Their suggestion stems from the analysis by gel electrophoresis, of the length of DNA fragments generated by incubation of a sequenced region of the *E. coli lac* operon containing PD, with UV endonuclease activities from *Micrococcus luteus*. A knowledge of the exact nucleotide sequence of the substrate used allowed for a very precise prediction of the length of the oligonucleotide products generated following denaturation of the DNA, if the enzyme activity catalysed cleavage of phosphodiester bonds immediately 5′ to PD sites. Their experiments yielded unexpected results which have been interpreted in terms of an alternative molecular mechanism for the enzymatic incision of UV-irradiated DNA at PD sites, that is, a PD-specific DNA glycosylase catalyses cleavage of the 5′ *N*-glycosylic bonds of the dimerized pyrimidines and the resulting apyrimidinic sites are attacked by apurinic/apyrimidinic (AP) endonuclease, resulting in cleavage of phosphodiester bonds. This two-step mechanism is entirely consistent with the observation of nicks bearing 3′OH and 5′P termini located 5′

Pyrimidine dimer–DNA glycosylase
Dimer monomerization by photoreversal
T

Fig. 1 Diagrammatic representation of experimental protocol. Only one strand of a duplex DNA molecule is shown. The figure indicates postulated hydrolysis of the 5' glycosylic bond of a thymine–thymine dimer, yielding an apyrimidinic site. Subsequent monomerization of the dimer by direct photoreversal results in the release of the 5' thymine of the dimer as free thymine.

with respect to PD in duplex UV-irradiated DNA incubated with *M. luteus* correndonucleases I and II (ref. 15).

In view of the remarkable similarity in the properties of so-called T4 endonuclease V and *M. luteus* correndonucleases I and II, we have sought evidence for a PD-DNA glycosylase activity in preparations of T4 enzyme known to catalyse the nicking of UV-irradiated DNA. Enzyme-catalysed hydrolysis of the *N*-glycosylic bond linking either one of the dimerized pyrimidines to deoxyribose in DNA would leave the corresponding base in covalent linkage only with its partner in the dimerized structure (Fig. 1). Subsequent monomerization of the PD should result in the liberation of free thymine (Fig. 1) which can be readily detected by established chromatographic techniques. Our experimental approach has been to demonstrate that the formation of free thymine from UV-irradiated DNA is dependent both on incubation with T4 enzyme activity, and on the monomerization of PD by the technique of direct photoreversal.

Regarding the latter procedure, it has been clearly demonstrated by others that the formation of pyrimidine dimers in DNA by exposure to UV radiation at about 254 nm is a reversible process[16,17]. When *E. coli* DNA is irradiated at 254 nm under standard conditions, the rates of PD formation and reversal ultimately become equal and a state of dynamic equilibrium is attained in which ~7% of radioactively labelled thymine is in PD. Thus, further irradiation at 254 nm under these conditions does not result in measurable net dimer formation or dimer monomerization. However, when *E. coli* DNA is initially irradiated at 254 nm in the presence of $AgNO_3$, photosensitized dimer formation results in the conversion of as much as 20% of the thymine to thymine-containing PD[18]. Further irradiation of this DNA at 254 nm following removal of the photosensitizer results in measurable reversal of PD, until once again a steady state is reached at a level of ~7% thymine-containing PD. In the present experiments we have employed the technique of direct photoreversal to investigate the release of free thymine from *E. coli* DNA (containing about 17% of its thymine in PD) previously incubated with or without a T4 enzyme preparation.

Figure 2 shows the sedimentation profiles in alkaline sucrose gradients of UV-irradiated DNA incubated with the T4 enzyme. It is clear that the smallest amount of enzyme used in these experiments is saturating with respect to the number of DNA strand breaks and/or alkaline labile sites generated in the DNA. Unirradiated DNA incubated and sedimented under identical conditions showed no reduction in sedimentation velocity in alkaline sucrose gradients (data not shown). The incubation conditions described in Fig 2 also result in the release of free thymine. (Table 1 and Fig. 3). However this product is only observed when, following incubation of UV-irradiated DNA with the T4 enzyme preparation, the reaction mixture is subjected to direct photoreversal. Free thymine is not detected when unirradiated DNA incubated with enzyme is subjected to photoreversing light (Table 1), nor is this result obtained when UV-irradiated DNA not previously incubated with the enzyme is exposed to photoreversing light (Table 1).

These results strongly suggest that the T4 enzyme preparation contains a DNA glycosylase activity that catalyses the hydrolysis of one of the *N*-glycosylic bonds linking the dimerized pyrimidines to deoxyribose in DNA (Fig. 1). This suggestion is consistent with the fact that PD are quantitatively the major photoproduct in DNA irradiated at 254 nm, and to our knowledge are the only known photoproducts in DNA that can generate thymine as a product of their photolabilization. Our conclusions are also supported by the results of extensive previous studies with the T4 enzyme which have demonstrated that this activity recognizes pyrimidine dimers exclusively in UV-

Table 1 Release of free thymine from DNA containing thymine dimers

			Total free [^{3}H] thymine detected	
^{3}H-labelled thymine-labelled substrate	T4 enzyme	Incident photo-reversal fluence (kJ m^{-2})	(c.p.m. per ml of reaction mixture $\times 10^{-3}$)	(% of [^{3}H] radioactivity as thymine-containing PD)
Unirradiated *E. coli* DNA	Absent	0	<0.04	<0.001

	Present	11.5	<0.04	<0.001
UV-irradiated *E. coli* DNA (17.5% thymine as thymine-containing PD)	Absent	0	<0.04	<0.001
	Absent	4.3	ND	—
	Absent	8.2	ND	—
	Absent	12.3	<0.04	<0.001
	Present	0	<0.04	<0.001
	Present	4.3	14.4	16.5
	Present	8.2	21.3	24.3
	Present	12.3	26.6	30.4

[^{3}H]thymine-labelled *E. coli* DNA (1.5×10^4 c.p.m. μg^{-1}) was prepared by standard methods. DNA containing 17.5% of ^{3}H-thymine in PD was produced by germicidal irradiation at 254 nm with an incident fluence of 2 kJ m^{-2} in the presence of Ag^+ photosensitizer according to the procedure of Rahn and Landry[18]. Tritiated UV-irradiated or unirradiated DNA (100 μg ml^{-1}) was incubated at 37 °C with or without 9.4×10^4 units ml^{-1} of the phosphocellulose fraction of T4 endonuclease[9] in 10 mM Tris–HCl *p*H 7.8, 10 mM Na_2 EDTA, 100 mM NaCl for 45 min in a total volume of 3.0 ml. Following incubation, each was deproteinized by incubation at 60 °C with 50 μg per ml Proteinase K for 1 h followed by extraction with an equal volume of $CHCl_3$. Irradiated or unirradiated ^{3}H-DNA (131 μg total) that had been incubated in the presence or absence of enzyme was diluted with 10 mM Tris–HCl *p*H 7.5, 1 mM Na_2EDTA to give a final activity of 5.0×10^5 ^{3}H c.p.m. ml^{-1}. Unlabelled DNA was added to these mixtures to bring the final A_{254} to 2.0. The mixtures were then subject to photoreversing irradiation and duplicate aliquots (0.2 ml) were withdrawn at the incident fluences stated. ^{14}C-thymine (9,530 c.p.m. NEN) was added to each aliquot as an internal marker for the chromatographic identification of free ^{3}H-thymine by TLC. The aliquots were evaporated to dryness and the residue extracted three times with 15 μl absolute ethanol. The extracts were spotted directly on thin layer plates and developed as described previously[22]. [^{3}H] and [^{14}C] radioactivity were measured in individual chromatogram fractions; total [^{3}H] free thymine was calculated by normalization to 100% recovery of the [^{14}C] standard. Separate ^{14}C-thymine samples were run with each chromatogram to allow for correction of channel spillover during radioactive counting of the two isotopes in a Beckman LS 250 liquid scintillation spectrometer. Replicate measurements agreed to within 5%. (ND = none detected.)

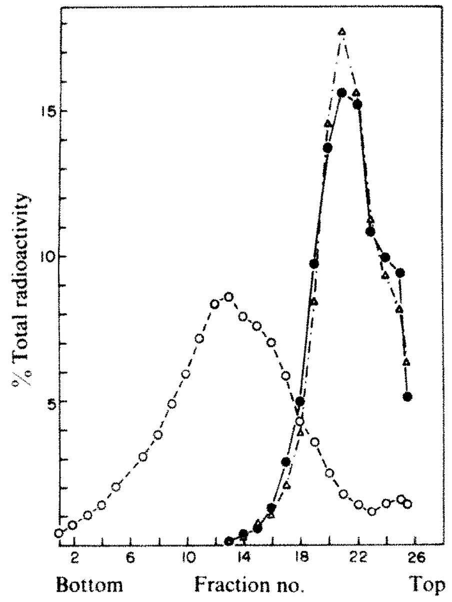

Fig. 2 ^{3}H-thymine DNA (0.5 μg, 21% thymine-containing PD) was prepared as described in the legend to Table 1 and incubated at 37 °C for 30 min with (●) or without (○) 9.4×10^4 units per ml of the phosphocellulose fraction of T4 endonuclease[9] in 50 μl reactions containing 10 mM Tris–HCl pH7.8, 10 mM, Na_2EDTA, 100 mM NaCl. The reactions were stopped by the addition of 50 μl 5% alkaline sucrose, and layered onto 4 ml 5–20% alkaline sucrose gradients. The DNA was sedimented at 30,000 r.p.m. in an SW56 rotor for 11 h at 20 °C. The gradients were fractionated and processed for measurement of radioactivity as described by Reynolds[23]. To demonstrate apparent completion of incision, a reaction containing enzyme was prepared and incubated as above, and then incubated with an additional aliquot (4.7×10^3 units) of enzyme for a further 30 min (△). Incubations with even higher amounts of enzyme yielded identical sedimentation profiles (data not shown).

irradiated DNA[2,7,11,19–21]. Thus, for example, removal of PD by enzymatic photoreactivation of UV-irradiated DNA in permeabilized *E. coli* results in the loss of all sites sensitive to the T4 enzyme[20]. In addition, in both duplex and single stranded UV-irradiated DNA incubated with the enzyme there is a stoichiometric relationship between the calculated number of PD in the DNA and the measured number of strand breaks[7,11,19,21]. Further evidence in support of PD-DNA glycosylase activity associated with the T4 enzyme preparation is provided by independent studies by Seawell *et al.* (manuscript submitted). Using the same preparation of T4 enzyme, these investigators have shown that under incubation conditions that are strictly limiting with respect to enzyme concentration, UV-irradiated DNA is subject to hydrolysis of phosphodiester bonds in strong alkali or following incubation with AP endonuclease at near-neutral pH. These are expected properties of DNA containing apyrimidinic sites generated by the action of a DNA glycosylase activity. Alkaline lability of T4 enzyme-treated UV-irradiated DNA and/or the presence of AP endonuclease activity associated with the T4 DNA glycosylase is also indicated in the present studies by the reduced sedimentation velocity of the DNA in akaline sucrose gradients shown in Fig. 2.

Table 2 Photoreversal-dependent release of free thymine from UV-irradiated DNA incubated with extracts of *E. coli* infected with phage T4v^+ or T4v_1

Extract of *E. coli* infected with	Free thymine (c.p.m./20 μl of reaction mixture) Photoreversal	No photoreversal
Phage T4v^+	380	<20
Phage T4v_1	<20	<20

Extracts of *E. coli* cells infected by wild type (v^+) and mutant (v_1) phage T4 were prepared by sonication in 50 mM Tris–HCl, pH 8.0 as described previously[7]. Extracts (0.87 mg total protein in each) were incubated at 37 °C for 30 min with 150 μg ^{3}H-thymine labelled *E. coli* DNA (3.0×10^4 c.p.m. per μg, 10% of [^{3}H] in thymine-containing PD) plus 35 mM Tris–HCl pH 8.0, 10 mM Na_2 EDTA, 100 mM NaCl. The final volume of each of the two incubation reactions was 1.6 ml. Following reaction, the mixtures were extensively deproteinized by incubation with 100 μg per ml Proteinase K at 60 °C for 2 h, followed by extraction with phenol and $CHCl_3$. The mixtures were made 0.5 M in NaCl and the DNA was precipitated overnight at −20 °C with two volumes of absolute ethanol. The DNA was collected by centrifugation and resuspended at a concentration of 150 μg ml^{-1} in 10 mM Tris–HCl pH 7.5, 1 mM EDTA. Half of each reaction mixture was subjected to 10 kJ m^{-2} photoreversal irradiation fluence; the other half was kept as a control. Aliquots (20 μl) of each reaction were spotted on thin layer chromatography plates. Free thymine was determined as described in the legend to Table 1. [^{14}C] thymine standard samples were run on adjacent lanes of the same thin-layer plate.

Note from Table 1 that the highest photoreversing fluence used in these experiments (12 kJ m^{-2}) is not yet saturating with respect to free thymine formation. Yet even at this fluence, the amount of radioactivity present in the free base is equivalent to that present in ~30% of the thymine-containing PD measured in the DNA. Since the DNA is uniformly labelled with ^{3}H-labelled thymine, each thymine-containing dimer attacked by the enzyme and subsequently reversed by irradiation, should release on the average one half of its radioactivity as free thymine (Fig. 1). Thus the radioactivity in free thymine equivalent to 30% of the thymine-containing PD in DNA represents the product of the reversal of 60% of such dimers. Clearly the PD-DNA glycosylase demonstrated in these experiments is not a minor contaminant of the T4 enzyme preparation used.

Finally, our studies indicate that the T4 PD–DNA glycosylase is a product of the v gene of phage T4, since extracts of T4-infected *E. coli* failed to catalyse the production of free thymine under the experimental conditions described (Table 2). A question of obvious interest is whether or not the v gene also codes for an AP endonuclease activity that is physically associated with the PD–DNA glycosylase activity. The release of free thymine dependent on the photoreversal of PD in DNA provides the basis for a specific and convenient assay of T4-induced PD–DNA glycosylase activity and we are currently purifying this enzyme to physical homogeneity from T4-infected

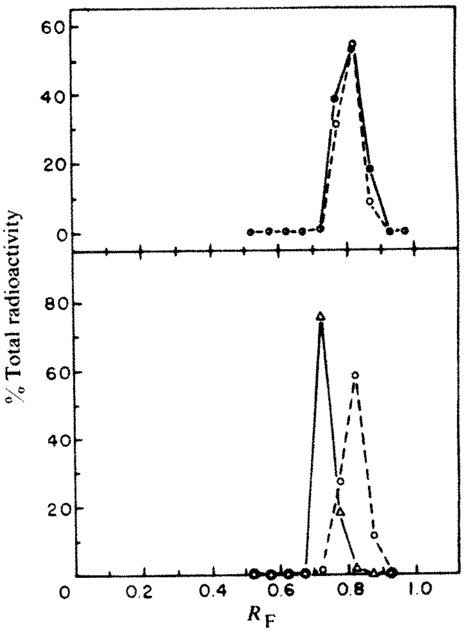

Fig. 3 Chromatographic identification of free ^{3}H-thymine in the ethanol-soluble phase generated by photoreversal irradiation of T4-enzyme treated irradiated DNA. Upper panel; portions of the ethanol-soluble phase of the photoreversal reaction containing added ^{14}C-thymine were applied to silica gel thin-layer chromatography plates and developed with water-saturated ethyl acetate/n-propanol (4 : 1)[17]. The plates were then fractionated at 0.05 R_f increments and the radioactivity in each fraction was determined after elution into water by liquid scintillation spectrometry[22]. Phosphorylated species migrate in this system with an $R_f = 0.1$ (ref. 17). Lower panel: ^{3}H-thymidine and ^{14}C-thymine were mixed and applied to an adjacent lane of the same plate depicted in the upper panel and analysed identically following development. No radioactivity migrated with an $R_f < 0.5$ in either chromatogram (data not shown). ●, [^{3}H] reaction product; △, [^{3}H]TdR standard; ○, [^{14}C]T standard.

E. coli. The availability of purified enzyme will hopefully facilitate a more detailed examination of the relationship of PD–DNA glycosylase to AP endonuclease activity, and of other questions concerning the detailed molecular mechanism of the incision of UV-irradiated DNA by this enzyme.

We thank Ms Pat Seawell for the preparation of T4 enzyme used, Ms Seawell and Drs Ann Ganesan, Thomas Bonura, Rick Reynolds and Jack Love for helpful discussions. These studies were supported by research grants from the USPHS and The Foundation—March of Dimes, and by contract with the US Department of Energy. E.H.R. is supported by an MSTP training grant from the USPHS and E.C.F. is the recipient of a research career development award from the USPHS.

Calcium-induced decrease in membrane fluidity of sea urchin egg cortex after fertilization

Judith Campisi* & Carl J. Scandella

Department of Biochemistry, State University of New York,
Stony Brook, New York 11794

Fertilization of the sea urchin egg is a dramatic example of cell activation resulting from the interaction of an external stimulus, the spermatozoon, with the cell surface[1]. Growing and quiescent cells may have different membrane states[2]. Here we report membrane fluidity measurements on a surface membrane fraction, the cortex, isolated from unfertilized and fertilized eggs. The fluidity of the fertilized egg cortex, measured by electron spin resonance (ESR) spectroscopy using 5-doxylstearate as a probe, is less than that of the unfertilized cortex. In the intact egg the intracellular Ca^{2+} concentration increases after fertilization and this transient rise seems to be localized in the cortex[3]. The addition of Ca^{2+} to the cortex fraction isolated from unfertilized eggs triggers a fluidity decrease *in vitro*. The fluidity decrease seems to represent a Ca^{2+}-induced change in membrane structure rather than a direct interaction of Ca^{2+} with phospholipid headgroups.

Bulk membrane fluidity of sea urchin eggs increases after fertilization or partial activation by ammonia[4,5]. We could not determine the effect of fertilization on plasma membranes of intact eggs because 5-doxylstearate probably partitions throughout egg membranes[5] and plasma membrane accounts for only a smalll percentage of the membrane present. The egg cortex can be isolated in a functional form[6–9] (see Table 1 legend for details). The cortex fraction contains several components in addition to plasma membrane. The extracellular vitelline layer of the unfertilized egg becomes the fertilization envelope after fertilization[10]. The hyaline layer surrounding the fertilized egg cortex holds the blastomeres together[11]. Cortical granules, membrane-delimited vesicles ~ 1 μm in diameter, line the inner surface of the plasma membrane of unfertilized eggs and fuse with the plasma membrane within seconds of fertilization[10]. The addition of Ca^{2+} to the unfertilized egg cortex triggers the discharge of cortical granules *in vitro*[6,10], a process analogous to the cortical granule exocytosis which occurs as the intracellular Ca^{2+} level rises after fertilization[3]. When viewed by scanning electron microscopy or phase contrast microscopy, our cortex fraction consisted of nearly intact cortical hulls and smaller, morphologically unidentifiable membrane fragments. On addition of Ca^{2+} to the unfertilized egg cortex fraction the cortical granules disappeared and each cortical fragment twitched and became less opaque by phase contrast microscopy. By this visual assay our cortex preparation was apparently more than 90% pure. The purification of plasma membrane in this fraction was at least 10-fold, as judged by the specific activities of mitochondrial and endoplasmic reticulum enzyme markers, and nucleic

Table 1 Enzyme and nucleic acid content of cortex fractions

Sample	Cytochrome *c* oxidase specific activity U per mg protein per min	Relative	NADH oxidase specific activity U per mg protein per min	Relative	Nucleic acid protein (w/w)
Unfertilized egg homogenate	1.38	(100%)	0.48	(100%)	0.135
Unfertilized egg cortex	0.092	6.5	0.056	11.6	0.012
Fertilized egg homogenate	1.33	(100%)	0.65	(100%)	0.128
Fertilized egg cortex	0.11	8.3	0.083	12.7	0.013

Enzyme activities, protein and DNA content were measured for cortex fractions isolated from unfertilized and fertilized *Strongylocentrotus purpuratus* eggs. The procedures used were modifications of the methods described by Schatten and Mazia[7] and Grainger[9]. The samples were maintained at 15 °C throughout the isolation. The jelly coat was removed by incubating eggs for 2 min in seawater (Instant Ocean, Aquarium Systems) titrated to *p*H 5 with HCl. Dejellied, unfertilized eggs were washed in isolation medium containing (mM): glycine, 350; NaCl, 300; $MgCl_2$, 4; EGTA, 10; Tris base added to a final *p*H of 7.6. The eggs were hand-homogenized (8–20 strokes) in a Teflon–glass homogenizer in isolation medium containing 0.2 mg ml^{-1} soybean trypsin inhibitor. Cortices were collected by centrifugation at 700*g* for 10 s, washed once with isolation medium–soybean trypsin inhibitor, then washed twice with isolation medium. For cortex isolation from fertilized eggs, 3 volumes of 10 mM dithiothreitol in artificial seawater titrated to *p*H 9.1 with Tris base were added to dejellied, fertilized eggs 20 s after addition of sperm. This treatment dissolved the fertilization envelope[20]. After 4 min, 9 volumes of Ca^{2+}-free seawater were added with stirring. Ca^{2+}-free seawater contains (mM): NaCl, 460; $MgCl_2$, 55; KCl, 10; $NaHCO_3$, 2.5; EGTA, 10; titrated to *p*H 8.0 with Tris base. After 10 min stirring, the eggs were allowed to settle, then washed with isolation medium and homogenized as described above. Protein and nucleic acid were assayed spectrophotometrically[21]. Cytochrome *c* oxidase and NADH oxidase were assayed as described elsewhere[22,23].

acid content (Table 1). From the data of Schroeder[12] we estimate that 50% of the membrane surface in the cortex fraction is plasma membrane and 50% cortical granule membrane. The purity of plasma membrane in the cortex fraction compares favourably with that of other purified plasma membrane fractions from animal cells despite the presence of cortical granules.

We measured membrane fluidity in the cortex fraction isolated from fertilized and unfertilized eggs. The order parameter, *S*, derived graphically from the ESR spectrum of 5-doxylstearate, decreases from 1 to 0 as the system becomes less ordered[13]. 5-Doxylstearate does not reside in neutral lipid droplets in these conditions[5], and the rapid, anisotropic motion revealed in the ESR spectrum means that 5-doxylstearate is probably not bound to protein[5]. Thus, an increase in order parameter may be interpreted as a decrease in membrane fluidity[5]. *S* measured for fertilized egg cortices isolated 30 min after fertilization is 3.2 ± 1.3% greater than when measured for unfertilized cortices from the same batch of eggs (Table 2). This change is about 50% greater than the change in *S* of bulk membranes[4,5], and is in the opposite direction. The response of this surface membrane fraction to fertilization seems to be distinct from the response of intracellular membranes.

An increase in *S* also accompanied the *in vitro* discharge of cortical granules of the unfertilized egg cortex (Table 3). In expts 1–5, cortical granules were discharged by adding a sufficient quantity of 0.1 M $CaCl_2$ just to titrate the 10 mM EGTA present in the isolation medium. The average ΔS observed for calcium addition *in vitro* was about the same as the average ΔS observed in the cortex fraction after fertilization. For example, the average $\%\Delta S$ measured at ambient temperature for unfertilized relative to fertilized egg cortices was 3.4 ± 1.8 compared with an average $\%\Delta S$ of 3.3 ± 0.6 for the change induced by addition of Ca^{2+}, measured at ambient temperature. The cortical granules of unfertilized egg cortices spontaneously discharge in isolation medium lacking EGTA. Spin labelled cortices allowed to undergo spontaneous discharge after removal of EGTA also exhibited an increase in *S* (expt 6). Mild heat treatment in the presence of EGTA discharges cortical granules. Cortices treated for 2 min at 40 °C in isolation medium containing 10 mM EGTA exhibited a similar increase in *S* (expt 7).

Table 2 Order parameter of cortices isolated from unfertilized and fertilized eggs

Expt	Temperature	*S* unfertilized cortex	*S* fertilized cortex	ΔS (%)
1	Ambient	0.669	0.683	2.1
2	Ambient	0.657	0.687	4.6
3	12 °C	0.756	0.777	2.8

Each experiment represents cortices isolated from the eggs of a different animal. 5-Doxylstearate in methanol was dried onto the wall of a test tube under a stream of nitrogen. A cortex suspension (1 ml) (Table 1) was added, the mixture was incubated for 10 min at 15 °C, then a cortex pellet was collected by centrifugation for 10 s at 700 *g*. The wet cortex pellet was washed with 0.5 ml isolation medium, then transferred to a Pasteur pipette sealed at one end. The molar ratio of spin label added to cortex phospholipid was approximately 1:30. ESR spectra were recorded from samples in sealed Pasteur pipettes on a Varian E-104A or E-4 ESR spectrometer equipped with a Varian temperature control accessory. Microwave power was 10 mW and modulation amplitude was 1 or 2 G. *S* was measured graphically from the spectra[13]. Multiple measurements of these samples indicated that the accuracy of the $\%\Delta S$ measurement is ±0.5%.

The exocytosis of cortical granules seems to be self-propagating in *vivo*[10] and *in vitro*[6] and a release of Ca^{2+} from the cortex may be involved[3]. Ca^{2+} interacts with the polar head group of phospholipids, rendering them less fluid[14], but that is an unlikely mechanism for the effects described here. The intrinsic association constant of Ca^{2+} for negatively charged phospholipids is of the order of $10\ M^{-1}$ (S. McLaughlin, unpublished results). We estimate that the Ca^{2+} concentration is less than 1 μM for all the samples studied here except those lacking EGTA or containing added Ca^{2+}. The intracellular Ca^{2+} concentration was estimated to reach 2.5–4.5 μM after fertilization[3]. At these concentrations less than 1% of the negatively charged lipids should carry bound Ca^{2+}, even considering that the surface concentration of Ca^{2+} may be 100-fold greater than the bulk concentration because of the effect of the membrane surface potential[15]. It seems clear that Ca^{2+} triggers the observed decrease in fluidity of the cortex but it apparently acts through membrane proteins rather than directly on the phospholipid bilayer.

Table 3 Effect of *in vitro* cortical granule discharge on order parameter of unfertilized egg cortex

Expt	Method of discharge	Temperature (°C)	*S* before discharge	*S* after discharge	ΔS (%)
1	Add $CaCl_2$	Ambient	0.595	0.617	3.7
2	Add $CaCl_2$	Ambient	0.591	0.608	2.9
3	Add $CaCl_2$	12	0.727	0.748	2.9
4	Add $CaCl_2$	12	0.771	0.818	6.1
5	Add $CaCl_2$	12	0.753	0.776	3.0
6	Remove EGTA	12	0.759	0.790	4.1
7	Heat	12	0.747	0.800	7.1

Each experiment represents cortices isolated from a different animal. Measurements were made as described in Table 2 legend. $CaCl_2$ was added to washed, labelled cortices as 0.5 M $CaCl_2$–0.5 M Tris base. The *p*H after Ca^{2+} addition was 7.6 ± 0.1. EGTA was removed by washing with isolation medium lacking EGTA. Heat discharge was effected by warming the sample to 40 °C for 2 min. Multiple measurements on these samples indicated that the accuracy of the $\Delta S\%$ measurement is ±0.5%.

Fluorescence photobleaching recovery measurements on mouse eggs revealed 10–100-fold slower rates of lateral diffusion on the cell surface after fertilization[16]. Studies on the rheological properties of the sea urchin egg surface showed that the cortex of the cell stiffens in response to fertilization[17]. These results seem consistent with the decrease in fluidity reported here.

These changes in fluidity are sufficient to alter the activity of membrane-bound enzymes such as adenyl cyclase and $(Na^+ + K^+)$ATPase by several fold (refs 18, 19 and M. Sinensky, unpublished results), assuming that the enzymes undergo the same change in fluidity as does the spin probe. The fluidity change could have an important role in the transition of the membrane from its quiescent to its proliferating state[2].

Part of this work was carried out in the laboratory of V. D. Vacquier. This work was supported by NIH grants HD-12986 (to V.D.V.) and GM-23218 (to C.J.S.), and by NIH training grants GM 07212 and CA 09176.

BOOK REVIEWS

The essential Lamarck

R.W. Burkhardt

Lamarck ou le Mythe du Précurseur. By M. Barthélemy-Madaule. Pp.185. (Editions du Seuil: Paris, 1979.) Approx. 55F, £7.

JUST as it was once common in natural history to view a wide array of species as existing primarily for the benefit of man, so too was it once common in the history of science to consider a large number of scientists as being adequately understood once they were identified as the 'precursors' of later thinkers. It is a mark of the growing maturity of the history of science that the 'precursoritis' that plagued the field as recently as a generation ago has now generally disappeared. French historians of science, most notably Alexandre Koyré and Georges Canguilhem, were prominent among those who argued that precursorship is a concept that is antithetical to the appreciation of scientific ideas in the past. Now Madeleine Barthélemy-Madaule, Professor of Philosophy at the Université de Picardie, has taken the insight of Koyré and Canguilhem and applied it to the case of Jean-Baptiste Lamarck (1744–1829), the French biologist who for about a century has been acclaimed, especially in France, as one of the great precursors of modern evolutionary thought.

Lamarck is a good choice for illustrating the problems of the notion of precursorship. His name is well known, but the ideas for which he is remembered fail to illuminate either the nature of his own work or the scientific problems of his day. Madaule's book is not the first study to make this point. The rethinking of Lamarck's place in the history of science began with papers written by Charles Gillispie in the 1950s and has continued up to the present. It is refreshing, nonetheless, to find that a book published in Lamarck's own country on the 150th anniversary of his death is directed more toward the issue of relocating Lamarck in his own historical context than toward the issues of who deserves the title of 'founder of evolution' or what Darwin owed to Lamarck.

Madaule has not attempted to provide an extensive treatment of Lamarck's life and work. She has sought instead to examine some of Lamarck's essential concepts in order to make clearer the interrelations of the ideological and the scientific elements of Lamarck's thought. At the same time she has sought to put to rest the "myth" of the precursor. As she explains, this is to be achieved through "the exploration of the possibilities of an epoch, the vigilant notation of the concepts that are utilized and of those that are not" (page 74). After an introductory chapter on Lamarck's life, she successively considers his ideas on nature, the relation between the animal "series" and environmental "circumstances", the inheritance of acquired characters, and adaptation. These are concepts in Lamarck's thought which have often been discussed, but Madaule manages to bring good sense and originality to her analysis of each of them. Her final chapter surveys how Lamarck came to be identified as a precursor of various later thinkers.

M. LE CHEVALIER DE LAMARCK.
Professor of Botany of the National Institute

Mary Evans Picture Library

The author's treatment of the role of "ideology" in Lamarck's thought is intriguing, but it is surprisingly narrow given her references to Canguilhem's and Althusser's thoughts on ideology in science. The ideological element she identifies in Lamarck's thinking is a theological one, manifesting itself in Lamarck's concepts of nature and the animal series and the relation of these concepts to Lamarck's thoughts on "the Supreme Author of all things". Madaule's observations on the ambiguities and tensions in Lamarck's presentation of these concepts are excellent and constitute an important contribution to Lamarckian scholarship. However, her reference to the ideological element in Lamarck's thinking as a "survival" (page 76), her view of the progressive elimination of this element along the route from Lamarck's evolutionary theory to Darwin's (page 139) and her phrase "ideological contamination" (page 141) suggest that she is operating with a restricted and generally negative view of the role of ideology in science. It is curious that Lamarck's commitment to a naturalistic explanation of mental as well as physical phenomena does not qualify in some measure as "ideological" and is not subjected to closer historical and philosophical scrutiny.

It is also curious that in a book devoted to placing Lamarck's thought in its own historical context considerable space is given to the issue of whether or not recent developments in molecular genetics have brought back the possibility that acquired characters may indeed be inherited. It would have been more appropriate to devote this space to examining how Lamarck's thinking developed over time, how the concepts selected for treatment here fit in with the rest of his scientific and philosophical thought, or how his views compared with those of his contemporaries. Madaule only scratches the surface of this part of the historical task. Generally speaking, her philosophical orientation makes her more sensitive to the apparent relation of elements within Lamarck's thinking at a given time than to the ways in which his thought was a dynamic, evolving entity. Her discussion of Lamarck's thoughts on species, for example, confuses the structural relations within one of Lamarck's general discourses for the historical situation in which the problem of species change came to be especially crucial for him.

Madaule acknowledges that history is reconstructed according to the concerns of the historian. What she has tried to offer the reader is "a Lamarck seen in his own epoch through the dimensions of a perspective produced by the contemporary world" (page 175), the perspective in question being that which concerns itself with the interrelations of science and ideology. She has succeeded in demonstrating the interest of Lamarck's case for the history of science, even though there is much more of interest in Lamarck's thinking than she mentions. Given the important kinds of questions she has posed, and allowing that new perspectives will provide additional questions to ask about Lamarck's case in the future, there is every likelihood that Lamarck will continue to be of considerable interest for the history of science when his next major anniversary comes around. □

R. W. Burkhardt is Associate Professor of History at the University of Illinois, Urbana, and author of The Spirit of System: Lamarck and Evolutionary Biology.

Reviews of bonding

S. R. Elliott

Electrons and Transitions. Vol. 39 of *Structure and Bonding.* Series editors J. D. Dunitz, J. B. Goodenough, P. Hemmerich *et al.* Pp.120. (Springer: Heidelberg and New York, 1980.) DM64,$35.90.

VARIOUS themes are common to the different branches of chemistry; one such, underlying inorganic and physical chemistry in particular, is bonding and its concomitant structure. This is the title of a continuing series published by Springer, each book comprising a collection of articles. The latest addition is Vol. 39, subtitled *Electrons and Transitions.*

This volume contains three articles. The first, by D. W. Clack and K. D. Warren, is entitled "Metal–Ligand Bonding in 3d Sandwich Complexes". The review concentrates on the bonding between the metal and the ligand rings for various series of first-row transition metal sandwich complexes containing from three- to eight-membered carbocyclic rings. Experimental data from electronic spectra, ESR and photo-electron spectroscopy are compared with the predictions obtained principally from the authors' INDO SCF molecular-orbital calculations. The article runs to 41 pages and 80 references are included.

The second article, "Ligand Polarization Model for the Spectra of Metal Complexes: The Dynamic Coupling Transition Probabilities", is by S. F. Mason. Crystal field theory, the principal independent-systems model in which metal–ligand overlap is neglected, has been extremely successful in accounting for the character of the structure and bonding of metal complexes. Nevertheless, its shortcomings are not confined to neglect of metal–ligand electron exchange. In a first-order independent-systems treatment, either the ligands perturb the metal ion (crystal field theory) or, in the other extreme, the metal ion perturbs the ligands (ligand polarization model). This article, of 39 pages and 82 references, considers applications of the latter approach to oscillator strengths of lanthanide and transition metal complexes, rotational strengths of chiral coordination compounds and the Faraday effect terms of achiral complexes.

The final article, by L. R. Balsenc, is "Sulfur Interaction with Metallic Surfaces and Interfaces studied by Auger Electron Spectroscopy (AES)". This sets out to review the contribution of AES to the studies of the behaviour of sulphur on and with metallic surfaces including, amongst others, gas adsorption and desorption kinetics, surface and grain boundary segregation, corrosion, passivation and catalyst poisoning. This technique has several advantages; it is very surface-sensitive and adsorption-site positions can be deduced from the angular-dependent Auger emission from single crystal substrates, and the method's high speed of data acquisition is of great use in kinetic studies. In contrast to another commonly used technique, X-ray photo-emission spectroscopy (XPS), AES is some 20 times more sensitive for sulphur detection, although XPS is far superior in the elucidation of the chemical state of the atoms by means of the 'chemical shift' since the shift is very small compared with the Auger peak width and hence easily obscured. The review is short, only 32 pages, but contains an extensive bibliography, and will be of interest in both the academic and industrial spheres.

In summary, this is a well presented book with only one niggling detail, the use of the American spelling, sulfur, although all other usage is English; the book's appeal should lie primarily with researchers in those fields represented by the articles included. □

Floras finished and in progress

Peter D. Moore

Flora Europaea, Vol.5. Edited by T. G. Tutin, B. H. Heywood, N. A. Burges *et al.* Pp. 452. (Cambridge University Press: Cambridge, UK, and New York, 1980.) £37.50, $85. *Flora Palaestina,* Part 3. Text pp. 481, plates 757. By N. Feinbrun-Dothan. (Israel Academy of Sciences and Humanities: Jerusalem, 1979.) IL500, $55.

"THE publication of this final volume of *Flora Europaea* represents a landmark in European floristics". So begins the preface to Vol. 5, and one can detect a flavour of relief coupled with the justifiable pride of this statement. The concept of a European flora was formed some 26 years ago and it was then hoped that it could be completed within 12 years; but the gestation period of this *magnum opus* proved far longer than was anticipated. This must make the final parturition a yet more satisfying occasion for the editorial committee.

The final volume is dedicated to the monocotyledons and it follows the same style adopted in previous volumes. The British botanist will find few surprises in the arrangement and nomenclature; we are already accustomed to such transmutations as *Endymion* to *Hyacinthoides* and we could have predicted movements within the genus of marsh orchids, *Datylorhiza. D. purpurella* and *D. praetermissa* are now regarded as subspecies of *D. majalis.* The subspecies *ericetorum* of *maculata* is absorbed into ssp. *maculata.*

These, however, are trivia. The importance of this work is the establishment of an authoritative description and definition of the flora of the whole of Europe. It is the first such account ever published and it is unlikely to be surpassed in our generation. The editors are to be admired for having devoted a large portion of their working lives to the project, and Cambridge University Press are to be congratulated on undertaking such a gargantuan publishing task and for the high standards of production. The complete set of five volumes now costs in excess of £150, but this is a wise investment for any serious botanist, amateur or professional, who wishes to be fully informed about the wealth of Europe's flora.

The development of the *Flora Europaea* project has not been an isolated process. Floras covering adjacent regions of south-west Asia are proceeding apace. Within the Soviet Union, *Flora Europaea* covers the entire area west of the Ural Mountains, to 60°E, and on the southern side of the Black Sea P.H. Davis' work *Flora of Turkey and* *the East Aegean Islands* is continuing to develop. Publication of this series of volumes from the University of Edinburgh Press began in 1965 and still proceeds. Similarly, to the south of the Caspian, K. H. Rechinger, based in Vienna, continues to work upon *Flora Iranica*, which commenced publication in the early 1960s.

A further, well advanced project is *Flora Palaestina* which is being published by the Israel Academy of Sciences and Humanities, Jerusalem. The recently published third part of this series covers the Ericaceae to Compositae, and the geographical range of the Flora encompasses Israel and the west and east banks of the Jordan rift valley, south to Elat and Aqaba. There are keys to genera and species of Palestinian plants plus detailed descriptions of each species. These descriptions include notes concerning the ecology and habitats of the plants, as well as their geographical range within the study area and their full world range. These are useful notes which are not generally found in *Flora Europaea* because of pressure on space.

Each part of *Flora Palaestina* is accompanied by a volume of plant drawings which are of very high artistic quality and botanical accuracy. Five artists have been employed in this task, but a commendable uniformity of style has been maintained. Since a fair proportion of the plants illustrated are widely distributed in the eastern Mediterranean, these drawings will prove useful and interesting to European botanists as well as to the Israelis. Which leads one to the question whether a similar set of illustrations could be prepared to accompany *Flora Europaea?* Herculean, perhaps, but nevertheless a profitable exercise. □

Peter D. Moore is Senior Lecturer in Plant Sciences at King's College, University of London, UK.

Pore structure and flow modelling

D. J. Gunn

Porous Media. By F. A. L. Dullien. Pp. 396. (Academic: New York and London, 1980.) $42, £23.60.

IN THE preface Professor Dullien gives the primary purpose of this book as "presenting in an organised manner the most pertinent information available on the role of pore structure and then putting it to use in the interpretation of experimental data and the results of model calculations". In pursuit of these aims the, book is divided into two principal parts, the first of which is devoted to the description of pore structure, the second to flow properties of porous media.

Work on pore structure is described in two 70-page chapters. In Chapter 2, "On Capillarity in Porous Media", the description of capillary pressure measurements in porous media is followed by a description of pore network models of capillary tubes and capillary pressure functions generated by network models. In Chapter 3 porosity and permeability are defined, the measurement of pore size and pore size distribution is considered, and the measurements of pore size distribution are described for a range of materials. Single-phase flow in porous media is considered in Chapter 4 and includes a survey of some of the available correlations between flow and pressure gradient, statistical permeability models and network models, with sections on gas flow and diffusion, and non-Newtonian flow. The description of multiphase flow of immiscible fluids, Chapter 6, is mainly directed to the flow of oil and water through both consolidated porous solids and unconsolidated solids, while the last major part of the book is Chapter 7 on miscible displacement and dispersion.

The emphasis of the book is on fundamental studies of interest in petroleum recovery and production, although topics such as the formation, flow and dispersion of micro-emulsions that are of interest in secondary recovery are not considered in detail. The book would have been more helpful if the description of models for flow and dispersion in porous media was more critical. The most important criteria for the success of a model description are that the model should be well founded, and that it should describe experimental phenomena without invoking significant further measurements to define the parameters of the model when applied to a particular situation. Some of the model descriptions of dispersion in porous media, although considered in some detail in the book, have not been shown to relate to experimental measurements of dispersion, while the use of a bivariate pore size distribution to estimate permeability requires more experimental work than a direct measurement!

However, for those who have already been introduced to the study, the publication of a research monograph on flow in porous media is timely because of the economic importance of techniques for secondary oil recovery. Further, it is very useful to have this comprehensive survey available as an aid in process development and in the mathematical modelling of field flows. □

D. J. Gunn is Reader in Chemical Engineering at the University College of Swansea, UK.

Macromolecules in 3D

Colin Blake

Teaching Aids for Macromolecular Structure. Compiled by Richard J. Feldmann and David H. Bing. Instructor manual pp.114 with 116 stereoslides; student kit 49 stereoslides with viewers. (Taylor-Merchant: New York, 1980.) Instructor kit $210, student kit $15.

THE APPLICATION of the X-ray diffraction technique to crystalline and paracrystalline biological materials has produced a solid body of information on the structure and function of many biological macromolecules. After an initial period of scepticism concerning the significance of the results, this material has now become reasonably well integrated into the broad field of biochemistry, and is now routinely taught at the undergraduate level, not only to biochemists, but also to those in other more biological or physical sciences. Teaching this material is however fraught with problems, most of which derive from the sheer complexity of biological macromolecules. Although the repetitive structures of DNA, the α-helix, β-sheet and even the collagen helix are fairly easy to visualize, the molecules of t-RNA, supercoiled DNA and most proteins and enzymes are much more difficult to illustrate. To overcome these difficulties a variety of short cuts are no doubt taken; the most extreme is to ignore all of an enzyme except its catalytic site, which at best does less than justice to enzymes and at worst gives a completely distorted view of the *raison d'être* of the subject, the attempt to understand the characteristic integration of structure and function exhibited by biological macromolecules. To say this does not necessarily imply criticism of the people who use the short cuts; it probably has much more to do with the sheer difficulty of producing teaching material that shows the extent of the structure – function integration. Even with a complete set of plastic and wire models, and mono and stereo slides there are problems: models are either too small or too complex to point out particular features to a class of students, and slides, even those in stereo, have of necessity to be simplified and cannot show all the features of a complete molecule. And, of course, many departments are not comprehensively equipped in this way.

With these problems as an overt background, a new aid for teaching macromolecular structure has just become available. Called TAMS, an acronym for Teaching Aids for Macromolecular Structure, it has been compiled by Richard Feldmann of NIH and David Bing of The Harvard Medical School. TAMS consists of a large ring-back folder containing a students' text, a teachers' text and a collection of 116 2″ x 2″ colour stereo slide pairs. A selection of the slides has been included on seven large cards which together with a simple but ingenious stereo viewer are packaged in a small plastic wallet for use by individual students. Although a small stereo viewer is included in the TAMS folder the stereo slides are intended for projection to the class using two normal slide-projectors (a stereo projector may not be suitable), an aluminized screen and polarized viewing glasses. Details of the simple modifications needed to be made to the projectors and an address where the screen and glasses can be obtained are included.

The text of TAMS is essentially a straightforward description of the contents of each slide, and need not be considered further. The slides are the heart of the system and it is on their technical quality and illustrative suitability that TAMS must be considered. One must say at once that the technical quality of the slides is quite superb. The vast majority of them are computer-drawn, coloured and shaded views of space-filling models of nucleic acids, proteins and their ligand complexes, that paradoxically do not, and at the level of accuracy shown, could not exist. Nevertheless the illusion of looking at three-dimensional, coloured space-filling models of a variety of biological macromolecules is totally convincing and one that students will readily accept, certainly with enjoyment and one hopes also with understanding and insight. Technically these slides are so good that one feels rather churlish in making criticisms: but there are two aspects on which I feel some dissatisfaction. First, although the muted colours are very agreeable to look at there are some difficulties in distinguishing the colours that are described as "light charcoal" and "pale blue" but which appear as very similar shades of light blue-grey. Also, the bluish shading of white spheres and the white highlights on pale blue or even pink spheres can lead to confusion. Secondly, and more importantly, the very success of the space-filling illusion appears to have seduced the compilers into using them almost exclusively, when many more line drawings would have been very valuable in providing aids to identifying particular features in the often complex space-filling picture.

Having established the technical excellence of the slides, one now has to consider how well they illustrate the seven "themes" of TAMS: Peptide Bond, Alpha Helix, Beta Sheet, Tertiary Structure, Quaternary Structure, Prosthetic Groups and Active Sites. Here I must confess to active disappointment, particularly in the case of the student cards, with both the overall organization of the material and the way in which it is illustrated in individual slides. The first student card on the Peptide Bond gets off to a very bad start. Four of its seven views illustrate a molecule called Synthetic Di-Alanine, with no more explicit description in either student or teacher text, but which is not the expected alanylalanine but an acetyl derivative whose additional methyl group perversely complicates the intended illustration of the spatial relationship of the methyl side chains and the peptide group. The final slide on this card shows a proline residue almost edge-on in the myoglobin molecule which thankfully illustrates rather ineffectually the text's repetition of that old misconception that prolines cannot be accommodated in helices. Why it was decided not to use this card to illustrate the Ramachandran dipeptide analysis, or why the card on Tertiary Structure does not consider the Levitt and Chothia classification of protein structure is not explained in the text, but what is shown in no way replaces these important insights into the principles of protein structure. The card on Active Sites brings out another problem — that of identifying particular residues in a complex, space-filling picture. Because no visual guide is given it is really very difficult, even when one knows what one is looking for, to identify the serine and histidine in the active sites of the serine proteinases. I can see many students giving up slides like this, and there are quite a number of them, simply because of the difficulties of identification. In contrast the other kind of slides in which specific features are picked out in particular colours can be immediately comprehended and represent the proper use of the system. One has to conclude that the primary requirement of teaching material, that it should be closely organized and absolutely clearly illustrated, has not been consistently borne in mind when TAMS was being planned. Finally, the choice of material in the cards and in the main body of the slides is not as comprehensive as it might be: there are no examples of fibrous proteins or carbohydrates, no illustrations of viruses apart from two slides of the filamentous type, there is insufficient consideration of intracellular proteins and too much emphasis on certain small proteins, most notably parvalbumin and cytochrome *c*. Of course one is aware that the authors are dependent on information being made available from recent research, which may account in part for the restricted choice of material, but certainly not all.

I have no wish to overemphasize the deficiencies in the choice and display of the material in TAMS. There are many slides which are both a joy to look at and which illustrate important aspects of protein and nucleic acid structure that could scarcely be demonstrated in any other way. The small set of views of nucleic acid structures is particularly striking, and especially that of supercoiled DNA, while in the enzyme collection the visualization of the deep cavities in which the active sites of carbonic anhydrase and carboxypeptidase are located is most successfully carried off. Once seen, many teachers will see slides of this kind as essential and irreplaceable visual aids to their courses in macromolecular structure. For this reason TAMS must be welcomed and Feldmann and Bing commended for overcoming the considerable technical and commercial difficulties they undoubtedly faced in making these slides generally available. Nevertheless a slight sense of disappointment of an opportunity missed persists. In the second edition of TAMS, one would ask the compilers to ignore McLuhan's notorious motto "The medium is the message" which they use to preface the text, and suggest that they keep the medium but think about improving the message. □

Colin Blake is in the Laboratory of Molecular Biophysics at the University of Oxford, UK.

Polymer science and scaling

M.A. Moore

Scaling Concepts in Polymer Physics. By Pierre-Gilles de Gennes. Pp.320. (Cornell University Press: Ithaca, New York, and London, 1979.) $38.50, £23.

OUR KNOWLEDGE of the physics of long, flexible polymer chains has been greatly extended in recent years by important developments in both experimental and theoretical techniques. On the experimental side the advent of high-flux neutron beams has made it possible to observe a labelled chain in a sea of chemically identical but unlabelled chains. This is done by replacing some of the protons of a polymer by deuterons which scatter neutrons more intensely than protons. Extensive data on long-range conformations and correlations have now become available. A traditional tool for studying polymers in solution has been that of light scattering, which has been improved almost beyond recognition by the development of the 'photon beat' method which now allows study of the dynamics of polymer chains in the frequency range 1^6–10^6 cycles.

Alongside this development in experimental technique there has been a sharpening in our theoretical understanding brought about by the discovery of the close connection between polymer statistics and phase transitions. This discovery has enabled concepts useful in the study of critical phenomena such as scaling and critical exponents to be transferred to the field of polymer science. De Gennes has been the foremost worker in this area and his book is essentially a collection of the results which he and his co-workers have obtained by the application of scaling ideas. These results have been largely confirmed by the new experimental methods and the general agreement between theory and experiment is most impressive. However, the scaling method only gives an understanding of 'universal' properties such as, for example, the molecular weight dependence of the dimensions of a flexible polymer molecule in solution. Numerical prefactors, which are specific to a given monomer, are not predicted by this approach.

In the book the scaling concept is applied to a great variety of topics. Polymers in dilute and semi-dilute solution, theta solvents and good solvents, gels, melts and the dynamics of single chains and networks are just some of the problems successfully treated. It is not easy to apply scaling ideas and much physical insight is needed to get correct results. De Gennes has such insight and he is also adept at explaining his reasoning. Further work is now needed to derive scaling results in a more systematic way, and in the last chapter de Gennes outlines the renormalization group which probably provides the best way of putting the scaling approach on a firmer theoretical foundation.

The book is written mainly for experimentalists in polymer sciences who wish to incorporate the recent theoretical advances into their mode of thinking and for polymer theorists who want to achieve a qualitative understanding of the scaling method. It is an excellent work and no worker in the field can afford to be without a copy. ☐

M.A. Moore is Professor of Theoretical Physics in the University of Manchester, UK.

Applied bifurcation theory

Michael Berry

Bifurcation Theory and Applications in Scientific Disciplines. Edited by O. Gurel and O.E. Rössler. Pp.708. (New York Academy of Sciences: New York, 1979.) $85.

THIS IS a collection of over 50 papers presented at a conference held in New York in 1977. Bifurcation is sudden qualitative change in the solutions of an equation or system of equations, produced by the smooth variation of one or more parameters. As might be expected on the basis of such a general definition the papers cover a vast range of subjects, well indicated by the titles of sections into which the book is divided: mathematics, biology, chemistry and chemical engineering, physics, ecology, economics, engineering, and experimentation and simulation. What all these subjects have in common is that they involve nonlinear equations, and the reason for the emergence of bifurcation theory as a separate discipline is that for some classes of nonlinear equations the bifurcation behaviour is beginning to be well understood.

In the simplest case of all, dynamics is ignored (i.e. the system's state is considered to change very rapidly) and bifurcation theory reduces to the classification of equilibria, accomplished by Thom's theory of catastrophes. In several papers here a refined version is applied to analyse the types of buckling that occur in elastic structures under increasing load in the presence of imperfection (of design or manufacture) described by several parameters.

When dynamics is taken into account, the variety of possible bifurcations is much greater, but the following sequence of events is quite common: as a parameter P increases, a stable equilibrium bifurcates into a stable closed orbit (Hopf bifurcation), which in turn bifurcates into one of twice the length, and so on, in a cascade of successive 'subharmonic bifurcations' accumulating at a finite value of P, beyond which the motion is aperiodic and chaotic. Such behaviour occurs, for example, in the ecological equations for the numbers of individuals in successive generations of a population reproducing in an environment with finite resources, or in the physiological control equations governing respiratory and haematological disorders, or in preturbulent fluid regimes with different Reynolds' numbers. In several papers the mathematical models give a very good description of experimental results, but when structurally stable behaviour is expected (and found) in a wide variety of contexts, it is important to be quite precise about what theory is being tested.

The general standard of exposition is high, but I cannot resist quoting one example of intolerable jargon:

> The bootstrap principle of adaptability theory is: The assumption of the hierarchical and compartmental structurability of the state description of biological systems is self-justifying within the framework of adaptability theory in the sense that such structurability is a necessary condition for efficient adaptability.

I strongly recommend this book to anybody wanting an introduction to this fertile new field of applied mathematics. ☐

Michael Berry is Professor of Physics at the University of Bristol, UK.

Source book on cadmium

M.H. Martin

The Chemistry, Biochemistry and Biology of Cadmium. Edited by M. Webb. Pp.476. (Elsevier/North-Holland: Amsterdam and New York, 1980.) Dfl. 165, $80.50.

THIS book is the second volume in a series on topics in environmental health, and consists of 11 chapters by different authors.

Most of the contributions are concerned with mammals including human beings, and indeed the editor states that the book attempts to integrate the toxicological aspects of cadmium in animals (*sensu* mammals) and human beings with the chemistry and biochemistry of the cadmium ion. The singling out of soils, plants and aquatic organisms as other environmental components to be considered serves to highlight the absence of contributions on air, terrestrial invertebrates and non-mammalian terrestrial vertebrates. In addition the preponderance of discussion on metallothioneins (cadmium, zinc, copper and mercury), some three chapters amounting to 22% of the book and also mentioned in the aquatic context, further unbalances the presentation.

In his remarkably brief preface, scarcely half a page, the editor states that he expects that the individual chapters of the book will be read as complete entities. To this end the various articles provide useful reviews on specific topics by authoritative contributors. The various chapters are relatively up to date, most including references to some 1979 literature, although some appear to have been completed before others. In fairness to the individual authors space could have been found in the preface to mention dates of completion of the reviews.

The presentation is relatively lavish and is consistent with the Elsevier/North Holland Biomedical Press standards, with matching price. Like many books of this multi-author type, its main use is likely to be as a source book of specific aspects of cadmium biochemistry rather than as a comprehensive treatment of the environmental biology, toxicology and biochemistry of cadmium. ☐

M.H. Martin is Senior Lecturer in Botany at the University of Bristol, UK.

Blackwell Scientific

In their advertisement (p.xxi) in the 12th June issue of *Nature*, titles and authors of two books were transposed. *Introduction to Modern Virology*, 2nd edn, is by S.B. Primrose and N.J. Dimmock; *Pharmaceutical Microbiology*, 2nd edn, is by W.B. Hugo and A.D. Russell.

nature

17 July 1980

What to do about new herbicides

THE British government has made a muddle for itself over the herbicide 2,4,5-T, rightly held by farmers to be one of the best ways of ridding fields of nettles, thistles and other weeds. Since the middle of the Vietnam War, it has been known that commercial preparations of the material are potentially dangerous because of the small quantities of dioxin which they contain. The Seveso accident dramatized the potential danger of the contaminant. Since then, the British government (like many others) has taken steps to limit the concentrations of dioxin permitted in manufactured lots of the herbicide, but by doing so has appeared merely to excite the morbid interest of trades unions and their members. In recent weeks, unions with as little naturally in common as the National Union of Agricultural and Allied Workers (NUAAW) and the Association of Scientific and Managerial Staffs (ASTMS) have taken up cudgels against this apparently beneficent chemical (*Nature*, 10 July), asking that its use should be stopped. The government's capacity to make a rational response, or even to decide what to do, has been entirely undermined by the belated and shamefaced confession by the Minister of Agriculture on 20 June that his department has misled not merely itself but other bodies to which it has proffered reassuring advice by its mistaken estimate of the amounts of 2,4,5-T used in Britain.

The toxicology of the dioxin and of 2,4,5-T are by no means precisely catalogued, but some of the bare bones of the story are simple. Dioxin, an exceedingly stable chemical, causes chloracne in largeish doses but is also teratogenic and is known also to be carcinogenic. So much is clear from laboratory studies but also, unhappily, from accidents in which human beings have been put at risk. Laboratory studies have also shown that 2,4,5-T itself may be a teratogen. Whether it is also carcinogenic at doses which are not also acutely toxic remains an open question. But it is beyond doubt that dioxin is a much more potent teratogen than the pure herbicide. Such laboratory evidence as exists is unfortunately incomplete. The Advisory Committee on Pesticides (PAC) of the Ministry of Agriculture, Fisheries and Food quoted in March 1979 data which suggest that mice and hamsters suffer teratological consequences only at doses which are also toxic. Doubt has however been cast on this conclusion, so that there are some who say that the effective teratological doses of the two materials are related by a factor of 10^{-4} or thereabouts. If this should be the case and because the permitted concentration of dioxin in otherwise pure chemical 2,4,5-T is one part in 100 million, the foetus of a pregnant woman eating commercial 2,4,5-T by the spoonful is more likely to be damaged by the principal ingredient than by the dioxin contaminant. The recognition of this possibility has come as a shock to many observers of the scene, and to the NUAAW in particular. It is of course ironical that the government, by taking steps to limit the damage that might be done by the contaminant in a commercial herbicide, should have served only to focus attention on the potential dangers of the herbicide itself.

None of this suggests that 2,4,5-T as used in Britain (or elsewhere that intensive agriculture is practised) should be considered an immediate danger. The total amount of the active ingredient used in Britain appears (whereby hangs a tale) to be of the order of 100 tonnes a year, something of the order of 100 grams a year for each of, say, a million agricultural workers. The current recommendation of the Food and Agriculture Organization and the World Health Organization is that 24 milligrams per day entails no risk of teratogenic damage. Even if British agricultural workers perversely chose not to spray all the herbicide on nettles but, rather, ate it or fed it to their pregnant wives, a substantial fraction of the total quantity now used would have to be diverted in this way before widespread damage was caused. Because most of the herbicide used does actually end on nettles and not in people's cups of tea, because 2,4,5-T is distinguished from dioxin by its relative instability and because the indirect consequences of the use of the material are likely as a consequence to be small, it is hard to think that harvested food can be seriously contaminated.

So why is there so much fuss? The most serious issue is that questions have been raised about the basis for the recommendations of PAC about the safe levels of 2,4,5-T. The question is by no means an easy one to settle. Such data as are to be found in the literature are not part of systematic and controlled studies, while many of them derive from the early 1970s when the need to distinguish between the effects of dioxin and 2,4,5-T was not fully appreciated (and the technical capacity to distinguish between them analytically was only meagre). Yet there is some reason to suspect that the recommendations of PAC are not as solid as they might have been. This, no doubt, is one of the issues that the several government committees concerned, PAC itself but also the committees of the Health and Safety Executive (HSE), will be trying to resolve before the summer is out. Nobody should be surprised if it turns out that the available data are insufficient for an informed conclusion to be possible.

Whatever the outcome, it is inevitable that the mere shadow of doubt cast on the recommendations of PAC will call into question the constitution of that body, which is one of those vaguely defined entities of which British bureaucracy is proud to boast. The committee is for practical purposes responsible for licensing the uses made of pesticides. Its positive recommendations have the force of legal licences. Negative recommendations are the equivalent of bans. To outsiders, the great anomaly in the constitution of PAC is that manufacturers are not required by law to submit new pesticides, or new formulations of old pesticides, to the committee. Compliance has always been, and remains, voluntary. Even so, to the surprise of many people, the system has worked well and imaginatively — the regulation of the organochlorine pesticides has, for example, been sensible. Equally surprising, there is no evidence that manufacturers deliberately keep new products from the eyes of the committee — the fear that there would in that case be a statutory scheme is enough to keep them all on the straight and narrow path. Such loopholes in the British arrangements for the regulations as there are centre on the import of materials manufactured overseas but not recommended by PAC, but again there is no evidence that this is substantially abused. The danger now, for the Advisory Committee on Pesticides, is that if it should turn out that it has erred on the side of what may seem to be complacency in such an important (or at least controversial) matter as 2,4,5-T, the pressures for converting from a voluntary to a statutory scheme will be almost irresistible. That would mean, for all concerned, more bumbledom.

The second issue that will keep the civil servants busy through the summer is that the Ministry of Agriculture has grossly underestimated the quantity of 2,4,5-T being used in Britain. For the past two years, the ministry has been saying that the quantity was something like three tonnes a year, largely on the basis of a survey by major users, the Forestry Commission in particular. Quite inexplicably the ministry, proud as it is of its connections

0028-0836/80/290193-02$01.00

with farmers through the Agricultural Advisory Service, failed to appreciate that the chief use of 2,4,5-T is for spraying crops and grassland to get rid of weeds. But even the revised estimate of 50 tonnes a year has had to be doubled to more than 100 tonnes in the light of figures supplied by Customs and Excise of the quantities of the herbicide imported. The broader issue here is that the ministry has for several years resisted complaints that its surveys of the use of pesticides on British farms are adequate.

What, while these questions are being resolved, are the unions (and their members) to do and think? By all accounts, PAC will make a detailed investigation of the specific allegations of damage done to people that have been mentioned by the agricultural workers, but that cannot be a quick job. What the union must do is what it should have been doing all along — to make sure that workers spraying pesticides wear adequate protective clothing. Mr Clive Jenkins of ASTMS is frying other fish. To his usual preoccupation with the recruitment of members, he appears to have added a wish to back the Health and Safety Executive rather than the Ministry of Agriculture as the arbiter of what pesticides are safe. His inclinations are understandable, for union representation on HSE is laid down by law. In reality, however, both executive and ministry have a finger in the protection of agricultural workers, while HSE is solely responsible for the occupational risks of chemical plants where 2,4,5-T may be manufactured. Even Mr Jenkins is on solid ground when he argues that the executive has dealt ineptly with recent problems. Whatever the strength of these complaints, however, it would be a great misfortune if the use of a herbicide whose value is unquestioned were to be needlessly and prematurely banned simply because the government has made a hash of this affair.

Nato, France and the neutron bomb

WHILE many parts of France enjoy the spectacle of protests against the building of civil nuclear power stations, there has been hardly a complaint at the French government's announcement that one of its recent nuclear tests was that of a neutron bomb. Just possibly the explanation is that French taxpayers accept the theory of strategic deterrence hook, line and sinker, and are persuaded that French neutron bombs are intended never to be used but that the civil nuclear power stations being built in France are meant to be used, and quickly. It is, however, more probable that the silence which has greeted the announcement of the neutron bomb betokens a general agreement by the French population with the national strategy which has been working out since the mid-1950s. Whatever the explanation of the domestic reaction, opinions appear to have been much changed by the new development. The *Suddeutcher Zeitung* was saying last week, for example, that the neutron bomb means that France is no longer a token nuclear power. What does it all mean?

For the best part of a quarter of a century, France has been the odd man out in European defence. The roots of the present policy appear to go back to Gaullist days, and to the theory advocated by General Jean Gallois that each nation should possess a nuclear striking force somehow commensurate with its own importance to a potential adversary. In reality, they probably have more ancient origins. It is too easily forgotten that the French have long memories, as long perhaps as those of the Irish. The French experience of two world wars is a sufficient justification of the conviction that nation states should in the last resort be masters of the means of their own defence. The painful withdrawal of France from NATO was as much a reflection of this belief as of overt distrust of the assurances in the NATO treaty or of disagreement with NATO strategy. Only this can properly explain how, even with the passage of two decades, France remains on the sidelines, now consulting closely with NATO and behaving as if a full-blown member, but stolidly opposed to rejoining the club.

From this point of view, the development of the neutron bomb is logical enough. So long as France holds to the view that the time may come when the defence of France by Frenchmen (without help from elsewhere) may be necessary, it plainly makes sense that France should be equipped with those nuclear weapons which, at least in theory, could be used tactically in European circumstances without inviting massive retaliation from the other side. Whether, of course, the financial cost of this new investment is worthwhile, only the government of France can judge. Apparently, however, the taxpayers most immediately concerned have no objection. Two years or so from now, which is the soonest the new weapons could be deployed, France may thus be the only nuclear power to risk deploying these new weapons in a theatre where their use makes sense.

The consequences for states on both sides of the German border are not easy to foresee. The most comforting calculation is that France will equip itself with only a modest force of neutron bombs, one so modest that it could have no decisive influence in a major European conflict. Certainly there has been no protest yet from the East at what the French are planning that compares with the trouble evoked when the United States announced its intention to deploy neutron weapons in Europe more than a year ago. Perhaps the President of France was able to stave off trouble when he met Mr Brezhnev in Warsaw last month, or perhaps the protest is yet to come. Whatever the future, however, it seems inevitable that the latest developments in France will change the regard of other European states for the non-NATO member among them. But this time, unlike the early 1960s, France will tend to be regarded not as the black sheep of Europe but as a symbol of the implicit belief now strengthening in Europe that European responsibility for its own defence is not merely prudent but necessary. The Gallois doctrine, after a long hiatus, is catching on.

So is there a chance that in the years ahead Western Europe as a whole will accept that it must, in the last resort, be responsible for its own defence? And what will be the consequences? The tendencies in this direction which have become apparent in the past few years differ markedly from those which carried France out of NATO twenty years ago. There are few in Western Europe who now doubt the commitment of the United States to European defence. Their anxiety, rather, is that this commitment has been one of the few reliable components of a foreign policy which has as often mystified as reassured. Escapades such as the abortive attempt to rescue the American hostages in Iran are worrying for Europeans not so much because of the direct risk of a conflagration, limited though it might well have been, but because they cast doubt on the machinery for consultation within NATO and on the process of policy formation in Washington. These doubts will not go away when the American election has been decided. There are also, however, other forces tending to strengthen European hankerings after a European defence policy. It becomes increasingly anomalous that the European Community has only the most slender means for formulating policy towards the rest of the world — the brief declarations tagged on to communiques such as that issued from Venice a few weeks ago are no substitute for a foreign policy. Moreover, it becomes ever more apparent that Western Europe is evolving its own sense of priorities as to how relationships with the East should be conducted. Chancellor Schmidt's visit to Moscow, sceptically regarded at the outset by the United States, has nevertheless opened the possibility of constructive discussions about medium-range missiles in Europe that could, if by some remote chance they succeeded, be a great boon to the industrialized West and East alike. On the face of things, the French neutron bomb (not yet a weapon) is a gesture of national independence, but it will curiously also help to strengthen Western Europe's growing tendency towards coherence and indendence.

Congress supports technology centres

Washington

Plans are now being advanced to implement one of the key proposals made by the Carter Administration last year to help stimulate technological innovation — the setting up of a number of "generic technology" centres. The proposal has so far escaped budget cuts in Congress.

The purpose of each "generic technology" centre would be to carry out research and development in a particular area of technology underlying a range of industrial needs, rather than being related to any specific product. Typical examples given include welding, tribology, the study of new composite materials and the general area of automated manufacturing.

Officials at the Department of Commerce are now putting together detailed proposals from industry to establish three or four such centres. The hope is that, if Congress can be persuaded to allocate the $5 million requested for the programme, initial work on the centres would be under way by the beginning of the next fiscal year on 1 October.

The idea behind the centres is that the government should provide seed money to stimulate research of a type which no individual company may be prepared to support, but which is likely to benefit groups of companies or whole industries. Each centre would be jointly funded by industry, initially with the government picking up most of the bill, but with government support dropping to 20 per cent or less after five years.

Each centre, according to details published by the department last month, will have responsibilities in three main areas: first, to maintain a substantial in-house research and development effort; second, to provide a range of technical services, including consultants, information, training facilities and technology evaluation; and, finally strategic planning of technology development.

The idea has already found many sympathetic ears in the US Congress. The Senate, for example, recently passed an innovation bill, originally proposed by Senator Adlai Stevenson, Jr, chairman of the Science and Space Subcommittee, aimed specifically at encouraging research links between industry and universities by setting up a number of "centres for industrial technology". The Senate bill has already been accepted in principle by the Science and Technology Committee of the House of Representatives.

The private sector is also keen. Technology centres were one of the chief recommendations of the Research and Development Advisory Panel to last year's domestic policy review of innovation. The committee recommended that direct federal support of new technology generic to process or product innovation in wide spectra of industries "should be strengthened and recognized as federal policy". Its chairman, Dr Jack Goldman of the Xerox Corporation, remains enthusiastic about the Stevenson bill.

Some controversy remains, however. For example, should the universities be research contractors for groups of companies setting up a particular generic technology centre, as the Department of Commerce seems to recommending? Or should universities be given a more prominent role from the start as the point of contact between government and industry?

The second strategy has been advocated by the National Science Foundation, which has set up a number of university-based co-operative research centres under a programme initiated in 1973. The most successful of these has been the Polymer Research Center at the Massachusetts Institute of Technology, now self-financing from industry sources with an annual budget of $600,000.

NSF's own plans for expanded efforts in this direction had to be trimmed by $2 million when the Administration revised its budget request to Congress in April. But NSF officials are convinced that their approach, using universities as "surrogates" for federal contact with industry, has several advantages over what one refers to as the Commerce Department's "pie in the sky" efforts to forge ambitious links between government and industry virtually from scratch.

David Dickson

Carnesale for NRC chairman

Washington

Dr Albert Carnesale, professor of public policy at Harvard University and deputy director of the Center for Science and International Affairs there, was nominated last week by President Carter for the newly-upgraded chairmanship of the Nuclear Regulatory Commission (NRC). Dr Carnesale is a nuclear engineer by training, with experience of both arms limitation and non-proliferation negotiations. This, together with his reputation as a "moderate" on nuclear issues, has led both anti-nuclear and pro-nuclear groups to greet his appointment with a cautious welcome.

Carnesale's involvement in nuclear energy debates, for example as a participant in the Ford-Mitre study of 1976 and as head of the technical coordinating committee for the US delegation to the International Nuclear Fuel Cycle Evaluation (INFCE), nevertheless suggests that his views are closely aligned with the Administration's position on sensitive issues such as nuclear reprocessing and non-proliferation policy.

Dr Carnesale received a master's degree in engineering at the Drexel Institute in Philadelphia, and subsequently a PhD at North Carolina State University. After five years working as a nuclear engineer with the defence contractors Marietta Martin, he joined the Arms Control and Disarmament Agency, and was a senior adviser to the US delegation which negotiated the first Strategic Arms Limitation Treaty (Salt I) in 1972.

He returned to North Carolina State University as head of the division of environmental studies in 1972, subsequently moving to Harvard in 1974, where he now teaches a class at the Kennedy School on "Technology, War and Peace", while remaining a government adviser on various defence and nuclear issues.

Dr Carnesale refuses to be drawn on specific ideas about the current problems of the NRC, which has been under considerable strain following its handling of the Three Mile Island accident and its aftermath last year. But he said last week that he considers the safety of existing reactors to be "the first item of business for anyone".

On the reprocessing of spent fuel, whose deferral by President Carter is now under renewed attack in Congress, Dr Carnesale points out his agreement with the conclusion of the Ford-Mitre study (subsequently accepted by INFCE) that at present there is no economic case for recycling fuel from thermal reactors.

He considers the INFCE exercise to have been a "success" in generating an international dialogue on nuclear fuel cycle issues, even though it failed to endorse many aspects of US policy. "It has to be judged in a far wider perspective than the reports themselves", he says. But he refuses to be drawn on whether the United States, as some of the more ardent congressional supporters of its non-proliferation policy had argued, should have taken a bolder stance in registering areas in which it disagreed with the final consensus.

Waiting for approval . . .

0028-0836/80/290195-02$01.00

This is one area where Dr Carnesale's views are likely to be closely examined by Congress when it considers his nomination. The NRC's refusal to grant an export licence for nuclear fuel to India has already prompted moves to circumscribe its responsibilities for reviewing exports as detailed by the Non-Proliferation Act signed in 1978. Legislators are soon to consider whether to veto President Carter's decision to overrule the NRC and grant the licences. But they will want to know how sympathetic Dr Carnesale is to the proposals of Mr Gerard Smith, head of the INFCE delegation, that some of the more stringent provisions of the NNPA be amended.

Dr Carnesale's appointment is said to have been actively canvassed within the White House by the Office of Science and Technology Policy, keen to defuse what has recently been called "the most politicized agency in town" — as well as to see strong leadership given to a body which, prior to the Three Mile Island accident, relied more heavily on collegial decision-making by its five commissioners.

David Dickson

Policy analysis

UK adventure?

Can pure reason throw light on the relationship between technical innovation and social change, assisting the first and softening the consequences of the second? This is the inspiration of the brave gamble launched last week in London by the Leverhulme Trust, the Science Research Council (SSRL). Between them, the three organizations plan to spend £2.55 million setting up an organization known as the Technical Change Centre. Sir Michael Swann, the retiring chairman of the BBC, will run the governing body of the new centre, but a director has yet to be found.

The centre is intended as an instrument of policy analysis; it will seek, in other words, to influence events. Its sphere of operations was last week defined more confidently by example than by precept — it may look into public perceptions of the hazards of nuclear power, opportunities in but also the social consequences of microelectronics and the question whether academic training at the postgraduate level is good or bad for British industry. The sponsors' interest in the gamble is best explained by Sir Michael Swann's plaintive question why Britain, the leader in technological innovation for two centuries, should have failed so dismally since the Second World War.

Swann is the boss

The centre has venerable antecedents. Four years ago, the SSRC flirted with the notion of setting up in Britain an equivalent of the Washington-based Brookings Institution, but failed to find charitable partners for that venture. The new venture is in part a survivor of that plan, but with the difference that the SRC is an equal partner with the SSRC, that the Leverhulme Trust will contribute 60 per cent of the cost of the first five years and that the terms of reference, still broad, have been made more narrow.

Last week, the sponsors of the centre were frank in their estimate of their success. Much will depend on the director they can recruit; they also confess that they may be beaten by the intractability of the problems they tackle. They plan to make a cool appraisal of their venture (which may get under way by the beginning of 1881) in about four years. If things are going well, they would hope to give it at least a second lease of life.

Precisely how the centre's work will evolve plainly awaits the appointment of a director. For Sir Michael Swann emphasized last week that its policy will evolve independently of the interests of the sponsors. He explained, however, that the SSRC has a special interest in policy analysis of this kind more or less as an end in itself, while the SRC has a more specific interest in receiving advice on how its own budget should be disposed.

The core of the governing body has already been recruited, and includes the chairmen of the two sponsoring research councils (Sir Geoffrey Allen and Mr Michael Posner), Dr Duncan Davies (Chief Scientist at the Department of Industry), Sir Alastair Pilkington (soon to retire as chairman of Pilkington Brothers, the glassmakers) and Mr Philip Hughes (chairman of Logica Limited, a software house). It is intended that the board, when complete, should include representatives of trades unions.

Sir Michael Swann says that the absence of the Agricultural and Medical Research Councils from the list of sponsors has no significance, but plainly the new centre will be looking to them as well as to other organizations for funds with which to carry out sponsored research; the funds so far available amount to just over £500,000 a year, but the centre would hope to recruit a further £200,000 a year of soft money. While most of its work will be carried out in-house, it will also support work at other centres in the United Kingdom, thus no doubt helping to ensure that it is not regarded too much as a threat by existing academic centres.

Teaching companies

Victims of success

The British Science Research Council and the Department of Industry are in difficulties about the financing of their joint teaching company scheme. Paradoxically, their problems have arisen because the scheme is proving more successful than originally foreseen.

When the teaching company scheme was set up five years ago, the aim was to secure the participation of about 20 companies by 1980. Interest has been such, however, that 33 companies are now involved and many more are hoping to join. The SRC and DoI agreed to fund the scheme on a fifty-fifty basis but the rapid expansion has meant that this year the DoI may not be able to pay its share. The total cost of the scheme has risen from £0.5 million in 1979 to an estimated £1.5 million this year, of which the DoI can contribute only £600,000.

The SRC is confident that it will be able to take up the slack in 1980; the real problems will arise in future years, especially if expansionary pressures persist. The SRC's contribution could probably increase to about £1 million a year, but other sources of finance would then have to be found. A panel of industrialists, civil servants and academics is to be set up at the end of this month, with a remit to make recommendations by the end of the year.

The objective of the teaching company scheme is to introduce industry to the skills universities have to offer and at the same time to provide recent graduates with industrial experience. Typically, a company agrees to take on three recent graduates, called associates, in each of the first two years of membership.

The SRC and DoI between them pay the associates' basic salaries, incidental expenses, cost of any special equipment they need and the cost of any replacement staff needed in universities. The company's major expense is usually that of implementing recommendations for improvements.

The pressures to expand the scheme come not only from companies wishing to join but also from those already in the scheme who say they have found it so useful that they are reluctant to leave. So far, only two companies have actually left the scheme. Because of the pressure on funds, the SRC is now beginning to talk to several companies about ways of terminating formal membership.

Both industry and universities seem to be enthusiastic about the scheme. Industry effectively gets a free consultancy service and is able to tap otherwise inaccessible resources. Universities have the opportunity to put some of their academic work into practice.

Technological forecasting

Rush programme

The European Commission's FAST project, a five-year programme in science and technology forecasting set up in 1979, is up to its eyes in applications for funds. Invitations to tender for part of the £1.35 million budget were sent out early this year; and by the deadline of 10 April some 224 applications had been received from 176 institutions. Research projects relating to Europe 10, 20 and 30 years ahead must be completed by mid-1982, although the 30-40 successful applicants will be officially notified only in September.

FAST's director, Ricardo Petrella, says this compression of the timetable is inevitable, given that the programme was funded for only five years by a decision of the Council of Research Ministers on 25 July 1978. The FAST team of six scientists and four assistants spent most of 1979 defining the nature of the programme. The research phase of the programme now beginning must end during 1982 and early 1983 with the specification of research and development priorities for Europe the ultimate object of the exercise.

For the participating universities and research institutes, there will be little time to come to grips with what are complex issues — "microelectronics innovations in the context of the international division of labour", for example, and "social acceptability of biotechnology-based activities". This may account for what one observer outside the commission has called the unimaginative nature of most of the applications.

The applications are also biased to short-term issues. Petrella's team distinguished three broad sectors of problems — work and employment, the role of information technologies and the role of biotechnology — which Petrella identifies as of greatest importance over periods of 10, 20 and 30 years respectively. Some 100 applications were received for research in the first sector, 70 in the second but only 35 in the third. The final selection of projects will, however, be more uniformly divided.

The short perspective of the FAST applications might have mattered less if a parallel proposal within the European Science Foundation had come to fruition. The plan had been that the ESF, an independent body uniting national research councils throughout Europe, should have mounted an "additional activity" on "the socio-economic consequences of technical development", paid for by those among its members wishing to participate. This proposal, which would have been concerned with more basic and less policy-orientated objectives than is FAST, was thrown out by the ESF's social science committee last year.

One of the objectives of FAST, defined by the 1978 European Council decision, is "to establish an *ad hoc* system of collaboration between specialized research groups within the community and so create a series of community forecasting networks". All very well — but what can be done on a European scale that is not already being done nationally? ("Send me the answer on a postcard", one UK government science adviser asked one of the FAST team.) It is a question of scale and regionality, according to Mark Cantley, head of the FAST biotechnology programme. Investigation of the manpower and training implications of biotechnology-based industries, for example, requires consideration of international transfers and coordination. The distribution of benefits and risks associated with microelectronics and its applications is similarly a regional matter.

FAST itself is also under test, however. The earlier, small-scale "Europe plus 30" study recommended the establishment of a Community Forecasting Institute. The council rejected that in 1978 and instead set up FAST for a provisional five years. Petrella and his team naturally hope that the experiment will be continued.

Soviet energy

No shortage?

The Soviet Union and its socialist allies have no energy crisis ahead, according to Petr Neporozhnii, the Soviet Minister of Energy and Electrification. This confidence, he said, was based on estimates of the Soviet Union's fuel reserves — more than 50 per cent of the world reserves of coal and more than 33 per cent of the world reserves of oil and gas. Furthermore, the Soviet Union's hydroelectric capacity is potentially larger than that of the United States, Canada and Japan taken together.

The minister was speaking on the English-language service of Moscow Radio beamed to North America. Inevitably, he compared Soviet energy policy with that of the United States. The latter, he said, has in its oil shales "more than several Saudi Arabias" — but the "American monopolies" find it more profitable to import oil and raise retail prices of oil products than to develop new deposits. The minister glossed over the fact that one of the main barriers to the use of shale is environmental pollution. Estonia, which burns much shale in thermal power stations, is a major source of pollution in the Baltic area.

Neporozhnii's confidence is to a large extent supported by the latest figures from PetroStudies (Malmo). This independent team monitors Soviet oil and energy exports on the basis of trade figures with individual countries. According to the report for 1979, published last week, the Soviet Union is now the second largest oil exporter in the world (next to Saudi Arabia), exporting 164 million tonnes in 1979, and for the past six years has been the world's leading oil producer, with an annual target for 1980 of 606 million tonnes. The same confidence was shown by Dr Mikhail Tolkachev of the Soviet Academy of the National Economy, reporting to a meeting of the International Institute of Applied Systems Analysis earlier this month. This year, said Tolkachev, Soviet natural gas production is expected to reach 4.2 million m^3 per day, an increase of more than half a million m^3 since last year.

Soviet claims to energy sufficiency are not new. Neporozhnii's talk, however, is interesting in that it virtually ignored nuclear power, except for a passing mention of plans for integrating the Soviet grid with those of the various Comecon countries and the construction of the new ETL-750 transmission line to connect Rzeszow in Poland with the Khmelnitskaya atomic power station in the Ukrainian SSR. This is the more surprising since Neporozhnii put considerable stress on the Soviet planners' 'concern for the future" — as exemplified in the long-range energy plan launched 20 years ago with the construction of the Bratsk power station in Siberia. The same concern, said the minister, has led to long-term plans for the production of synthetic liquid fuel, the use of solar and geothermal energy and even "the heat of ordinary sea water".

To most Soviet energy planners, however, nuclear power is usually a key topic in any speech on energy prospects. In April 1979, Academician Anatolii Aleksandrov, president of the Soviet Academy of Sciences, and himself formerly a leading figure in the nuclear energy programme, stressed that it was atomic energy and coal which would help the Soviet Union to avoid what he called the "imminent energy crisis". The Soviet nuclear programme does not, however, appear to be keeping up with the demand.

Last month, at an All-Union conference on nuclear power held, appropriately, at Energodar, Sapozhnikov, one of Neporozhnii's deputy ministers, stated that the construction of nuclear power stations must be doubled and new commissioned capacity raised to 7,000-10,000 MW per year. The target is an overall nuclear generating capacity of 100,000 MW within the next 10-12 years.

According to Fedor Ovchinnikov, another deputy minister of energy, the short-term programme is for water-moderated water-cooled reactors of up to 1,500 MW capacity. Officially at least, there are no anxieties on environmental grounds. Yurii Markov, a spokesman for the Ministry of Energy and Electrification, wrote recently in *Sovetskaya Rossiya* that Soviet nuclear power stations are so safe that their surroundings "are used as recreation areas, where families come and picnic, gather mushrooms and berries and go fishing in the cooling ponds".

Technological change

Worry about jobs

Washington

The new report on science and technology policy (see *Nature,* 10 July, page 96) published by the Organization for Economic Cooperation and Development (OECD) is being cold-shouldered in Washington largely because of its warning that undirected technological change may be contributing to the rising level of unemployment. The report, prepared by a group of outside experts, sets out to identify the main elements of the social and economic environment for science and technology which are likely to affect OECD countries during the 1980s.

The report emphasizes the need to revitalize technological innovation in order to help remedy many of the afflictions of the 1970s, especially sluggish economic growth and escalating inflation. To this uncontroversial conclusion, however, it adds that technological innovation must be guided so as to ensure that its potential benefits are not overshadowed by the destruction of jobs.

The extent to which technical change, in both manufacturing and service industries, may be contributing to growing unemployment, expected to reach 8.5 per cent next year, is receiving more and more attention, particularly at state and local levels. Pennsylvania's legislature, for example, is considering a bill intended to reduce unemployment by banning automatic petrol stations and toll collection booths, among other measures.

In Washington, by contrast, the government resists the notion that it must act to soften the impact of technical change on employment. Last year's domestic policy review of industrial innovation, for example, concluded merely that "the key to successful adjustment is warning time"; and the national Labor Technology Forecasting System subsequently promised by President Carter has yet to materialize. The dominant argument is that once rapid economic growth has been re-established, jobs lost through technical change in one sector of industry will be replaced elsewhere. In any case, there is growing antagonism towards government intervention in the regulation of innovation, so that the lack of enthusiasm for the OECD report is no surprise.

The report started as an internal study within OECD to examine the relationship of technical change to the problems of inflation, unemployment and long-term economic growth. In part, it was intended as a counter-analysis to the official OECD report "Towards full employment and price stability", produced by a committee chaired by Professor Paul McCracken and published in 1977.

The new report challenges the McCracken thesis at two related levels. First, it argues that the economic problems faced by OECD countries in the early and mid-1970s were not, as McCracken suggested, merely a manifestation of cyclical economic changes that could be resolved through conventional policy instruments. Rather, the new report argues, they reflected deeper structural changes requiring a more radical approach.

More specifically, the report challenges the McCracken committee for underestimating the impact of technical change on social and economic policy, and for characterizing the declining rate of innovation as a problem that will resolve itself "naturally" with a revival in demand. Instead, the report argues that adequate policies for science and technology must be central to any attempt to tackle the joint problems of high inflation and unemployment. These problems, it argues, tend to depress the rate of innovation; but a slackening of innovation makes their solution more difficult.

Government action is therefore necessary, the report argues, to ensure both a faster and a "more balanced direction" for technical change. But in the United States, where most government economists accept the McCracken thesis, this has met with a certain scepticism. A particular source of irritation has been the report's warning that a general substitution of capital-intensive for labour-intensive techniques in manufacturing industry may be exacerbating unemployment.

Professor Richard Nelson of Yale University, a member of the OECD expert group, admits that the committee which prepared the report was "schizophrenic" on the employment issue. Thus it argues that "a significant acceleration of technical advance and productivity growth would make the unemployment problems easier to deal with" but also warns that more capital-intensive technology may further worsen the condition of the labour market.

The report adds that structural unemployment is now an "important feature of the economic landscape". The hypothesis is an increasingly familiar one in Europe, particularly in Britain where it has been argued forcefully by, among others, Professor Christopher Freeman of the Science Policy Research Unit at the University of Sussex, a member of the group which prepared the OECD report. Economists here prefer to point to similar concerns in the late 1950s and early 1960s that the automation of production might create serious unemployment; in the event, excess labour was absorbed into the rapidly-growing service sector.

Academic economists tend to be more agnostic than their government colleagues. Dr Robert Lund of the Massachusetts Institute of Technology, who has examined studies carried out at Sussex on the impact of microelectronics, says that "we did not find the kinds of employment impacts that seemed to be predicted". But he adds that "I do not know if we have enough data to say that we have the right answers".

Government policy-makers are less equivocal. The OECD report came in for substantial criticism when a draft was circulated last year. Strenuous, and ultimately successful, efforts were subsequently made within OECD to ensure that the report was published as the opinion of a group of experts rather than with the organization's official backing.

The net result, however, is that the report's potential impact on policy has been blunted, which Professor Nelson for one regrets. "On the employment question, it may not be quite right, but it is more correct than some of the discussions now taking place." **David Dickson**

Thermonuclear fusion

Soviets bid half

Brussels

The cost of the International Test Fusion Reactor (INTOR), estimated at $1,000 million, would be more than halved if the machine were built in the Soviet Union. This is the opinion of Dr L G Golubchikov, head of the fusion division of the Soviet State Committee on the Utilization of Atomic Energy who has been seeking to stimulate a greater commitment to the project from the West during his participation in the eighth international conference on plasma physics which ended last week.

The project, which so far consists largely of a design study, is being planned by the International Atomic Energy Agency (IAEA). American reaction at the conference, however, was cool. It might cost half as much, but it would take twice as long, was one opinion.

INTOR, whose study by the IAEA was proposed by the USSR in May 1978, is nevertheless agreed to be a constructive exercise in one respect: by concentrating attention on the severe engineering difficulties of the tokamak fusion reactor, it is helping to define the experimental questions which must be tackled in the next generation of large tokamaks (JET in Europe, T-15 in the USSR, TFTR in the United States and JT-60 in Japan). However, it is also generally agreed (except by the USSR) that the INTOR design is unlikely to see the light of day as a piece of hardware, at least in the medium term.

What appears most likely is that the recent proposal (*Nature,* 10 July) for a Fusion Engineering Device (FED) in the United States at a hardware cost of $1,000 million will capture (and double) the US fusion budget. FED, largely the work of the Princeton Plasma Physics Laboratory, is less ambitious than the Oak Ridge National Laboratory's proposal, the Engineering Test Facility (ETF), which in turn was less ambitious than INTOR. Moreover, it is felt in the US Department of Energy that collaboration with the USSR on a project of the scale of INTOR would be fraught with bureaucratic difficulties.

0028-0836/80/290198-02$01.00

Japan would also consider collaborating with the United States on FED although it is a little early for formal approaches to have been made. Professor Husini, a Japanese representative on the IAEA's International Fusion Research Council, said last week that Japan would be "very interested" in such a joint venture, on the basis of sharing costs.

This leaves the European Community in the cold beyond JET, unless it also joins in FED, which is by no means out of the question. The European Commission has been considering the next European Torus (NET) in a small committee headed by the Italian physicist Professor R Toschi of Frascati; but, said one Italian, "the FED recommendation means NET will have to be completely rethought. Perhaps we can build a device a step beyond FED and five years later."

The USSR would clearly be disappointed if INTOR goes little further than the project definition, which is to be presented to the IAEA next year. "The West has the bigger energy problem" said Golubchikov. The Soviet authorities are thus less bullish about fusion. It would thus assist the Soviet fusion community greatly if the next steps could be international. And Golubchikov believes the technical problems that will face FED or INTOR will be so great that Soviet participation will be necessary if there is to be rapid progress. After all, the USSR invented the tokamak — which appears to be the only viable ignition device at present — and built the only working superconducting tokamak (T7).

Robert Walgate

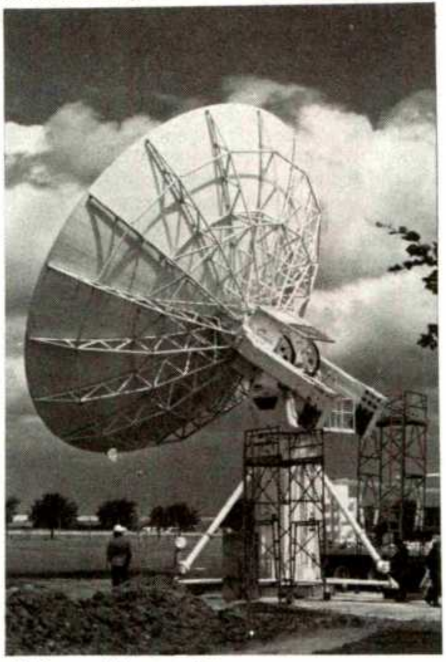
Laboratory merger

Harwell again

Several large research facilities in Britain will be completed late, and Britain's capacity to contribute to new international projects will be impaired, as a result of pressures on the budget of the Science Research Council. This is the view of Sir Geoffrey Allen, chairman of the SRC, speaking at an Open Day at the newly-merged Rutherford and Appleton Laboratories last week. Although the science budget has been let off relatively lightly in recent public expenditure cuts, he said, a 10–15 per cent increase of the budget would be needed to complete existing projects within the original timetables and to start new ventures.

One victim of these enforced delays is the Spallation Neutron Source, at present under construction at Chilton, across the fence from Harwell. It will now be completed in 1984, two years later than originally planned, largely because it has been necessary to spread out the funding of the £12 million project. Allen is also concerned that Britain may not be able to contribute fully to the building of a new European synchrotron radiation source (*Nature*, 20 May) or to the European Space Agency's plan to build an astrometry satellite, Hipparcos.

The proposed European synchrotron radiation project, devised by the European Science Foundation, would require a new international agreement among the partners; Allen plainly fears that the SRC budget may be too tight to allow Britain to contribute. Hipparcos presents a different problem. It will be paid for out of ESA's mandatory science budget to which all member states, including Britain, contribute annually on the basis of GNP. Allen's concern here is that British laboratories should recapture some of the cost by making viable bids for the ESA contracts.



Dish awaiting satellite

The merging Appleton and Rutherford Laboratories are hoping to overcome this manpower problem by training and redeploying people as their projects come to an end, or as timetables are extended. The laboratories claim some success in these directions, but acknowledge that there must be limits to the extent to which staffs with different, highly specialised backgrounds, for example in radio and space physics (Appleton) and high-energy physics (Rutherford), can be fully redeployed.

A major reason for the merger is to save costs, including some staff. The SRC hopes to shed about 40 administrative jobs by not replacing those who choose not to move to the new site. Most of the scientific staff are expected to move, however, and those who do not will be replaced. So far about a third of the 300 Appleton staff have moved. The rest will do so before the end of 1981.

The plan to close the site of the Appleton laboratory at Ditton Park cannot be implemented precisely as originally hoped, however. Some of its instruments will not be compatible with the Chilton site; some millimetre wave and radio equipment, for example, will be sited 60 miles away to avoid interference from the spallation neutron source and 70 MeV linac.

Judy Redfearn

Siberian science

Marchuk on top

Last month's meeting of the Supreme Soviet confirmed the appointment of Academician Gurii I Marchuk as head of the State Committee for Science and Technology. The confirmation was a formality; Marchuk's appointment took effect last January, when the then head, Academician Vladimir A Kirillin, resigned (coincidentally on the day that Academician Andrei Sakharov was exiled to Gor'kii).

Marchuk came to the State Committee from the Siberian branch of the Academy of Sciences, of which he had been chairman since 1975. That branch, based on the science centre of Akademgorodok outside Novosibirsk, was originally set up, in 1957, as part of Khruschev's overall plan to decentralize the economy. Its activities have always, therefore, been closely related, at least formally, to the needs of Siberia.

The Siberian branch would therefore share the blame if science failed to play a full part in the opening up of the Siberian heartland. In the autumn of 1976, criticism of the Siberian branch did in fact break out. The State Monitoring Committee at the outset criticized the Academy of Science's Far Eastern Science Centre for failing to make a proper practical contribution to the national economy. The campaign turned to more and more prestigious institutions, finally attacking the Siberian branch itself. At that point, Marchuk fought back, and with an impressive battery of arguments demonstrated that, so far from slacking, the branch was alive and flourishing and more than pulling its weight.

In his new job as head of the State Committee, Marchuk is responsible for the whole of Soviet science planning, the coordination of research and development and the subsequent implementation of research. Marchuk's Siberian experience will be invaluable, for Siberia remains the major area of Soviet capital investment.

Last April, a special conference of the Central Committee of the CPSU advocated increased investment in the fossil-fuel-bearing regions of West Siberia, apparently because a lack of amenities is making it hard to attract scientists and engineers to the area. The new Baikal-Amur Mainline railway was planned from the beginning as a joint exercise in engineering, ecology, demography and economics.

Plans to divert the major Siberian rivers south were, however, delayed during the last five-year plan, although, in response to complaints at the possible global environmental consequences, the Soviet government announced that no such changes would occur. It has however mounted a major environmental study of the region, with the result that Siberian

0028-0836/80/290199-02$01.00

environmentalists have had unparalleled opportunity for field work in the past decade. This has involved the photography of the area from manned and unmanned spacecraft, ground-level geophysical surveys (which on one occasion discovered glaciers far to the south of where they were expected) and the drawing up of ecological guidelines for the engineers. There must be no tree-felling on slopes of more than 15 degrees and no insecticides — construction gangs plagued by the ubiquitous Siberian mosquitoes must use protective netting or swatters.

In spite of all this care, a recent report from the Chita Hydrometeorological Observatory suggests that the development of the BAM zone is running into environmental problems. In the north Transbaikal area, it appears, there is very little wind; the air masses remain static for a considerable time and industrial emissions become concentrated. Long before the BAM railway itself is officially opened, the pollution in the Chara valley is already, say the Chita scientists, some 50-100 per cent greater than that in the European part of the USSR — the centre, at present, of Soviet industry.

Vera Rich

CORRESPONDENCE

Biko's doctors

SIR, — The Faculty of Medicine of the University of the Witwatersrand has strongly attacked the decision of the South African Medical and Dental Council that there was no evidence of improper or disgraceful conduct on the part of the doctors who treated Mr Steve Biko before his death in detention. The Faculty Board has resolved unanimously to dissociate itself publicly from the council's decision, taken at a closed meeting on 17 June 1980.

At a meeting held on Friday, 27 June, the Board of the Witwatersrand University Medical Faculty unanimously adopted a resolution on the "Biko doctors". The resolution reads: "The Faculty of Medicine of the University of the Witwatersrand, Johannesburg, has considered the decision of the South African Medical and Dental Council, taken at a closed meeting on 17 June 1980, that there was no evidence of improper or disgraceful conduct on the part of the doctors who treated Mr Steve Biko before his death, and that there was thus no need for a disciplinary hearing.

"Bearing in mind the revelations under cross-examination at the inquest, and the fact that the magistrate presiding at Mr Biko's inquest had considered that the matter of the Biko doctors should be referred to the South African Medical and Dental Council, the Faculty expresses its deep concern and disquiet at the finding that there was no evidence of improper or disgraceful conduct and that the matter should be dropped. The faculty feels that there was *prima facie* evidence of improper or disgraceful conduct, which should have been subjected to the careful scrutiny of a Medical Council Disciplinary Committee hearing.

"The Faculty is of the opinion, furthermore, that this decision of the Medical Council may seriously affect the good standing of the South African medical profession both at home and abroad and, therefore, publicly dissociates itself from this decision.

Further, the Faculty endorses and supports the Guidelines for Medical Doctors concerning Detainees and Prisoners, adopted by the 29th World Medical Assembly of the World Medical Association in Tokyo in October, 1975, and known as the "Declaration of Tokyo". This states, *inter alia*, that a doctor must have complete clinical independence in deciding upon the care of a person for whom he or she is medically responsible (Article 5), and that a doctor shall in all circumstances be bound to alleviate the distress of his fellow men, and no motive — whether personal, collective or political — shall prevail against this higher purpose (Article 8).

"The Executive of the Board of the Faculty of Medicine is requested to ensure that the views of the Board are communicated widely to the public and to the medical community, both in South Africa and abroad."

In accepting this resolution, the Faculty stressed that "We are not saying that the doctors are guilty. We are saying that there is sufficient evidence for a Disciplinary Committee enquiry to be instituted and that a decision should be taken about the behaviour of the doctors on the basis of a full, fair, impartial and thorough Disciplinary Committee hearing. The South African Medical and Dental Council is supposed to be the watch-dog of the ethics of our profession and they have been zealous — and some would suggest over-zealous — in the severity of the punishment that they have meted out, not only for major infringements but for what many would regard as minor infringements of the ethics of medical practice. Yet, in the present case, it is difficult to accept that the Medical and Dental Council has applied its collective mind to the problem of the Biko doctors in a purely objective and dispassionate way."

In moving the resolution, Professor Clive Rosendorff, Head of the Department of Physiology at the Medical School, made this statement:

"This is all a source of great embarrassment and distress to many doctors in South Africa who are proud of the high ethical standing of their profession, both within this country and abroad. I believe that we have a responsibility to indicate to the world that we disapprove of the decision of the Medical Council to drop the matter. We should like it to be known that we dissociate ourselves, as an institution and as a body of concerned citizens and doctors, from their decision. We do this because we feel that it is morally indefensible for a matter as important and serious as this to be dropped before it has reached the Disciplinary Committee stage. We do this because we feel that the ethical standards of our profession have been compromised; because as doctors we have a humane concern for our patients and their welfare; because we are worried about the possible effects of the decision of the Medical Council on the future treatment of prisoners and detainees by the authorities; and because we are worried about the repercussions of the Medical Council's decision abroad. Already there are signs of a campaign to cut ties with doctors from South Africa, both at international congress level and in the recognition of our degrees abroad.

"Countries with which we have most dealing and reciprocity agreements, Great Britain, Australia, New Zealand, the Netherlands, Belgium, the United States of America, Canada, have always been happy to accept the *bona fides* of the S.A. Medical and Dental Council. However, there are already indications that rethinking on this point has started. The British Medical Association Ethics Committee is to examine the Biko doctors decision of the S.A. Medical and Dental Council. In Geneva, the World Health Assembly has called on member countries to review their medical ties with South African doctors."

My Faculty believes that it is vitally important that we distance ourselves from the decision of the Council. As a group of concerned doctors and Medical School teachers, we are worried that the South African Medical and Dental Council might, by its decision, have called in question its own credibility as an objective and unbiased guardian of the high standards of the medical profession in South Africa.

Yours faithfully,

PHILLIP V. TOBIAS

Dean, Medical School,
University of Witwatersrand,
Johannesburg, S A

Russian continues

SIR, — May I, as Head of the Department of Russian and Soviet Studies at the University of Lancaster, be allowed to comment briefly on Vera Rich's piece in the last issue of *Nature* (3 July). Her remarks concerning the diminishing provision for the study of Russian in Britain, in contrast to the proposed expansion in Finland, are entirely justified. Her statement, however, suggesting there has been an "overnight decision to close down the Russian Department of the University of Lancaster" is incorrect and seriously misleading.

As part of a broader policy document which purported to be a strategy for the 1980s, a small Vice-Chancellorial committee at Lancaster recently *recommended* the gradual phasing-out of five small academic departments, including Russian. The document was subjected to widespread and vociferous criticism throughout the University and was finally *withdrawn* at a meeting of the University Senate on 11 June.

The department, therefore, still exists and will continue to exist — with an increased undergraduate enrolment in 1980-81. Moreover, in addition to its full degree programme of Russian history, politics, language and literary studies, and in the context of your article, it plans to mount a new elementary Russian language course which will be available for scientists who wish to acquire a reading knowledge of Russian and hence gain access to a major "medium of scientific communication".

Yours faithfully,

ALAN WOOD

University of Lancaster, UK

Dioxin disclaimer

SIR, — I wonder if you would be kind enough to allow me to comment on Alastair Hay's article in *Nature* (6 March) which indirectly implies that I had some part in the non-publication of the two investigations of Coalite workers.

Firstly I was never involved in the treatment of Coalite cases. Secondly, not only did I never suggest suppression of the data, but I repeatedly urged its publication — unsuccessfully.

It should be mentioned that the second and more far-reaching study to which Hay has referred was suggested to Coalite by the HSE since the first study was considered inadequate. I have never been shown the results of this second study by the company but obtained them by unofficial means.

Yours faithfully,

K.D. CROW

Princess Margaret Hospital
Swindon, UK

NEWS AND VIEWS

Tectonics of the Northwest European Continental shelf

from P.E. Kent

BOTH academic and industrial organisations are involved in exploration of continental shelves, but it is only intermittently that the large amount of data assembled by industry is made generally available. One of these occasions — five years from the previous major release[1] — took place at a conference held in London in February[2].

The conference in 1975 had been concerned mainly with the results of industrial exploration of the North Sea, at a time when drilling in the outer basins was just beginning. This year there was an increased input from other sources — notably regional compilations on the North Sea area by the Institute of Geological Sciences, and on the Norwegian offshore by the Norwegian Petroleum Directorate, while the oil companies added to North Sea data and described for the first time the structure and stratigraphy of the more westerly basins.

In the North Sea itself the nature of the crystalline floor was described from cores and radioactive dating at fifty sites. There is, as previously deduced, continuity of continental crust across the North Sea with a degree of attenuation indicated by gravity measurements and with Caledonian metamorphics with granite intrusions extending as far south as a line from Dundee to Stavanger. The area between this line and the Welsh-Brabant massif is occupied by lightly tectonised sediments, which have locally yielded Lower Palaeozoic faunas. It was again emphasised that development of the North Sea basin began in the Upper Palaeozoic, and that the Mesozoic fault pattern frequently relates to Caledonian progenitors.

Although the additions to North Sea data and detailed descriptions of additional fields are of considerable importance, the main access of new knowledge is of the basins nearer the edge of the continental shelf, from the Barents Sea to the Bay of Biscay, outlined in the following paragraphs.

The Norwegian Shelf, terminated seaward by the Faeroe-Shetland and Voring Plateau escarpments and extending to 68°N, is occupied by a series of basins partly separated by longitudinal and transverse faulted highs. In these basins sedimentary thicknesses exceed 12 kilometres, often in highly asymmetrical trap door-type half-graben basins which ended their fault-development with the 'Late Cimmerian' phase and which were essentially growth-fault controlled. Stratigraphic horizons have been partly dated in relation to those of the adjoining North Sea, and it is deduced that the greater part of the sedimentary sequence is Mesozoic, but that basinal development began in the Carboniferous.

In contrast to the northern North Sea, but in line with other fault controlled Mesozoic basins, inversion took place during the Cretaceous.

In the Barents Sea, more remote and also still undrilled, dating of horizons is less certain and depends on a combination of local dredgings, regional and stratigraphic trends (with Svalbard as a northerly control point) and deduction from world wide events.

The area shows two sub-basins, each with large salt diapirs which originated below the presumed Permian and hence believed to be Devonian/Carboniferous. The existence of salt of this date, if substantiated by drilling, could have an important influence on our understanding of Permo-Triassic salt deposition.

West of the Shetlands the notable feature has been discovery of a very large oilfield on the Rona Ridge. This has been credited with reserves in place of 3.5–4 billion barrels (around 500 million tons), but it is a heavy oil which will present major problems in extraction. The reservoir is mainly of Carboniferous and Devonian sandstones capping the scarp of a large down-to-the-ocean fault which bounds the main Rockall basin. The adjoining trap-door type basin on the eastern side of the Rona ridge is too shallow to have generated significant amounts of hydrocarbons, and it has to be concluded that the source rocks for this very large field lie in the deep Rockall trough itself, an area consequently considered increasingly attractive for future exploration.

The Northern Irish Sea, the site of discovery of a large gas field, is confirmed as essentially a Permo-Triassic basin analogous to the Cheshire Basin on land. An unexpected feature however is the discovery that it underwent inversion — a process of relatively rapid uplift at the end of the Mesozoic, partly counteracting the long period of Permo-Triassic subsidence, a feature now recognised widely on this continental shelf.

The Kish Bank Basin, a simple trapdoor subsidence lying off the Irish coast near Dublin, illustrates particularly well progressive basinal development from Upper Palaeozoic to Tertiary. The tectonised older Palaeozoic floor is followed by Carboniferous — possible Visean, then Westphalian B, C and D — Permian, Triassic and Jurassic (the latest formation surviving). The Carboniferous, Lower and Upper Triassic each thicken towards the 5,000m down-throw boundary fault system, which developed as deposition continued and moved also in the post-Jurassic, finally in the Oligocene.

In Cardigan Bay a very deep Mesozoic and Tertiary basin lies alongside the seaward continuation of the NE-SW Bala fault, which has a westerly downthrow of 4,000 metres. The oldest beds identified are Upper Carboniferous; these are overlain by Permo-Triassic and Jurassic sediments which total 7,000 metres in the centre of the basin. Contrary to earlier expectation the

Cretaceous is absent, and the faulted earlier Mesozoic is directly overlain by Tertiary sediments. In line with the development of other Mesozoic basins on the continental shelf it could be presumed that movement of the bounding fault was syn-sedimentary, but the five deep boreholes drilled in the basin were not sufficiently close to the fault to encounter marginal fans, if these exist. The Cretaceous may have been present and been eroded, perhaps a case of inversion of subsidence as in analogous basins elsewhere around Britain.

The Celtic Sea Basin: The Celtic Sea conceals one of the larger basins of the continental shelf, extending 300 km southwards from the Irish coast. Like the other basins of the region, the Celtic Sea basin has a long history, with late Palaeozoic rocks (Lower Permian) proved at depth. Basin development until the late Mesozoic was controlled by rift development. Undifferentiated continental Permo Triassic rocks and a largely complete Jurassic sequence ending with the Purbeck was followed by a thick development of strata in the Wealden facies (indicated as some 1,200 metres thick in the Kinsale Head field); the Wealden apparently extending through the Neocomian to early Albian — appreciably longer than in southern England.

The Kinsale Head gas-bearing structure is an anticlinal feature produced by an inversion of the central part of the basin, a process which gently arched the later Wealden and overlying beds — a close analogy to the English Weald.

The Fastnet Basin: The Fastnet Basin, an appendage of the Celtic Sea Basin extending southwestwards almost to the continental margin in Irish waters, is a fault-bounded subsidence, measuring 110 km from NE to SW and 35–40 km across, which has been investigated by gravity, aeromagnetic and repeated seismic surveys followed by nine exploration wells, unfortunately without any economic discovery. The general structural style is analogous to that of most other basins on the continental shelf, with a thick packet of earlier Mesozoic rocks affected by strong faulting which died out before or during the Upper Cretaceous. An Upper Palaeozoic floor was reached in two wells which respectively identified Lower Carboniferous (Tournaisian) and Devonian, succeeded by a 'normal' continental Permo-Triassic development and a greatly expanded Lower Jurassic. Unconformable Cretaceous begins with a Wealden episode more limited in time than that of the Celtic Sea but similar in facies and age (Berriasian) to that of southern England. It is itself unconformably transgressed by 'Greensand', Chalk and Tertiary sediments.

The closely spaced faulting is dominantly extensional, down-to-basin, most faults being truncated by the Cretaceous unconformity, but others dying out in the Upper Cretaceous. The few which have large displacements in the Upper Cretaceous show evidence of throw reversal, this being associated with extensive basin inversion. The inversion process began in the Lower Cretaceous and resulted in attenuation of both that formation and the Chalk over the area where the Jurassic is thickest, the Chalk itself being absent over an area 20 × 10 km.

The listric faulting developed during the Jurassic can be seen as extension in relation to the incipient Atlantic continental parting, but the development of strong basin inversion (normally characteristic of internal basins) might be taken to indicate that the limit of the continental crust lies at least tens of miles oceanward of the shelf break.

The Bay of Biscay: The concept of the Cretaceous anti-clockwise rotation of the Iberian peninsula relative to the rest of Europe is widely accepted and the paper submitted to the 1980 Conference most usefully integrated this incident with the results of oil company exploration along the northern Spanish coast. The continental split took place centrally in a little-disturbed shelf covered by Triassic and Jurassic rocks. The preliminary stretching associated with the development of the oceanic wedge produced tension faulting and the consequent development of trapdoor subsidence, with greatly expanded Upper Jurassic and Lower Cretaceous sedimentation in the marginal 7 km deep Spanish Trough in the south and in the shallower Armorican Trough to the north of the incipient parting. On the new evidence the split radiates not from Biarritz but 120 km further north in the Parentis basin. The Spanish Trough suffered strong compression in association with the Pyrennean orogeny (Upper Eocene) and has by some been regarded as the foredeep of a subduction zone, but if the stratigraphical datings given in this paper are confirmed the sedimentary accumulation long predated this compressional phase.

In summary, the basins on the Northwest European Continental Shelf lying north of the Hercynian orogenic belt are known in the majority of cases to have a history extending back to Carboniferous or Devonian, with the main subsidence taking place during the Permo-Triassic and Jurassic. Throughout this period the stress system seems to have been consistent and to have been relieved by tensional, often listric, faulting which may well be symptomatic of thinning of the underlying crust by a process of plastic stretching. This long taphrogenic period ended with the inception of Upper Cretaceous and Tertiary simple miogeosynclinal subsidence — a process which was however interrupted in a majority of the basins by an episode of inversion of the former downwarp. In some cases this inversion may be related to a shortlived change in shear stresses but it was apparently not limited to subsidences produced by Mesozoic faulting and is not yet fully understood. □

Special sites in genetic recombination

from John Rosamond

At the end of the 1978 Cold Spring Harbor Symposium, Frank Stahl suggested that genetic recombination was ceasing to be simply a geneticists domain, and that the time was right for a more biochemical approach. A number of people seem to have taken notice of this since considerable effort is being expended on the *in vitro* formation and analysis of intermediates in recombination. Of particular interest is the work of Stahl himself, and his collaborators at the University of Oregon, on the nature of special sites for genetic recombination. Their recent work suggests that such sites may be structurally complex (*Cell,* **19,** 785; 1980) and of fundamental importance in recombination.

Generalised recombination involves the exchange of genetic information between homologous chromosomes, and it used to be thought that the frequency with which recombination occurred was equal throughout all regions of homology. That this expectation is not always met was first shown by genetic studies of recombination in fungi[1]. The frequency of exchange was higher in some regions of homology than others, implying the presence of special sites (hotspots) in the genome which influence the frequency of recombination in that region. More recently, Stahl and his collaborators have been examining similar sites which promote recombination in bacteriophage λ. Their studies on these sites, termed Chi, not only have provided interesting information on the mechanism of genetic recombination at the molecular level, but also suggest that the involvement of special sites, such as Chi, in genetic recombination may be more widespread than was originally envisaged.

Chi sites are not present in wild-type bacteriophage λ, but are found as mutations that arise in response to selective pressure on a specific part of the λ life cycle. After infecting *Escherichia coli,* the λ genome circularises and replicates, initially by a Cairns-type 'theta' mechanism, to produce a pool of monomeric circular molecules, before

0028-0836/80/290202-03$01.00

switching to the 'rolling circle' mode of replication. Most progeny chromosomes are derived from the concatamers produced in this way, since the monomeric circular molecules are not a substrate for encapsidation. Transition from 'theta' to 'rolling circle' replication is facilitated by two λ genes, *red*$^+$ and *gam*$^+$; the *red*$^+$ gene product promotes replication by creating replication forks, while the *gam*$^+$ gene product inhibits a host nuclease which would otherwise prevent rolling circle replication. (This nuclease, exonuclease V, is the product of the *recB* and *recC* genes and is involved in a bacterial recombination pathway).

Consequently, when phage that are defective in these genes (λ *red gam*) are grown on *recBC*$^+$ bacteria, rolling-circle replication is prevented, and in order to organise the DNA into a form that can serve as a substrate for encapsidation, the monomer genomes must be recombined to form dimeric molecules. λ *red*$^-$ *gam*$^-$ phage do this relatively inefficiently, thereby producing small numbers of progeny phage and therefore small plaques.

In these circumstances, there are obvious advantages to be gained by increasing the efficiency with which the host recombination system is being used. Consequently, when λ *red*$^-$ *gam*$^-$ phage are repeatedly grown on a *recBC*$^+$ host, the small-plaque forming phage are eventually overgrown by mutants with a large plaque phenotype[2]. This is the Chi$^+$ phenotype, which arises after mutation in one of at least four loci dispersed throughout the λ genome. It was suggested that these mutations (χ^+) increased the yield of progeny phage by accelerating the rate limiting step in the recombination pathway being used to form the dimeric precursors of mature phage DNA; it is the nature and properties of these χ^+ mutations that Stahl and co-workers have been investigating.

The presence of a χ^+ mutation in the λ genome increases the frequency of recombination near the mutation by about 10-fold. This stimulation decreases with distance, but can still be detected up to 2×10^4 base pairs away from Chi. There are four recombination pathways open to λ, and, in principle, Chi$^+$ might have enhanced recombination mediated by any or all of these. It transpired, though, that the action of Chi$^+$ is specific to the major bacterial recombination system, the so-called *recBC* pathway, which required the product of the *recA* gene as well as those of *recB* and *recC*[3]. This discovery led to the suggestion that Chi sites occurred in the *E. coli* genome as well as in λ, and functioned in bacterial recombination. Indeed it was found that λ *red*$^-$ *gam*$^-$ which include the *E. coli bio* operon behaved as though they carried a Chi$^+$ site, since they made large plaques on *recB*$^+$ hosts[4]. This property was not peculiar to the *bio* operon though, since by cleaving *E. coli* DNA with *EcoRI* and inserting random fragments into the λ genome, Malone *et al.*[5] estimated that Chi hotspots were present naturally in the *E. coli* chromosome at a density of 1-2 per 10^4 base pairs. Similar experiments, in which *EcoRI* fragments of DNA from *Saccharomyces cerevisiae* were inserted into λ, showed that yeast DNA also carries Chi sites[6].

Meanwhile, the phenotype of the χ^+ mutations in λ had been investigated in more detail and it was found that the enhancement of recombination due to Chi$^+$ was asymmetric (*Mol. Gen. Genet.* **140**, 29; 1975). Thus, χ^+C in the λ *cII* gene stimulated recombination to a greater extent in the *J-N* region to the left of χ^+C than it did in the *P-R* region to the right, although χ^+C was closer to the *P-R* interval. This leftward bias of Chi$^+$ activity was common not only to all the Chi$^+$ sites arising by mutation in λ, but also to all the naturally occurring Chi$^+$ sites found on the *EcoRI* fragments of *E. coli* DNA[6].

Of the several possibilities for this directional bias of Chi activity, two are most likely; either Chi could itself be an asymmetric sequence, in which case the directionality of Chi$^+$ activity will be dependent on the orientation of the sequence, or else the directionality could be imposed by some aspect of phage λ biology. If the directional bias were due solely to the orientation of the Chi elements, then artificially reversing the Chi sequence should lead to a reversal of the directional bias. Experiments to test this were done by excising *chi*$^+$-carrying *EcoRI* fragments of *E. coli* DNA from λ *red*$^-$ *gam*$^-$ phage and

NATURE

100 years ago

A sad balloon accident has taken place at Le Mans, and may be referred to as illustrating some useful facts relating to aëronautics. A man named Petit had ascended with two balloons connected by a long rope. The smaller, which was placed above, carried his son, almost a boy; Petit being in the larger with his wife. There was not much wind, and this foolish experiment would have ended without accident if Petit had not forgotten to loosen the neck of the balloon, so that no escape was left for the gas which was gradually expanding. When the balloon arrived at an altitude of 400 to 500 metres it burst in the vicinity of the "equator," and descended with great velocity, dragging the smaller balloon. Petit, who was devoid of any scientific knowledge, supposed his son was in danger, and with true heroism he cut the rope connecting the two balloons when at 250 to 300 metres from the ground. He placed his wife on the ring and remained himself in the car. The shock was so terrible that his spinal cord was broken, and he died on the following day. His wife was very badly hurt, and though in danger, is alive. If Petit had not cut the rope by an act of unintelligent devotion he would very likely have escaped, and his son would not even have touched the ground.

Through the kindness of General Myer we have received some further details concerning the extraordinary memory credited to the man in charge of the hat room at the Fifth Avenue Hotel, New York, referred to in Nature, vol. xxi. p. 562. He is an Irish-American about thirty years of age, Gilmartin by name, and has occupied his present position about a year. His sole duty consists in looking after hats during meal hours. The fact of his possessing a remarkable memory is indisputable, but still he is not looked upon as a prodigy by the hotel officials. They state that a Tommy Hart, now dead, who figured conspicuously in the "Stoke trial," was for a long time in charge of their hat-room, and was this man's superior as regards memory, and cited other instances of men now employed in different hotels throughout the country whom they consider his equals. It is very evident, however, that he possesses a wonderful talent for selecting the right hats, and mistakes are rare with him.

An occurrence, which may be partially or wholly attributable to the earthquake which Switzerland has recently undergone, is reported by the *Times* Geneva correspondent from Quarten, in the canton of St. Gall. A short time ago the people of the neighbourhood noticed signs of uneasiness about the Schnebelberg. The summit of the mountain appeared to be in a very precarious position, and it was feared that it might slip down and overwhelm the Schnebelwald, an extensive wood in the valley below. In anticipation of a possible catastrophe, great efforts were made to cut down and carry away as many trees as possible, though the men engaged in the work wrought at the peril of their lives. On Sunday fortnight, when fortunately there was nobody in the wood, a deafening report, like the firing of heavy artillery, resounded through the valley, and the mountain was hidden from view by a thick cloud of dust. When it dispersed, the Schnebelberg was seen to be shorter by a few metres, and the beatiful wood in the Murgthal has disappeared beneath a huge avalanche of stones and earth.

News from the Azores states that a disturbance of the earth has occurred in the island of St. George, resulting in the formation of another small island of about 18,000 square yards, and distant 600 yards from the shore.

It is stated that Col. Prjevalsky and his party are prisoners in the hands of the Chinese, who, it will be remembered, prevented him from proceeding to Lhassa.

From *Nature* **22**, 15 July, 252-254, 1880.

re-inserting them in the opposite orientation[7]. After inversion, some fragments that had been Chi^{+} become Chi^{-} and some Chi^{-} became Chi^{+}, while others showed no change in their phenotype. In all cases, though, the Chi^{+} phenotype showed the original leftward bias in stimulation of recombination. Clearly, reversing the Chi element does not lead to a reversal of the directional bias, which implies that some aspect of this bias is a property of λ and not of Chi. Nonetheless, the fact that the Chi^{+} phenotype is orientation dependent suggests that the Chi sites themselves are asymmetric nucleotide sequences.

Direct proof of this has come from the work of Gerry Smith and colleagues at Oregon[8,9]. They found the nucleotide sequence around the χ^{+} mutation in λ *cII* ($\chi^{+}C$) was strikingly devoid of any unusual structural features, such as obvious symmetrical regions, though they were unable, having determined the sequence of a single χ^{+} locus, to deduce the boundaries of the Chi site.

More recently, they have sequenced a second Chi site in λ (χ^{+} *B*, lying between *xis* and *redA*); comparison of this sequence with χ^{+}C sequence reveals a surprising extent of homology[10]. Within a region of 30 base pairs, there are 23 base pairs common to both sequences. The largest uninterrupted common sequence is 9 base pairs, with another common sequence of 6 base pairs to its left. Not only is the sequence asymmetric, but it may be that the nucleotide sequence of Chi sites is hyphenated, with regions of random base sequence separating specific nucleotide sequences. Such nucleotide sequences are found at the recognition sites of the Type I restriction endonucleases, and here too the asymmetry of the recognition site is reflected in the asymmetry of the restriction enzyme activity[11]. Again, though, the extent of the common sequence essential for the Chi^{+} phenotype cannot be identified; this will require the determination of the nucleotide sequence both of other Chi sites, particularly the *chi*$^{+}$ loci that occur naturally in *E. coli*, and of *chi*$^{-}$ revertants. Given the frequency with which Chi sites occur in the *E. coli* genome, if subsequent work shows them to have a complex, hyphenated sequence, this finding would argue both for a strong selective pressure for the maintenance of these sites and for their having a fundamentally important function. At present, although we know that Chi sites in *E. coli* DNA are capable of stimulating recombination when introduced into the λ genome, evidence that these sites perform a similar function *in situ* is circumstantial, at best.

Another major consideration is the mechanism by which Chi acts and the implications of that mechanism (be it confined to λ, or of more widespread application). Since, as noted above, we know that the stimulation of recombination by Chi^{+} is specific for the so-called *recBC* pathway, the underlying assumption is that Chi^{+} is recognised by a protein, so as to accelerate a rate-limiting step in the recombination process. The *recBC* pathway requires the activity of proteins coded by the *recA*, *recB* and *recC* genes (and possibly the *lexC* gene product as well); it remains possible that other, as yet unidentified, proteins are involved. We now think that the *recA* protein is involved in one or more of the early events in recombination, and probably promotes the formation of heteroduplex molecules[12]. We are less certain when (or how) *recBC* protein acts, although there is genetic evidence to suggest that it is involved late in recombination, perhaps in the resolution of heteroduplex DNA to form recombinant molecules[13]. Since it is thought that Chi also acts late in the *recBC* pathway[13] it seems more likely that the Chi nucleotide sequence is recognised by the *recBC* gene product than by the *recA* gene product. Disappointingly, efforts to show a specific interaction between Chi^{+} sequences and the *recBC* enzyme have been unsuccessful, although the problem is complicated by the diversity of the activities and mechanisms of the *recBC* enzyme[14,15].

Nonetheless, Stahl has offered a working hypothesis to describe the mechanism of Chi-stimulated recombination in phage λ, a component of which is that Chi is a specific site for the nucleolytic activity of the *recBC* enzyme[16]. Whether this idea is correct, and what its application might be to genetic recombination in other organisms, remains to be determined. □

The structure of zeolites

from L. V. C. Rees

ZEOLITES are silicates of sodium, potassium or calcium. There are two varieties of zeolites, with three dimensional cage-like lattice or open channel structure that allow zeolites to be used as 'molecular sieves'. The high-resolution electron microscope pictures of zeolites described in the previous issue of *Nature* (**286**, 111; 1980) were first revealed when a few early results were shown at two recent meetings.* The excitement they caused there undoubtedly arose from the ability of zeolite chemists to actually see the windows in the aluminosilicate crystals and not to be entirely dependent on the subjective interpretations of X-ray crystallographers.

Some of the most heated discussions took place among the small group of X-ray crystallographers who argued about the existence or otherwise of zero-coordinated cations in some zeolite structures and about the quality of the data presented by the respective X-ray groups[2]. The lack of large single crystals of zeolites was also bemoaned. It is, therefore, somewhat refreshing to actually observe the unit cells in these high-resolution microscope photographs and to find that Thomas and colleagues had to grind the 10-50 μm crystals down to smaller dimensions before they could be studied in the microscope! Not only can one now observe the apertures in these structures but we should be able to see the cations sitting in these windows when the resolution of the microscope is improved to 2.4Å and when zeolites which are known to contain cations in the apertures after dehydration are studied (for example, potassium form zeolite A).

High-resolution electron microscopy should also be of great help to zeolite chemists. Zeolites, when used as catalysts by the petroleum industry for the cracking of hydrocarbons, require to be frequently decoked at high temperatures. Much effort has gone therefore, in producing zeolites which are more thermally stable. The rates of vitrification in the electron beam described in the *Nature* paper by Bursill *et al.* should, hopefully, provide information on some of the factors which affect the thermal stability of zeolites. A method of treating zeolite Y to produce thermally, ultra-stable zeolite Y has been developed[3]. In this treatment aluminium ions are removed from the framework and deposited in the zeolite channels as hydroxoaluminium cations. Much doubt still exists as to the exact nature of these aluminium products and on the effect of the loss of the framework aluminium on

---

L. V. C. Rees is in the Department of Chemistry, Imperial College of Science and Technology, London.

*The British Zeolite Association met in Thornaby-on-Tees, 12–13 April, 1980 and the Fifth International Zeolite Meeting was held in Naples, 2-6 June, 1980.

0028-0836/80/290304-02$01.00

the crystallinity of the zeolite. High-resolution electron microscopy could possibly observe these hydroxoaluminium cations and, along with electron diffraction, the structure of the resulting framework could be ascertained.

Bifunctional zeolite catalysts are widely used for hydrogenation-dehydrogenation reactions. These catalysts contain the usual Bronsted and Lewis acid sites necessary to produce carbonium ions but also contain atomic platinum or other metallic elements in the zeolitic cavities. These metal atoms often diffuse from the cavities and aggregate on the surface of the zeolite crystals and the catalyst loses much of its effectiveness. High-resolution electron microscopy would be a useful tool to ascertain the factors affecting this aggregation process, provided the specimens display sufficient beam stability for adequate imaging to be performed.

Natural mordenites and synthetic mordenites are found to give the same X-ray diffraction patterns. From these X-ray studies the structure of mordenite has been determined. This zeolite has a main elliptical channel, running parallel with the *c* axis of dimensions 0.67 × 0.70nm. Natural mordenite, referred to as small-port mordenite, has an effective diameter of channel of ~ 0.4 nm while synthetic mordenite, called large-port mordenite has channels consistent with the proposed structure.

The absorbate molecules which can enter the natural mordenite channels are much smaller than the molecular which can be adsorbed in the synthetic mordenites. It has been suggested that a few fault planes in the natural mordenites would produce these results in this zeolite with a one-directional channel system. However doubts still remain as to the exact reason for this difference and it would be interesting to look at these two different forms using high-resolution electron microscopy.

The paper of Bursill *et al.* presents evidence of Si^{4+}/Al^{3+} ordering. This is another fascinating result of their studies. In a recent "Workshop on the Adsorption of Hydrocarbons in Zeolites" held in Berlin, Aldershaft from 19-22 November, 1979 Engelhardt *et al.* presented exciting results obtained by high resolution, magic-angle ^{29}Si n.m.r. which suggested that in a zeolite A which had an exact 1:1 ratio of Si:Al the majority of the Si ions in the framework were bonded through oxygens to three Al and one Si ions. Thus some Al-O-Al bonding must exist in this zeolite and Loewenstein's rule is not obeyed. Other confirmation of these findings can be found in the literature, for example four of the X-ray reflections in the paper by Pluth and Smith[4] do not comply with the Fm3c space-group proposed by these authors but are consistent with the Fm3 space-group which would exist if Si/Al ordering occurred in their zeolite A sample[5].

In the past many chemical analyses of zeolite A have found excess Al to be present in the material. To abide by Loewenstein's rule Barrer and Meier proposed[6] that some $NaAlO_2$ was occluded in the sodalite cages. However these new results suggest that this conclusion may not be necessary and we await further studies with great anticipation. ☐

Epidermal growth factor and mitogenesis

from Colin R. Hopkins

FOR exploring the interactions of hormones with their target cells epidermal growth factor (EGF) is an extraordinarily versatile probe. It can be loaded with radioactive, fluorescent, photoaffinity and even particulate labels without loosing its ability to find and follow its receptor. Because, in addition, it provokes a mitogenic response in the most widely used fibroblast cell lines EGF is currently the favourite of all labelled ligands.

The receptors for labelled EGF on cells cultured in low serum are of one class and randomly distributed[1-6]. On binding the peptide, the receptors aggregate and are then taken into the cell by endocytosis. The number and size of the receptor aggregates and the pattern of redistribution varies considerably in different systems and it is not yet clear if this is due to differences in the various kinds of EGF probe or to real differences in cell surface behaviour. Certainly the relationship between the degree of receptor occupation, the rate of receptor internalization and the strength of mitogenic stimulus is very complex. Thus, although only one class of EGF receptors appears to exist on most cells[7] several studies have shown that only a small proportion of the total population needs to be occupied for the maximum mitogenic response to be generated[8,9]. At low concentrations of peptide the rate of receptor internalization correlates well with mitogenic potency, but at higher concentrations internalization continues to increase proportionally but mitogenicity is much reduced[10].

Clathrin-coated pits, which play such a prominent role in low density lipo-protein uptake[11], play an important[3] and even exclusive[12] role in internalization of EGF in some cells whereas in others[5] uncoated pits seem to predominate. If coat components are found to play a part in either receptor attachment[14], or intracellular routing[15], then the differences may be functionally very important, perhaps relating to the selection of alternative intracellular destinations.

Ferritin-tagged EGF allows the identification of receptor complexes by electron microscopy[16]. After uptake, the complexes remain associated with the limiting membrane of the endocytosed vesicle until it becomes transformed into a multivescular body (MVB). The MVB forms when receptor-rich vesicles are pinched off from the limiting membrane of the vesicle into its internum. Within about 30 minutes the receptor-bearing vesicles disappear and the MVB transforms into a secondary lysosome containing free ferritin particles. This scheme neatly accounts for the earlier work of Das and Fox[9] who showed that the complete membrane bound EGF-receptor complex, and not just the EGF peptide, is degraded in the lysosome.

As the path of the EGF-receptor complex has been followed as far as the point of degradation, the crucial question is which step gives rise to the second messenger(s) responsible for mitogenesis. Is there a membrane based receptor-transducer mechanism acting near the beginning of the pathway, or is there a lysosomal 'activation mechanism' generating active fragments (cf Diptheria toxin[17]) acting near the end? Chemical modulations of the EGF-induced mitogenic response may help to choose between these alternatives although the most intriguing effects are induced by agents like amine compounds and colchicine, which have ill defined sites of action.

Among the more specific effects of these early stage modulators of EGF mitogenicity are those induced by phorbol esters[18,19] and glucocorticoids[20], which have been shown to alter the affinity of EGF receptors, and retinoids, which selectively increase the number of EGF

receptors available[21]. The importance of receptor aggregation has been indicated by the finding that cyanogen bromide-treated EGF which binds, but is poorly mitogenic, can be made considerably more potent when crosslinked with EGF antibody[22]. Here, the most straightforward interpretation — that potency is related to the number of occupied receptors able to aggregate and internalize — holds.

The effects of methylamine and colchicine, both of which enhance the potency of EGF without affecting the initial EGF-receptor interaction[23,24] are open to several interpretations. Methylamine seems capable of acting at two sites at least, since it has been shown to prevent the patching of rhodamine-labelled EGF (and prevent clustering into coated pits)[25] as well as reducing the rate at which EGF is degraded[26,27]. Studies using ferritin-labelled EGF show that concentrations of methylamine (10-30mM) which prevent visible patching of the fluorescent label allow some internalization of the EGF-receptor complex to occur[16]. It cannot be concluded, therefore, that the increase in EGF mitogenicity caused by methylamine is due solely to the prevention of internalization.

Ammonium compounds and amines have been shown to reduce EGF degradation so the potentiation of the mitogenic response seen with methylamine may be partly due to its action at the lysosomal level. The possibility that this is mediated by the inhibition of lysosomal hydrolase[28] has been removed by a study[29] in which leupeptin, the specific cathepsin B inhibitor, was used to inhibit EGF breakdown. While leupeptin retarded degradation so that EGF accumulated intracellularly the mitogenic response still correlated with the concentration of peptide in the medium. The effect of methylamine must, therefore, occur before the breakdown of the EGF-receptor complex. As an effect of amines is to reduce the formation of receptor-bearing vesicles within the MVB,[16] the vesiculation of receptor-rich membrane, either at the prelysosome stage, or at the plasma membrane seems a likely site for amine action.

A general mechanism, proposed by Maxfield[25] and Davies,[30] whereby receptor aggregation induced by monovalent ligands may be inhibited by agents interfering with transglutaminase, an enzyme capable of cross-linking adjacent glutamyl and lysyl residues, may explain the effects of methylamine. Methylamine is a strong inhibitor of transglutaminase at concentrations which inhibit patching of rhodamine labelled EGF[23] and as it readily penetrates cell membranes, it may act in a similar way at intracellular sites too.

These recent studies clearly show that the intact EGF-receptor complex is responsible for transmitting the mitogenic signal. The site of transduction is unclear, but the correlation between a reduction in the rate of degradation and enhanced potency suggests that the dismantling of the EGF-receptor complex and the termination of transduction are closely linked[24].

The role of endocytosis in the processing of the EGF-receptor complex remains unsolved. For the full mitogenic potency of EGF to be expressed, there is growing evidence that the target cell must be exposed to the peptide for periods of several hours[8,10,29,33] and thus the rapid rate at which receptor complexes are dispatched from the surface is particularly difficult to understand. All options must remain open, since at the present time there is no compelling reason why internalization should be regarded as an integral part of the transduction mechanism. Indeed, the possibility that signalling by the EGF receptor complex begins with aggregation on the cell surface and then continues throughout the lifetime of the complex is clearly worthy of serious consideration. □

The fenlands

from Peter Moore

THE fenlands of East Anglia have long provided a source of energy, in the form of peat, and a rich agricultural resource for the inhabitants of the area. Darby (*Medieval Fenland,* Cambridge University Press; 1940) collated much information concerning the exploitation of these lands and shows that as early as the 13th century peat was being cut for fuel in the fens. Drainage of the fens for agricultural development first became extensive in the 17th century, but it was not until the mid 19th century that the immense engineering problems involved in drainage were efficiently tackled. The installation of pumping machinery at that time led to permanent lowering of water tables and the full agricultural potential of the fens could be realized.

One consequence of drainage, which is evident even by casual observation, is the lowering of the land surface which has resulted from 'peat wastage'. Much of fenland now lies between -1.5 and -2.5m below Ordnance Datum, which means that the maintenance of low water tables in the soils requires the pumping of water into elevated drainage channels and rivers on its way to the sea. Despite the obvious nature of this development, however, there are no precise records of the rate of fall in the land surface, nor of the influence of various land use practices upon this rate.

The process of peat wastage has resulted from the gradual oxidation of surface layers as microbial activity has been stimulated by the lowering of soil water tables and the consequent removal of anoxic conditions. In addition, the peat has contracted in its structure as a result of drying and some has been lost by wind erosion, combustion and removal by man. Land use practices will have played an important part in influencing the rate of these processes.

Around 1848 (the precise date not certain) a cast iron post was sunk through the peat and embedded on wooden piles in the underlying clay at Holme Fen, 10 km south of Peterborough, and the history of this post has been the subject of research by Hutchinson (*J. Ecol.* **68**, 229; 1980), himself a civil engineer. When first established, the top of the post was flush with the peat surface and since that time many scattered observations and measurements have been conducted upon its progressive protrusion as the land surface fell. Hutchinson has collated these data and related them to records of the installation of new pumping machinery at various times and to variations in land use in the area.

The first drainage resulted from the

0028-0836/80/290206-02$01.00

construction of a channel in 1850. Within eight years, this gravity drainage system had produced a fall in the peat surface of almost 2m. A suction pump was then added, resulting in a further 0.7m fall over the next 20 years. This pumping was accompanied by the development of arable agriculture, which may have accelerated the surface lowering. A second pump, introduced in 1877 resulted in another rapid fall of a further 0.5m over the next ten years.

Agricultural depression then led to the abandonment of cereal growing over the site and the area was left as rough grazing and scrub game cover. No further lowering appears to have taken place until a further pump was introduced in 1920, but by this time a birch woodland had developed and, despite yet another pump being added in 1962, the total surface fall over the past century has been only about 0.7m.

The overall conclusions, therefore, are that the greater part of the fall in surface level occurred immediately after the introduction of drainage and can be accounted for simply on the basis of peat contraction as it dried, rather than by any loss of organic material. In the later stages of drainage, however, lowering was more gradual and was less closely related to improved drainage; here oxidation may have begun to assume the major role.

Of particular interest is the relationship between land use and shrinkage under constant drainage processes. The replacement of arable by pastoral farming resulted in a considerable deceleration of wastage. On the basis of this observation, Hutchinson questions the wisdom of the current emphasis upon arable farming in the fenlands. The conservation of these organic soils could, he claims, be more effectively achieved by keeping water extraction to the minimum acceptable level and by changing the agricultural emphasis to pasture. □

Cometary science

from M.K. Wallis

OBSERVATIONS of comets in the ultraviolet spectral region show great promise because most major components of the cometary coma (atmosphere) can be covered, instead of only dust and minor radicals such as CN and C_2.

Early in 1970, the first UV observations revealed huge atomic hydrogen comas, 15×10^6 km diameter in comet Bennett, fluorescing in H Lyα (1,216 Å). During the same period, observations at 1,304 Å and 3,085 Å showed that comas of atomic oxygen and the hydroxyl radical, though less extensive, were of comparable density. The relative proportions suggested H_2O as the unobserved parent molecule — and was seen as confirming the Whipple hypothesis of comets being 'dirty' ice conglomerates.

Comet Bradfield discovered last Christmas day, just after perihelion at 0.7 AU, is favourably placed for observation from the International Ultraviolet Explorer (IUE) satellite: Feldman *et al.* (*Nature* **286**, 132; 1980) have reported the first of a very promising series of results. Optically the comet appears small and unexciting, containing little dust and hardly a trace of an ion tail. But in the UV, it is remarkably similar to the two others, Comets West and Seargent, observed in this range (1,200–3,200 A) where H, O, CO, C, S, CS, OH, CO^+, CO_2^+ are identified. A high resolution scan of the OH (O, O) band is shown, the relative intensities of the components implying that the excitation is simply resonant fluorescent. Doubtless, a future detailed study will reveal some departure from purely resonant equilibrium, due to collisional disturbances of the populations as discovered in pioneering Liège studies of CN and CH bands (reviewed by Arpigny in *The Study of Comets NASA SP*-**393**, 797; 1976). Such investigations are delicate, requiring allowance for doppler shifts across a solar spectrum of high resolution. But with appropriate modelling they can give parameters hardly accessible except by a cometary space-probe, namely, the OH expansion velocity and density temperature of the colliding agents (H and e).

For inferring the rate of sublimation of H_2O from Comet Bradfield, there are some uncertainties, particularly those due to the expansion velocities of different components. Past authors have assumed different values and generally normalized on H rather than OH (Keller & Lillie, *Astr. Astrophys.* **62**, 143, 1978). After adjustment, the result for the new comet comes surprisingly similar to previous comets — less H_2O by a factor of 2-4, and only three times less than Comet Tago-Sato-Kosaka, a much more active and typically impressive comet. Given that outgassing from a single icy nucleus should vary as the surface area, it's rather suspicious that now five comets, adjusted to the same heliocentric distance, should have such similar rates of loss of H_2O.

The velocity of expansion of the inferred H_2O is unknown but taken by Feldman *et al.* as 0.5 or 1.0 km s^{-1}. Though uncertain, it's clear the velocity is well above the 0.25 km s^{-1} corresponding to ice subliming into vacuum at about 200 K. Arpigny's spectroscopic studies of CH confirm enhanced velocities (0.7-1.3 km s^{-1}) and also show that the temperature of the colliding agent is several hundred K. Clearly, cometary comas do not expand adiabatically into space, but are heated probably by the kinetic energy of fragments from chemical dissociation, such as photo-dissociation of H_2O releasing 2 eV per molecule (Shul'man *Dinamika kometnikh atmosfer* § 3.3; Kiev, 1972; Wallis, *Mon. Not. R. astr. Soc.* **166**, 181; 1974). This heat source more than compensates for adiabatic cooling and energy loss through rotational excitations of H_2O and other molecules in the bulk of the coma (Shimizu *Astrophys. Space Sci.* **40**, 149; 1976). The chemical energy would go primarily to H-atoms, being the light dissociation fragment. Its transfer to the heavier molecules, such as OH and H_2O is effected through collisions. Larger comets with larger collisional zones would have higher expansion velocities — if allowed for, this effect would increase the surprisingly narrow spread in derived outgassing rates.

Because the apertures of the IUE spectrographs were relatively small ($4.5\times9\times10^3$ km at the comet), the variation in intensity of the intense (O, O) band of OH out through the coma could be followed. Assuming velocities and transformation rates for the parent H_2O and the OH then allows deduction of the absolute production rates. For simplicity Feldman *et al.* use the Haser-Mokhnach model describing the transformation under steady radial expansion, but take the OH to have the 1.15 km s^{-1} velocity from photo-dissociation which should of course be isotropic in the local expansion frame. At large radial distances this simplification is acceptable (Wallis in *Cometary Missions* Remeis-Sternwarte Bamberg **12** (132), 97; 1979) but its use in the region of OH production ($3\text{–}10\times10^4$ km) means the result is rather uncertain. Unfortunately, as the H Lyα coma is optically thick in the central region, no comparable rate from the H production is derived. The only comet for which simultaneous H and OH results are available over an extended period is Comet Tago-Sato-Kosaka (Keller and Lillie *Astr. Astrophys.* **62**, 143, 1978). The aperture used there was much larger (2×10^5 km at the comet) and the 26 observations show two notable characteristics: the deived OH production dropped twice as fast as H during the first three days (comet moving from 0.78–0.84 AU) and the ratio of OH:H production over most of the observation period was 0.3 rather than the 0.5 expected if H_2O was dominant. As the authors commented, the uncertainty of the ratio is large, so future comparative results from Comet Bradfield will be of great interest.

M. K. Wallis is in the Department of Applied Mathematics and Astronomy, University College, Cardiff.

0028-0836/80/290207-02$01.00

Delsemme and Combi (*Astrophys. J.* **228**, 330, 1979) also suggested recently on the basis of their comet Bennett optical observations of the 'forbidden' oxygen transition [O I] 6,300 Å, that most of it cannot arise from H_2O or OH — perhaps photodissociating CO_2 produces the excited atoms O(^{1}D), but dissociative recombination of CO^+ could be an alternative source. However, CO^+ is found to be very weak in comet Bradfield's UV and optical spectra. Comet Bradfield's 'trans-auroral' line [O I] 2,972 Å detected by IUE is tentatively attributed to photodissociation of H_2O, but CO_2 or OH are more plausible; alternatively dissociative recombinations of CO_2^+ or OH^+ are energetically capable of giving the O(^{1}S).

Some years ago Vanysek and Wickramasinghe (*Astrophys. Space Sci.* **33**, L19; 1975) proposed that cometary particulates could be H_2CO polymers, this being more plausible on abundance grounds than the commonly assumed silicate grains. For interstellar grains, it seems now to be clear from the $3\mu m$ absorption feature that there can only be a small proportion of H_2O-ice, while general abundance arguments imply an organic composition (Whittet *Nature* **281**, 708; 1979; Hoyle & Wickramasinghe *Astrophys. Space Sci.* **69**, 511; 1980). So cometary scientists need to consider more carefully whether H_2O-ice really does constitute a major fraction of comet nuclei — the continuing IUE observations of Comet Bradfield could lead to a resolution of this fundamental issue. □

Natural Killer cells

from Rod Langman

NATURAL KILLER cells *in vitro* and *in vivo* was the theme of an Armand Hammer Cancer Workshop held at The Salk Institute, April 7-11, 1980. The three key questions that emerged from the discussions were, 1) Do NK cells show target specificity in killing? 2) Do NK cells operate as a tumour surveillance mechanism *in vivo*? 3) Have NK cells any other *in vivo* function?

NK activity can be specified by its lack of MHC restriction (which distinguishes it from T-cell killing) and the failure of anti-immunoglobulin reagents to inhibit it (which distinguishes it from ADCC or K-cell activity). Although it was thought that NK activity was tumour cell specific, there are now many exceptions to this generalization. It is now clear that there is some degree of specificity for particular cell lines or cell types, but it is not clear whether this is due to a difference in the target cells' ability to respond to NK lytic signals, or to a failure of the NK cells' ability to recognize the target, there being evidence for both possibilities.

The most convincing case of NK recognition specificity came from the cloned lines of NK cells described by Harvey Cantor (Sidney Faber Cancer Centre, Boston) which specifically kill target cells bearing a gp70 dependent determinant. Target cells not lysed by one NK clone could be rendered susceptible to lysis by infection with Moloney virus and killing by this NK clone could be inhibited by partially purified Moloney virus proteins. NK clones, which carry the Thy 1 and Lyt 5 markers, were derived from normal spleen after removal of Lyt 1$^+$ and Lyt 2$^+$ cells, and cloned in 'T-cell growth factor' medium. There were reports by Ron Herberman (NIH, Bethesda), Rolf Kiessling (Karolinska Institute, Stockholm), Hans Wigzell (Upsalla), and Noel Warner (University of New Mexico, Albuquerque) all showing that NK cells from different sources gave unique patterns of NK lysis on panels of target cells.

The Lyt-5 marker has proved valuable in Cantor's hands for dissecting the regulatory activity of interferon on NK cells. A selected Lyt-5$^-$, NK$^-$ cell population upon incubation with interferon gains the Lyt-5$^+$, NK$^+$ phenotype, and at the same time itself begins to release interferon thus providing a positive feedback control loop. The rapid growth of interest in the anti-tumour effect of interferon means that this kind of control will attract increasing attention.

The question of specificity as a function of the ability of target cells to resist NK lytic signals was raised when John Collins (Salk Institute, La Jolla) reported that NK resistant fibroblast cell lines could be rendered NK sensitive by the addition of cycloheximide before or during the NK assay. There was some discussion whether cycloheximide inhibited a 'repair' process operating in target cells, or an interferon induced protection of NK lysis. While neither explanation was entirely satisfying, there is little doubt that target cells vary drastically in their sensitivity to NK lysis.

John Collins also reported that NK activity might be relevant to tumour surveillance *in vivo*. Starting with fibroblast cell lines that had been transformed *in vitro* and found to be tumourigenic only in immune-deprived (thymectomised, irradiated, foetal liver restored) mice, he found that these lines were also NK sensitive. However, after passage through the immune deprived mice, the cell lines were tumourigenic in normal mice, and these tumours were now NK resistant. The immune deprived mice are deficient in NK activity at the time of tumour inoculation, but by 2-3 months these mice have half-normal levels of NK. The inability of these *in vitro* derived cell lines to grow as tumours in normal mice is closely correlated with acquired NK resistance. Reconstitution experiments in this system are in progress and may provide the best evidence to date that NK activity is indeed relevant to early surveillance against incipient tumours *in vivo*.

There were indications that NK activity might be involved in normal lymphopoiesis. Ross Basch (New York) presented preliminary evidence that the subpopulation of thymocytes killed by NK includes the large subcapsular cells which can 'home' back to the thymus in cell-transfer experiments. Rolf Keissling then emphasized the remarkable similarity between NK cells and those that cause hybrid-histoincompatibility (in some F$_1$ hybrid combinations, there is a failure of haematopoietic stem cells from one of the parental strains to repopulate irradiated F$_1$ recipients). Not only were the H-2D linked genetic controls and inhibitors of NK activity and hybrid-histoincompatibility essentially the same, but up to 20% of normal bone marrow cells can be killed by NK, although no data were available as to which bone marrow cells were killed. Jonathan Sprent (Philadelphia University) noted that in similar F$_1$ hybrid combinations, mature parental T and B cells fail to recirculate or function. These results, taken together, suggest the NK activity may in normal *in vivo* conditions play some part in regulating lymphopoiesis.

Throughout the meeting, it was difficult to avoid the impression that NK and killer T-cells were in some way related. Since NK lysis can be a property of both the killer and the target, there is a resemblance between restricted T-cell killing and NK. Consider in the case of NK activity a cell-surface marker protein that is essentially constant from species to species and is subject to modifications due to viral infection, or even transformation, of the cell. If the NK system had a small repertoire of receptors capable of recognizing modifications of the marker protein, it might represent a surveillance system, albeit rather unspecific and inefficient. One therefore wonders if the NK system is a relic which recalls a stage in the evolution of contemporary killer T-cells. In an immunodeficient animal such as the athymic Nude, this relic could still provide valuable protection in the absence of a fully functional T-cell immune system. □

Mid-Atlantic Ridge: zero-age geochemical variations between Azores and 22°N

H. Bougault*

Chief Scientist of the MAPCO Cruise, Centre Océanologique de Bretagne—BP 337, 29273 Brest, France

M. Treuil

Chief Scientist of the Project, Laboratoire de Géochimie Comparée et Systématique, 4, Place Jussieu, Tour 24/25 E3-75230 Paris, France

The MAPCO cruise of the RV J. Charcot sampled zero-age basalts along the Mid-Atlantic Ridge from the Azores Triple Junction to 24°N. Preliminary shipboard geochemical analyses together with earlier data show that some trace elements are not randomly distributed along the ridge. The latitude of the Hayes transform delineate two regions of rare earth element distribution: north from Hayes, is flat to light rare earth (or equivalent) enriched; south from Hayes, is light rare earth (or equivalent) depleted. These findings indicate large scale heterogeneity of the upper mantle.

THE IPOD program (International Phase for Ocean Drilling) has obtained many samples of igneous rocks from the ocean floor during the past five years. The studies related to this sampling and to samples collected by the more classical dredging method have provided many data which have been interpreted and discussed in terms of the fundamental processes of basalt genesis and the composition of the upper mantle. Some of these compositions are impossible to relate to one another by conventional magmatic processes of fractional crystallization, accumulation of crystalline phases and partial melting. In addition to these conventional processes, two main hypotheses have been proposed to account for the chemical heterogeneities in oceanic basalts that are observed at different scales. One of these hypotheses invokes magma mixing in one form or another; the second hypothesis assumes primitive heterogeneity of different source regions in the upper mantle. One interpretation does not preclude the other. Mixing, either of more or less fractionated liquids derived from the same source[1–3] or of liquids derived from different sources[4,5], is necessarily restricted to local areas. The mantle heterogeneity concept can also be considered as a large-scale (regional) property[6–9]. The research reported here is an attempt to examine regional heterogeneities along a portion of the Mid-Atlantic Ridge.

Area and techniques of analysis

The RV J. Charcot is equipped with a multi narrow-beam echo-sounding system (SEABEAM)[10] which produces a real-time bathymetric map of the sea floor. The system scans an area whose width, normal to the ship's track, is two-thirds of the depth. Because it allows the immediate observation of large scale structures and of fine scale features (20-m contour interval), the SEABEAM system permits relatively easy recognition of the rift valley and fracture zones (large-scale structures) and choice of a dredge site based on observation of fine scale features (such as, central high, volcano, steep slope). The objective of our analysis was to locate the inner floor of the central valley to dredge 'zero age' basalts. The rift valley area chosen for dredging was first surveyed by a track, approximately perpendicular to the ridge axis, roughly 30 miles long (15 miles to either side of the axis). This track was enhanced by a return profile located ~1.5–3 miles to the north or south of the initial crossing. In addition to providing information for dredging, each of these tracks constitutes data for structural interpretation. Dredge surveys and intermediate transits allowed us to obtain 54 transects of the ridge between 35°N and 24°N. Five profiles were made over each of three major transforms, Oceanographer, Hayes and Atlantis.

During this cruise, a new deredging system, 'active weight', was tried and used successfully. It is a percussion system: when the tension of the cable at the level of active weight, which is situated in front of the dredge, is approximately 3 tons, an impulse of 25 tons is communicated to the dredge. The system can act repeatedly at the bottom as it is reset by a return spring when no tension exists between the active weight and the dredge. Ten dredges along the ridge axis, with tracks of 0.5–1.5 miles, were attempted with this system and each dredge was half full to full of rocks. With this dredging method and with simultaneous use of SEABEAM, well positioned dredges can apparently be achieved with a minimum length of the dredge track, probably less than 0.5 miles.

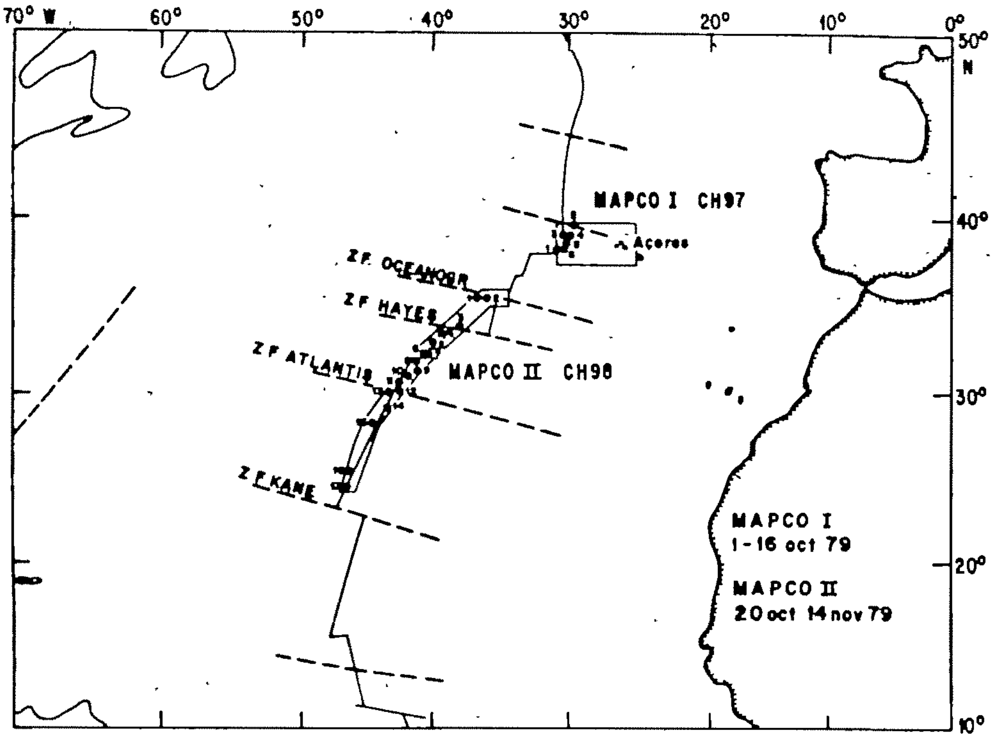

Fig. 1 Map of the studied area. Dots represent dredge sites

Thin sections were made on board and an X-ray fluorescence unit, similar to the unit used on board the Glomar Challenger[11,12], allowed us to obtain selected trace element and major element data. The precision of the data is comparable to that of an onland laboratory: ±1% (relative) for major elements and ±2 p.p.m. (absolute) for trace elements.

The primary objective of the first part of MAPCO (CH 97) was the structural analysis of the Azores Triple Junction between 39°N and 37°N (reported elsewhere); the primary objective of the second part of MAPCO (CH 98) and the secondary objective of MAPCO (CH 97) was to sample zero age basalts from the axis of the Mid-Atlantic Ridge The secondary objective of MAPCO (CH 98) was to collect bottom topographic profiles, with emphasis on examining the progressive increase in average depth of the rift valley floor from North to South along the ridge.

Results and discussion

Six dredges were attempted proximal to the Azores Triple Junction during MAPCO (CH 97) and four of these were successful, 17 dredges were conducted as close as possible to zero age during MAPCO (CH 98) and 16 were successful (Fig. 1). The morphologic nature of basalt samples recovered during both parts of the cruise is varied. Two-thirds of the total recovered material is comprised of pillow basalt; one-quarter is comprised of segments of glassy crust varying from 1 to 10 cm in thickness and up to 40 cm in length. The remainder of the material is comprised of small broken fragments. Most of the samples are remarkably fresh and have clean vitreous surfaces. The pillow basalts exhibit characteristic radial fracturing, glassy margins, and have very well preserved extrusive forms of lava fingers or tubes up to 15 cm long. The basalt crusts or sheets are glassy on both sides; the presumed upper portion of these crusts has a ropy appearance and the glass is occasionally oxidized and veneered by sediment, while the lower surface contains portions of thin vertical walls of large cavities (up to 20 cm diameter) and/or frozen droplets of basalt. In dredges CH 98 11 and 12 we recovered massive glass blocks up to 15 cm diameter, glass shards, and thin flat sheets (1 cm thick) of glass. The crusts or sheets are interpreted to be either fragments of large pillows or tubes that were rapidly emptied, or fragments of surfaces of lava lakes[13]. In addition to these basalt samples, scoriaceous basalts of probable subaerial origin were dredged at 900 m depth in the Azores Triple Junction area (CH 97 DR 05). One fragment of granitic metamorphic rock (garnet, cordierite) and a large number of blocks of sediment were recovered in dredge CH 98 DR 06 situated roughly 10 miles west of the rift valley axis.

Most of the basalt samples (two-thirds) are aphyric to subaphyric (phenocrysts <5%) Nearly all of these basalt fragments contain a few rounded plagioclase phenocrysts, possibly better referred to as xenocrysts, and one or two samples also contain rounded olivine phenocrysts. Microphenocrysts of euhedral olivine, quench olivine and plagioclase are all common. The remainder of the samples are porphyritic basalts (5–30% megacrysts, phenocrysts and/or microphenocrysts). Plagioclase is by far the dominant phenocryst phase; crystals are as large as 1 cm in length and are often rounded and partially reversely zoned. Some are better characterized as glomerocrysts. Most contain inclusions of glass or microcrystalline material. Olivine is a common, though usually minor, phenocryst phase. It is occasionally seen as rounded crystals up to 0.5 mm across but is generally subhedral to anhedral and fresh. Olivine contains rare small red-brown spinel. Clinopyroxene is observed infrequently as a phenocryst phase in these basalts, but is spectacularly present in dredge CH 97 DR 05 (in the Azores Triple Junction area) where it forms 15% of the rock

Extensive geochemical data from the northern region (Azores Triple Junction and FAMOUS area) and the southern

Table 2 Duplicate analyses of three samples of CH 97 DR 02—Sr, measured from the same pellet preparations as for Nb, Zr and Y determinations, has been used to improve the classification of rock types within one dredge, because of its relative higher precision, Ti was measured from a glass disk preparation

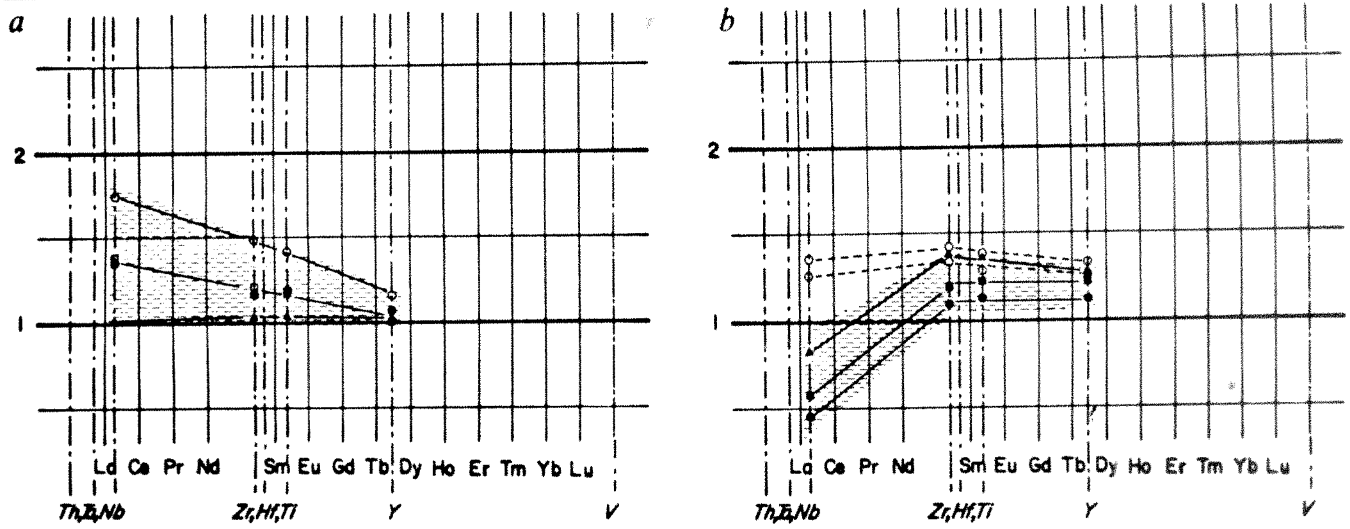

Fig. 2 Examples of extended rare earth diagrams including non rare earth hygromagmaphile elements. *a*, The spectrum observed in the Azores Triple Junction–FAMOUS area (data from refs 14, 16, 17, 23, 25); *b*, 22°N (data from refs 18, 19, 23). The preferred normalizing abundances corresponding to non rare earth elements are, in p.p.m.; Th, 0.028; Nb, 0.53; Ta, 0.031; Zr, 5.13; Hf, 0.128; Ti, 460; Y, 2.16; V, 22. In *a*, flat to light rare earth patterns, Nb, Ta and La plot at the same ordinate position (normalized Ta/La or Nb/La ratios are ≃1.09); *b*, light rare earth depleted patterns, Nb and Ta plot at a lower ordinate position than La (normalized Ta/La ratio is ≃0.5) see text.

region (22°N) have been interpreted as suggesting that there are significant differences in the isotopic compositions and trace element chemistry of the upper mantle sources between these two areas[14–20]. Table 1 summarizes these data for the FAMOUS area and 22°N (ref. 21). Clearly from our present knowledge only isotopic data obtained from basalts can be interpreted unambiguously in terms of mantle sources. Hygromagmaphile element ratios such as Hf/La (similar to Zr/La or Sm/La) in basalts depend on both mantle source and partial melting. The two different ranges of Hf/La in the FAMOUS area and at 22°N are interpretable in terms of different mantle sources (one for each region) in agreement with the isotopic data. The range of this ratio in each area is probably due to different extents or ways of melting[22,23]. As the main target of the MAPCO cruise is the examination of regional heterogeneities along a portion of the Mid-Atlantic Ridge, namely the transition between the Azores Triple Junction–FAMOUS area and 22°N, selected hygromagmaphile elements or their ratios can help, at least in part, to describe these heterogeneities or this transition.

It has been shown for some samples that elements whose ions present a rare gas electronic structure can be included in the rare earth Coryell–Masuda plot[24,25]; a comparative geochemical study of more than 300 oceanic basalts showing different rare earth patterns gave precise normalization values and relative behaviour of non rare earth hygromagmaphile elements compared with rare earth elements[26]. Figure 2 presents such a diagram for samples from the Azores Triple Junction–FAMOUS region and from 22°N (refs 14–19, 23, 25).

In the northern region the extended rare earth patterns are from flat to light rare earth enriched (Azores Triple Junction, FAMOUS, Sites 411, 412, 413 and 332, 334, 335 of DSDP);

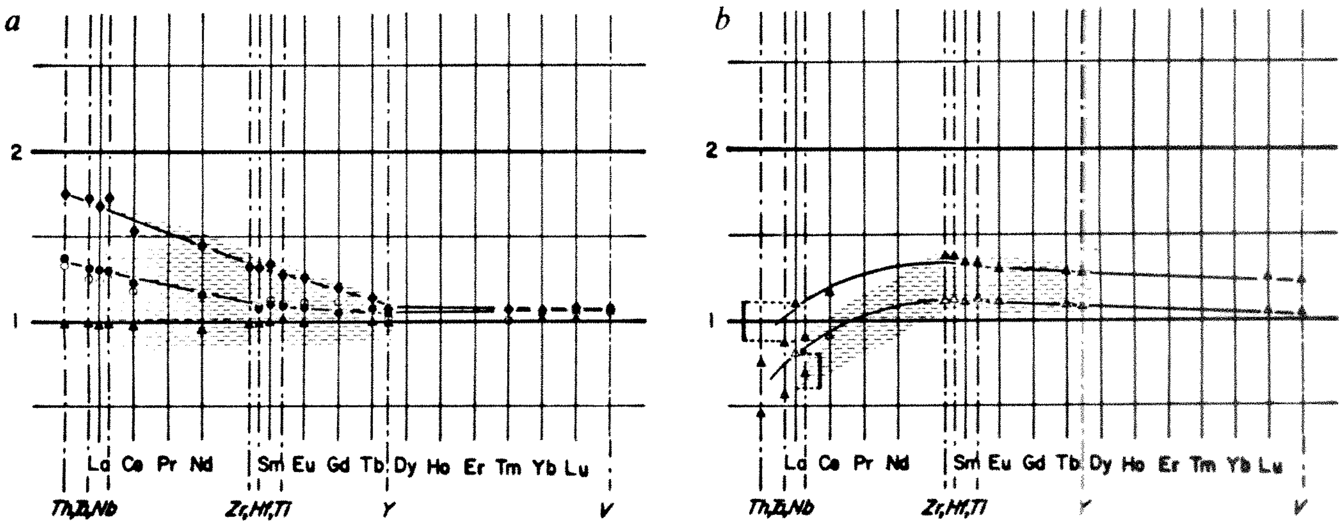

Fig. 3 *a*, Spectrum of non rare earth normalized patterns observed north from the Hayes transform. The end members of this spectrum are CH 97 DR 03 101, 39°N in the Triple Junction (○) and CH 98 DR 03 201, 33°N immediately north from Hayes fracture zone (FZ) (▲). The □, CH 97 DR 05 3.. at 38°N, ● CH 98 DR 02 1.. at 35°N (immediately south from Oceanographer FZ) have been chosen as examples showing similar distributions at different latitudes in this area. *b*, Spectrum of non rare earth normalized patterns observed south from Hayes transform. The plotted samples selected for examples are CH 98 DR 04, 33°N immediately south from Hayes FZ (●), CH 98 DR 07, 32°N (■) and CH 98 DR 17 301, 24°N (▲). The two exceptions (○) correspond to two groups in dredge CH 98 DR 08 at 31°N.

the normalized Ta/La or Nb/La ratio ($\simeq 1$) is independant of the light rare earth enrichment (as well as for 45°N, site 410, and Reykjanes sites 407, 408 and 409). In the southern region (22°N) the extended rare earth patterns are systematically light rare earth depleted; the normalized Ta/La or Nb/La ratio is 0.5. Knowing this behaviour of hygromagmaphile elements, rare earths and non rare earths, it is possible to use Nb, Zr, Ti and Y concentrations measured through X-ray fluorescence on board to obtain chondrite normalized diagrams equivalent to a rare earth diagram. The data may be interpreted in terms of mantle heterogeneity if these diagrams show sufficiently large differences as we know that a range of Sm/La or Zr/Nb ratios can be observed within a restricted area (FAMOUS and site 411, 412, 413 of DSDP).

Table 2 shows duplicate analyses of samples CH 97 DR 02 used to test the accuracy of measurements on board. Table 3 shows from north to south the results obtained during the cruise. Examination of these data indicates that the distribution of these elements is not random along the axis of the Mid-Atlantic Ridge as mentioned for rare earths by White and Schilling[27]. Nb concentrations, the most hygromagmaphile element investigated, clearly show lower values in the southern region than in the northern region. The range of variation of (Nb, Zr, Ti, Y) chondrite normalized patterns are shown in Fig. 3. North from the Hayes transform these patterns are flat to Nb enriched (equivalent to light rare earth enriched); south from the Hayes transform they are Nb depleted (equivalent to light rare earth depleted); one exception in the southern region is observed in CH 98 DR 08 where two groups of samples show flat or only slightly Nb depleted patterns.

The large difference of the chondrite normalized plots of Nb, Zr, Ti and Y (equivalent to rare earth plots) between north and south from Hayes transform allow us to interpret these preliminary results in terms of regional mantle heterogeneity. The suggested limit (latitude of the Hayes transform) will have to be confirmed by isotopic data. It will be also interesting to study the Ta/La ratio between the Hayes transform and 22°N to confirm whether or not the single normalized Ta/La ratio found so far ($\simeq 0.5$) for light rare earth depleted material comparatively to the single value ($\simeq 1$) observed for flat to light rare earth enriched materials.

The MAPCO cruise was supported by the Groupe Croute Océanique du Comité IPOD—France, the CNRS and CNEXO. We thank J. Bonnin for help in formulating this program and D. Needham for assistance with the cruise plan. The active weight system used during the cruise was developed by J. P. Allenou with the support of J. Y. Bervas. We also thank the Captain, the officers and the crew of the RV J. Charcot. Contribution no. 685 from the Departement de Geophysique, Géologie et Géochimie marines du C.O.B.

Flow patterns in the central North American ice sheet

W. W. Shilts

Terrain Sciences Division, Geological Survey of Canada, 601 Booth Street, Ottawa, Canada K1A 0E8

Patterns of glacial dispersal of lithologically distinctive erratics around Hudson Bay show the central portion of the North American Laurentide ice sheet to have been made up of at least two land-based centres, one that grew and dissipated in Keewatin, and one that grew and dissipated in Nouveau Quebec–Labrador.

AN accurate model of the flow patterns of the central portion of the North American ice sheet is of fundamental importance in reconstructing the palaeogeography of northern North America for the past million or more years. The configurations of the margins of the Laurentide sector of the Wisconsinan ice sheet during the last 10,000 yr of its existence have been detailed satisfactorily, but inferences about the ice flow patterns during glacial maxima and locations and growth mechanisms of centres of glacial outflow have been hampered by a paucity of data from the Canadian Arctic and sub-Arctic. Most inferences on these earlier events have been drawn indirectly from geophysical data, from limited isostatic data on raised and tilted lacustrine or marine shorelines, and from broad, large-scale reconnaissance mapping of glacial features (largely by airphoto interpretation).

Over the past decade much relatively detailed information has been obtained on the lithological character of glacial sediments, the orientation of ice-inscribed or ice-moulded features, and on the general stratigraphic framework of glacial sediments around Hudson Bay. These data, by defining paths of glacial transport of distinctive bedrock lithologies, permit the postulation of several constraints on timing and configuration of glacial flow for the central parts of the Laurentide ice sheet (at least as it was constituted during the Wisconsinan). These constraints have lead to a preliminary model for glacial flow that conflicts with many aspects of recently published ice sheet reconstructions[1–3]. Furthermore, although the model is crude, its gross features are unequivocal and are sufficiently accurate to use as a basis for speculating on the configurations, palaeoclimatological conditions and dynamics of the last Laurentide ice sheet.

The data on which the maps and conclusions of this article are based are principally the petrological compositions of till and related sediments from: (1) the Hudson Bay Lowlands and adjacent areas of the Canadian Shield; (2) southern District of Keewatin; and (3) Coats and Mansel Islands (Fig. 1). The petrology of tills has been characterized by determining the percentages of several distinctive pebble lithologies in the 2–6-mm fractions of $\sim$1,200 samples of surface and older tills. Pebble lithologies and geochemical and mineralogical dispersal patterns were noted for a further 7,000+ samples of till collected in southern District of Keewatin[4–6]. Field observations of erratic types present at each of several hundred localities throughout these regions have been integrated with the quantitative data, as have pebble lithologies of glacial or related bottom sediments collected from Hudson Bay by C. F. M. Lewis and B. V. Sanford.

The petrological data are supported by observations of orientations of ice-inscribed or ice-moulded features compiled or generalized from the Glacial Map of Canada[7], from measurements of striation directions on boulders or boulder pavements in tills exposed in stratigraphic sections in the Hudson Bay Lowlands, and from measurements of orientation of striations on bedrock, of fluting, and of minor moraine or drumlins within a 200,000-km^2 area where detailed mapping of surficial geology has been carried out in southern Keewatin and on Coats and Mansel Islands.

Bedrock sources of erratics around Hudson Bay

Figure 1 shows the locations of the major geological domains within and around Hudson Bay. The older Precambrian terrane is largely underlain by non-calcareous, crystalline gneiss and igneous intrusive rocks. These 'crystalline' rocks include major belts of deformed, metamorphosed volcanogenic and associated sedimentary strata that generally retain some of their original lithological characteristics.

Superimposed on the 'crystalline' terrane are belts of Proterozoic sedimentary and volcanogenic rocks that are generally much less affected by metamorphism and which contain lithologically distinctive facies. One of these, the Dubawnt Group[8], comprises a sequence of generally red sedimentary and volcanogenic formations that underlie an area of several tens of thousands of square kilometres west and south-west of Baker Lake.

Another Proterozoic depositional basin, the Circum-Ungava geosyncline[9], forms an almost continuous belt of sediments, including locally significant occurrences of iron formation, basic volcanic rocks, and basic or ultrabasic igneous rocks. The sediments of that part of the basin in and adjacent to Hudson Bay are predominantly dark grey to black greywackes, slates, various facies of iron formation, and minor dolomitic units.

A thick sequence of gently dipping, unmetamorphosed Palaeozoic carbonate rocks with minor clastic facies underlies much of Hudson Bay and extends for several hundred kilometres on land south and south-west of the Bay[10].

Because of the distinctive lithological differences among the erratics derived from each of these major geological domains, pebble lithologies in the tills around Hudson Bay are grouped into four general and easily defined categories. For convenience, these four types of erratics will be referred to as crystalline erratics, red erratics, dark erratics, and carbonate erratics, in order of the above discussion of their source areas.

Outcrop patterns of these four lithological types are such that by mapping the areal distribution of the glacial erratics derived from each, one can place constraints on the glacial flow paths that must have prevailed during transport of the erratics from their source outcrops. In this way flow lines can be generalized for the central part of the Laurentide ice sheet. By establishing patterns of dispersal of erratics for the surface drift, and by comparing lithologies of older glacial deposits with the youngest, inferences bearing on the similarity or dissimilarity of flow patterns for older glacial events may be

0028–0836/80/290213–06$01.00

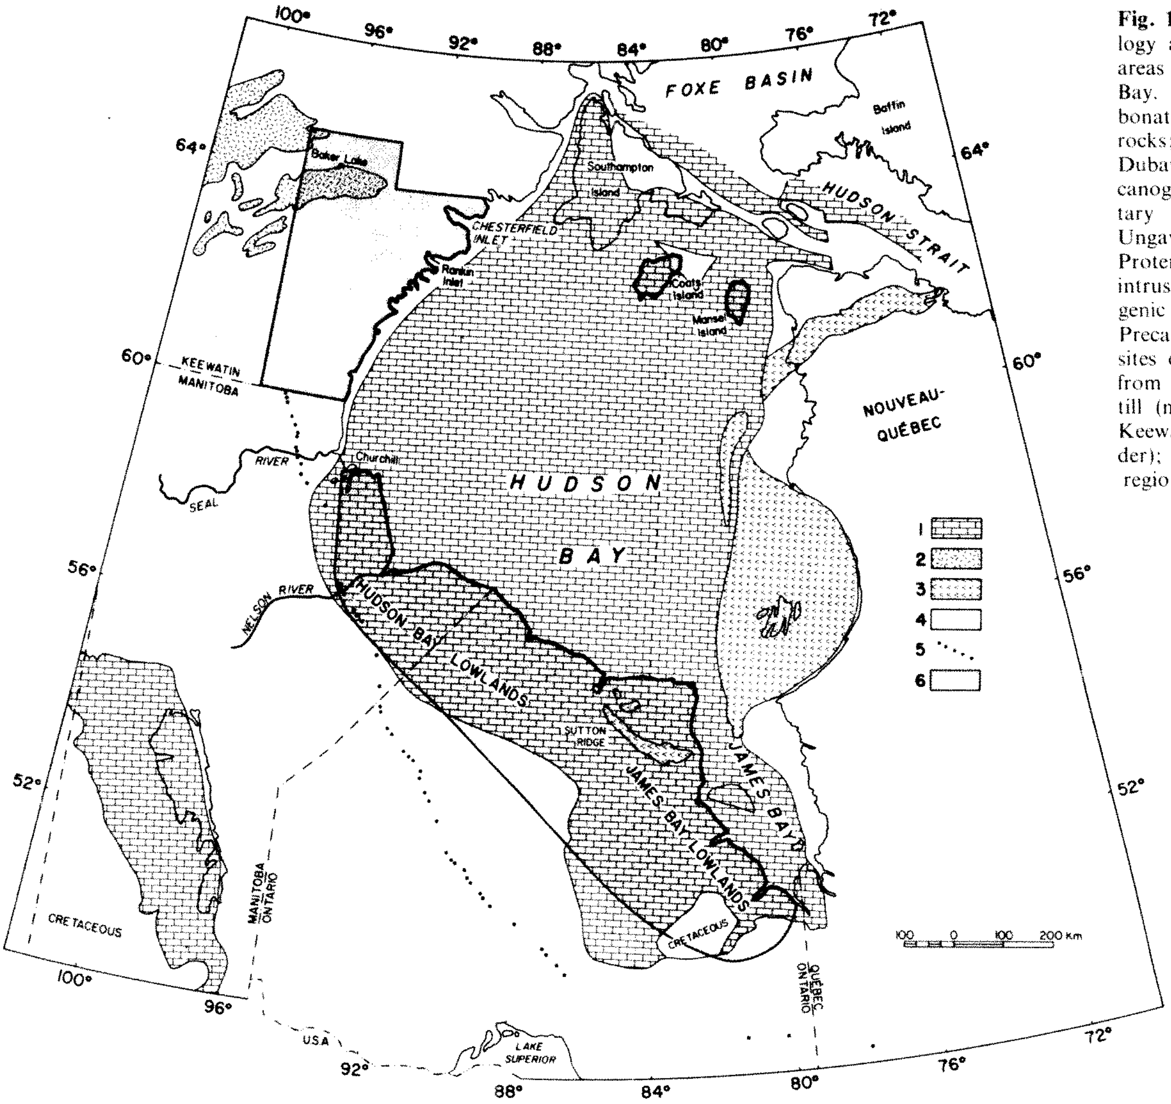

Fig. 1 Generalized geology and principal study areas around Hudson Bay. 1, Palaeozoic carbonate and minor clastic rocks; 2, Proterozoic Dubawnt Group, red volcanogenic and sedimentary rocks; 3, Circum-Ungava geosyncline, Proterozoic sedimentary, intrusive, and volcanogenic rocks; 4 crystalline Precambrian terrane; 5, sites of samples collected from boreholes through till (not shown north of Keewatin–Manitoba border); 6, principal study regions discussed in text.

Library SCIENCE COLLEGE

evaluated. Furthermore, by documenting the distance travelled by erratics during any one glacial event, one can make rough calculations of the time required for the distance of transport, as has already been done for the Dubawnt (red) erratics mapped on the mainland west of Hudson Bay[11].

Dispersal patterns around Hudson Bay

Dispersal of Carbonate erratics: south and south-west of Hudson Bay, carbonate erratics have been displaced hundreds of kilometres westward and southward onto crystalline Precambrian bedrock (Fig. 2). Carbonate erratics (20–30%) have been found in the fine gravel fraction of fine-grained, calcareous till 250 km from the nearest carbonate outcrops. The northern limit of westward carbonate dispersal is sharply defined in the vicinity of Seal River, just north of Churchill, Manitoba (L. A. Dredge, personal communication). Till from boreholes drilled north of Seal River bears no Palaeozoic carbonate erratics and has a non-calcareous matrix at least as far north as Chesterfield Inlet. South of James Bay, the Ontario–Quebec border (long. 79°30′) roughly divides the area of carbonate dispersal to the west from the area of non-calcareous drift to the east. Other than in the area of the late glacial Cochrane readvance, south-east of James Bay, no evidence has been found of eastward dispersal of Palaeozoic erratics east of James Bay or Hudson Bay (refs 12–14, and J. S. Vincent, personal communication). The rare Palaeozoic and Proterozoic erratics found east of the Bay and cited by Lee[15] as evidence of eastward dispersal are confined to zones of postglacial marine submergence and were undoubtedly emplaced by some form of ice rafting[13].

Although calcareous Palaeozoic debris could have been displaced eastward or westward from ice centred on Hudson Bay at some earlier time and could have been eroded and transported back into or across the Bay during later flow from Quebec or Keewatin centres, one would expect that at least some of the calcareous debris would have been left behind to be incorporated into the drift that now covers the areas adjacent to Hudson Bay. Certainly in other areas, where later ice flow has been at considerable angles to earlier flow, some components of the earlier flow have been left behind, although their frequencies are attenuated and their dispersal patterns modified. Such relict evidence of earlier dispersal has been observed in southern Keewatin[11] and in the Appalachian region of southern Quebec[16] where later major ice movements have not completely effaced earlier dispersal patterns.

Dispersal of dark erratics: dark grey to black sedimentary and volcanic rock fragments are widely distributed in drift throughout much the same area as that covered by till rich in carbonate erratics (Fig. 2). Isolated observations of dark erratics, iron formation and jasper have been interpreted[17,18] to indicate a source within the Circum-Ungava Proterozoic sequence that both underlies the eastern part of Hudson Bay and projects through the Palaeozoic cover in the Sutton Ridge[10]. V. K. Prest (personal communication, 1979) has noted widespread occurrence of dark erratics and oölitic jasper erratics in northwestern Ontario at least 1,000 km west of their nearest possible Proterozoic sources in association with fossiliferous Palaeozoic carbonate erratics over 600 km west of their nearest source. Dark erratics and associated iron formation commonly comprise 10–20% of the erratics (2–6 mm) in tills lying on Palaeozoic outcrops west and southwest of Hudson and James Bays. West of Hudson Bay, dark erratics are rare (generally ⩽5%) north of Seal River, and those that are found could reasonably be related to local sources within greenstone belts. Dark erratics make up at least 50% of the Precambrian erratics on Mansel Island and are found there in association with haematite–magnetite iron formation and other erratics which are common lithologies within the Circum-Ungava geosyncline[9]. Dark erratics are found on the east coast of Coats Island but are uncommon west of there.

Dark erratics are also found in older tills in numerous exposures throughout the Hudson Bay Lowlands and in a series of 6–20-m deep boreholes drilled in multiple tills overlying crystalline terrane west of the Lowlands. At given sites within the Lowlands, the concentrations of dark erratics (and also crystalline erratics) are generally similar among till sheets, including till sheets which predate the last interglacial stage[19,20].

Dispersal of red erratics: the pattern of dispersal of red erratics has been discussed in detail elsewhere[11] for that portion of the district of Keewatin east of the Keewatin ice divide. No red erratics occur north of a south-east-trending line from Baker Lake to the coast of Hudson Bay, just north of Rankin Inlet. In this region a well-developed southeastward-trending dispersal train of red erratics is superimposed on a poorly defined southerly train created during an earlier glacial flow event. Red erratics comprise 1–2% of the fine gravel in eskers and till on Coats Island. Distinctive cobble and boulder-size fragments of the red Pitz and Christopher Island Formations of the Dubawnt Group are numerous on Coats Island and can be ascribed confidently to outcrops that occur exclusively within a 100 km long belt that extends southwestward from the east end of Baker Lake (A. N. Lecheminant, personal communication).

No red erratics were found on Mansel Island, nor were they found in till-like bottom sediments from the floor of Hudson Bay between Coats and Southampton Islands. Red erratics comprise 1% of the gravel fractions of till samples near the Manitoba border, but no certain red erratics have been found as far south as Churchill. Although the true pattern of dispersal of red erratics between the Keewatin mainland and Coats Island is poorly known, the main part of the dispersal train seems to narrow northwards and to make at least a 90° bend, a configuration confirmed by the pattern of distribution of red erratics in till-like sediments from the bottom of Hudson Bay.

Dispersal of crystalline erratics: crystalline erratics are found virtually everywhere that it has been possible to make observations in the region covered by Figs 1 and 2. Crystalline erratics make up ~10% of the gravel fractions of all tills sampled in the southern Palaeozoic portion of the Hudson Bay Lowlands and make up 20% or more of the gravel-sized erratics occurring in tills from Hayes River–Nelson River northward. Crystalline erratics make up the bulk of the Precambrian erratics on both Coats and Mansel Islands. In the

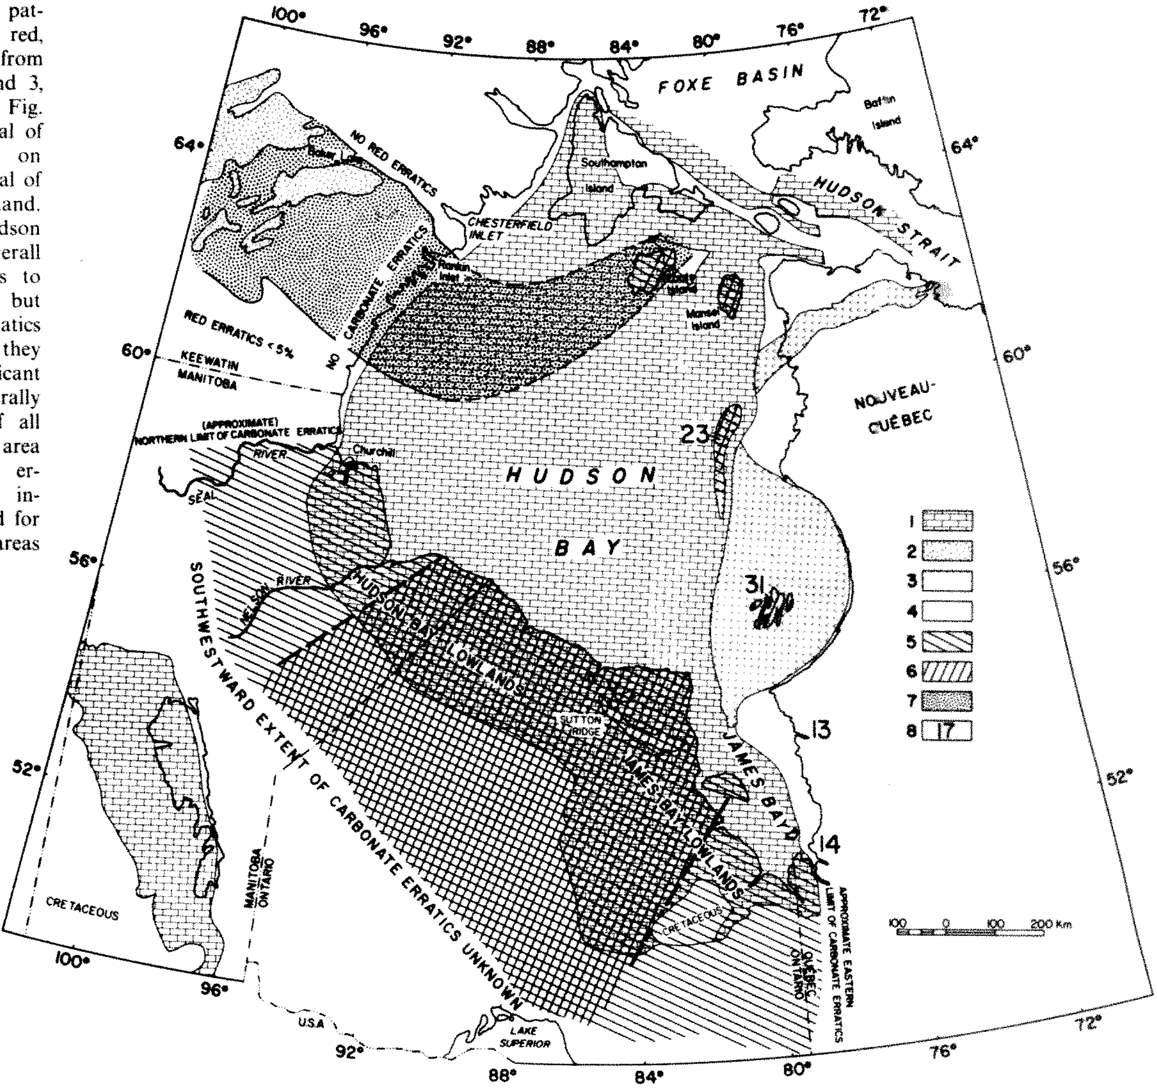

Fig. 2 Dispersal patterns of carbonate, red, and dark erratics from source areas 1, 2 and 3, respectively. 1–4, as Fig. 1; 5, area of dispersal of carbonate erratics on land; 6, main dispersal of dark erratics on land. South-west of Hudson and James Bays overall dispersal corresponds to carbonate pattern but dispersal of dark erratics is only shown where they make up a significant proportion, generally more than 15%, of all erratics; 7, principal area of dispersal of red erratics; 8, numbers indicate references used for data on erratics in areas indicated.

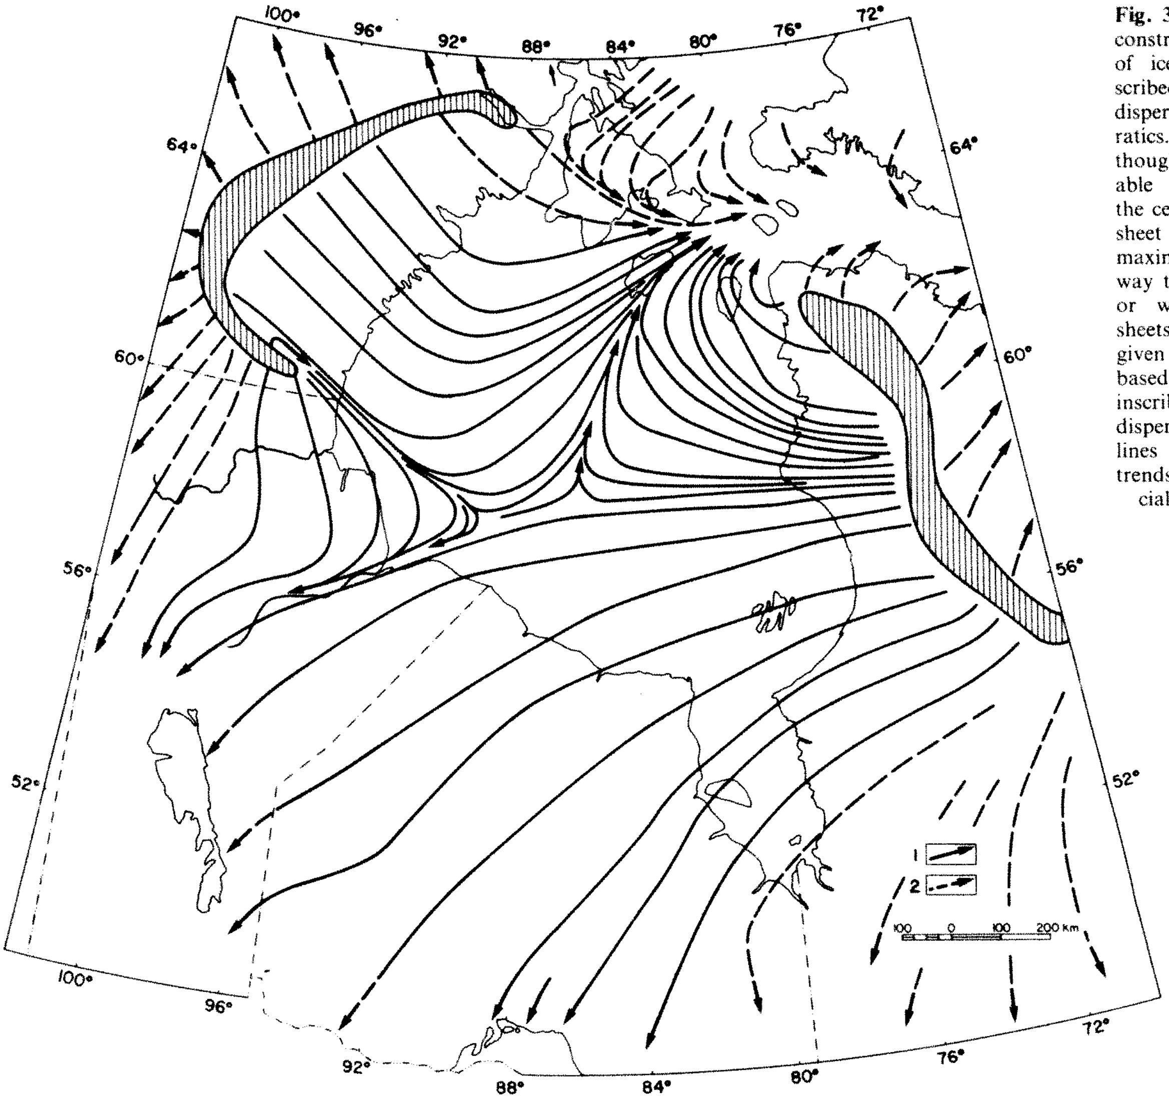

Fig. 3 Ice flow lines reconstructed from trends of ice moulded or inscribed features and from dispersal patterns of erratics. Although this is thought to be a reasonable reconstruction for the central part of the ice sheet at the last glacial maximum, there is no way to tell precisely how or where the two ice sheets interfaced at any given time. 1, Flow lines based on ice moulded or inscribed features and on dispersal patterns; 2 flow lines based on ice flow trends shown on the glacial map of Canada[7].

regions underlain by crystalline bedrock, crystalline erratics generally make up more than 95% of the gravel fraction, except down-ice from major dispersal areas of more erodable, less metamorphosed outcrops, such as the Palaeozoic carbonates or Dubawnt red beds.

In the district of Keewatin, geochemical and mineralogical dispersal patterns from several mineralized or mineralogically distinctive bedrock sources within the crystalline terrane east of the Keewatin ice divide invariably indicate eastward or southeastward glacial transport towards Hudson Bay.

Directions of flow from striation measurements

Numerous observations have been made (refs 19, 20 and B. G. Craig, unpublished data) of southwesterly oriented striations on boulder pavements within or between till sheets and on bedrock throughout the southwestern part of the James Bay and Hudson Bay Lowlands. Skinner's data clearly show that all tills preserved south-west of James Bay, including pre-Missinaibi (pre-Sangamon) tills, were deposited by glacier ice flowing from east-northeast. An exception to this general flow pattern is an area of clay-rich till associated with southeasterly oriented drumlins and striations that were probably formed during the Cochrane readvance[21], a southward and eastward late glacial surge. Observations[19,20,22] of southeasterly oriented striations on till stones and on Precambrian bedrock near the western edge of the Hudson Bay Lowlands from Churchill to the Ontario–Quebec border indicate that although southwesterly flow dominated all glaciations of this region, at some time during at least one glaciation, ice flow was southerly to southeasterly.

Hardy[14], among others, has shown that striations preserved in the eastern part of the Hudson Bay Lowlands invariably indicate ice flow westward or southwestward toward Hudson Bay. Andrews and Falconer[23] show that ice flow across the Ottawa Islands in the east-central part of Hudson Bay varied from northeastward to westward.

On Coats and Mansel Islands several directions of striae and fluting were noted, most being northward or northeastward, sub-parallel to the long axes of those islands. On Coats Island, however, the last direction of ice flow was eastward, presumably directly from Southampton Island or northern Keewatin.

In areas outside those discussed above striation directions are known or assumed to be similar to the main trends shown on the glacial map of Canada[7].

Discussion

Traditionally, the concepts regarding the configuration of the central part of the Laurentide ice sheet have been derived largely from observations of the amount of isostatic uplift of marine and lacustrine shorelines and from gravity data that seem to indicate that a significant amount of isostatic adjustment has yet to be made over Hudson Bay. These data have led to the belief that the locus of greatest ice loading, and hence the centre of glacial outflow at the maximum development of the last Laurentide ice sheet, was over Hudson Bay itself, notwithstanding the abundant glacial geomorphological evidence from regions adjacent to the Bay, all of which indicates ice flow radially away from centres of dispersal located in Keewatin and Nouveau Quebec. The terrestrial centres or ice divides have been explained as late glacial phenomena[24], formed when marine waters split a Hudson Bay ice dome into eastern and western segments with concomitant readjustment of ice flow patterns. Thus, the geomorphological features were thought to have been formed during the last 2,000–4,000 yr of the ice sheet's existence.

However, the time-transgressive nature of marine limit[11] combined with significant amounts of restrained rebound[11,25] in areas of marine inundation make interpretation of maximum uplift data difficult around Hudson Bay. In addition, recent measurements of marine limit on southeastern Southampton Island (124–157 m)[26], Coats Island (124 m) and the Ottawa Islands (156–163 m)[23] are lower than would be expected if the northern or north-central part of Hudson Bay had been loaded more heavily than adjacent areas on land. Vincent and Hardy[27] have shown convincingly that lacustrine strandlines which predate the marine incursion south-east of James Bay, are tilted upward towards a centre of uplift in Nouveau Quebec and not towards a centre over Hudson Bay as would be expected if an ice dome had existed there.

Although there is no firm evidence relating to the origin of the gravity anomalies that are found in parts of Hudson Bay, crustal blocks within the Bay seem to be in equilibrium with their adjacent terrestrial counterparts[28], suggesting that the anomalies may be in part a permanent feature of the crust under the basin.

From the above dispersal and geomorphological data, a map (Fig. 3) has been prepared showing probable flow directions in the central part of Laurentide ice sheet near a glacial maximum, but at an unspecified point in time.

The dispersal patterns of Fig. 2 show that an ice dome or domes could not have existed in the Hudson Bay basin unless some special conditions existed, such as the presence of a melt lake[3] or a frozen bed under the central portion of the ice sheet. Such conditions would have prevented erosion and transportation of the Palaeozoic carbonate rocks from beneath the Bay. Two facts that argue against special conditions are the consistent eastward dispersal patterns from distinctive sources in the crystalline terrain east of the Keewatin ice divide, well above and west of the central depression, and the abundant evidence of repeated episodes of intense erosion of the Palaeozoic and Proterozoic rocks that underlie the southern half of the Hudson Bay depression. The configuration of erratic dispersal patterns suggests, rather, that independent ice masses existed on either side of Hudson Bay.

The well defined northern limit of westwardly displaced carbonate lithologies along the Seal River in northern Manitoba indicates that ice from the Quebec centre never affected the western shore of Hudson Bay north of that river. The presence of red erratics on Coats Island and their absence on Mansel Island indicates that ice from a Keewatin centre was confined to the western portions of Hudson Bay, but the presence of dark erratics on Coats Island suggests that at some time ice from a Quebec centre flowed at least as far west as Coats Island. In any case, the dispersal patterns at the mouth of the Bay indicate that terrestrial ice flow centres were established well before marine waters divided the ice sheet. The lack of carbonate erratics east of Hudson Bay supports the interpretation that the pattern of westward dispersal of carbonate and dark erratics west and south-west of Hudson Bay was not related to a centre of dispersal within the Bay but to a centre on land to the east.

The general picture conveyed by the reconstruction depicted in Fig. 3 is one of independent Quebec and Keewatin ice masses in contact along discrete zones. The zone of contact in the northern part of the Bay was more or less between Coats and Mansel Islands. The contact zone depicted through the Hudson Bay Lowlands could have been as far north as Seal River and as far south as approximately the Quebec–Ontario border, based on the limits of carbonate dispersal. It is drawn at the Nelson River in this reconstruction because the amount of crystalline erratics in youngest tills north of Nelson River is considerably higher than in tills south of the river. The moderate concentrations of crystalline erratics in tills south of the river are assumed to have their origin principally in the crystalline terrain east of Hudson Bay. North of Nelson River the frequency of crystalline erratics doubles, and because there is no reason that a source area east of Hudson Bay would cause this enhancement, it is thought that much of the crystalline component was carried southward by Keewatin ice, from sources north-west of the lower reaches of Nelson River.

The shift through time of the contact of the Quebec and Keewatin ice masses in the southwestern Hudson Bay Lowlands explains the commonly observed presence of two sets of striae, one indicating flow from north or north-west, and one indicating flow from east or north-east. When the glacier from a Quebec–Labrador centre flowed over a given site, the latter sets of stria were formed; when Keewatin ice displaced the Quebec ice at the same site, the former directions prevailed. The strong evidence of westward to southwestward dispersal through the western Hudson Bay Lowlands suggests, however, that the Keewatin centre had a minor role in most of the Lowlands, either by virtue of its inability to erode and transport or because it did not flow long enough over most of the region to effect significant erosion and transportation.

That the position through the Hudson Bay Lowlands of this zone of contact between Quebec and Keewatin ice masses seems to have shifted considerable distances with time probably reflects the relative strengths and timing of ice build-up in the two centres of ice dispersal. It is tempting to speculate that within the central part of the Laurentide ice sheet the Labrador–Quebec centre of outflow predominated in the early and maximum stages of glaciation and that the Keewatin centre became relatively stronger during the later stages. Certainly in the last stages of glaciation there was a significant break in the vicinity of the Quebec–Ontario border between ice retreating towards a centre in Quebec and ice retreating generally northward or northwestward towards a Keewatin centre. The Cochrane readvance[14,30] seems to have been independent of the Quebec ice and may, therefore, have emanated from an ice mass shrinking toward a Keewatin centre.

The magnitude of the distances of transport of all erratics, more than 1,000 km in the case of the carbonate and dark erratics and at least 600 km in the case of the red erratics, demonstrates that ice flow was maintained from Keewatin and Quebec centres of outflow along discrete flow paths for significant periods of time, as already suggested elsewhere[11,30]. The duration of ice flow necessary to effect these distances of transport for erratics of any given till sheet must have been of the order of several tens of thousands of years if the reasoning used by Shilts *et al.*[11] or by Boulton *et al.*[29] is followed.

That erratic transport occurred along specific flow lines over such long periods of time seems to be incompatible with the concept that there could have been any prolonged period of glacial flow with a configuration other than that depicted on Fig. 3. Thus, it is concluded from the constraints of time and configuration of dispersal discussed above that ice flow was maintained from centres located east and west of Hudson Bay throughout one or more glacial stades of the Wisconsinan Stage. Lithological similarities between pre-Wisconsinan and Wisconsinan tills in the Hudson Bay Lowlands suggest that similar centres also existed during earlier glaciations.

Conclusions

In the region around Hudson Bay, the configuration of dispersal patterns for distinctive suites of glacial erratics indicates that a centre of ice flow or ice dome could not have existed over the Bay unless some special conditions existed that prevented erosion and transportation of debris from the Bay's limestone floor. Dispersal data agree with glacial geomorphological data in that they indicate ice flow from centres on land in Keewatin and in Nouveau Quebec–Labrador.

The distance of dispersal along clearly defined flow paths from the centres east and west of Hudson Bay is so great that the time required to form the major erratic trains of the Wisconsinan glaciation may have spanned most of that glacial stage, leaving little time for the development of a major ice dome over Hudson Bay.

Thus, I conclude that it is unlikely that an ice dome could have existed over Hudson Bay during the Wisconsinan nor is it likely, based on compositions and striated boulder pavements of pre-Wisconsinan tills of the Hudson Bay Lowlands, that an ice dome existed during the earlier glacial stages represented by these deposits. Centres of ice dispersal are thought, rather, to have developed and decayed on land east and west of Hudson Bay. Hudson Bay received ice flowing from Keewatin and Quebec throughout the last glacial stage. Reconstructions of the palaeoclimatology and dynamics of the Laurentide ice sheet might better be based on the multiple dome model presented here rather than on the less complex 'single dome' model.

Samples and unpublished data on which the discussions of glacial flow southwest of Hudson Bay are based were provided by Polar Gas Consortium through W. D. Roggensack and by B. C. McDonald, R. G. Skinner, B. G. Craig and C. F. M. Lewis. Canadian Coast Guard icebreaker CCGS Pierre Radisson provided helicopter support and a logistical base for study of Coats and Mansel Islands. Analyses of samples from Keewatin were partially funded by Atomic Energy of Canada Limited. Most of the analyses of pebble fractions were carried out by C. A. Kaszycki and P. Honarvar.

Invertible DNA determines host specificity of bacteriophage Mu

Pieter van de Putte, Steve Cramer & Micheline Giphart-Gassler

Department of Molecular Genetics, State University of Leiden, Wassenaarseweg 64, 2333 Al Leiden, The Netherlands

The function of the invertible G region of bacteriophage Mu is apparently to confer different host specificities on Mu. Two products of genes S *and* U, *situated in the G region are not needed for the infectivity of Mu G(−) particles. In the Mu G(−) phage the* S *gene product and the 21-K polypeptide, presumably the product of gene* U, *are missing. Instead, two other polypeptides with different molecular weights are observed.*

THE invertible G region of bacteriophage Mu is 3,000 base pairs long and has short inverted repeats at its ends[1]. When Mu is propagated lytically in *Escherichia coli* K12 the G region is fixed in one particular orientation G(+), whereas when Mu stocks are prepared by induction of a Mu *cts* prophage the DNA consists of 50% G(+) and of 50% G(−) molecules[1,2].

A Mu gene *gin* situated in the β part of the Mu genome (Fig. 1) is essential for the inversion of the G area[3]. Only G(+) particles can infect *E. coli* K12 (refs 3, 4), but it has been speculated that the G(−) particles may be infectious for organisms other than *E. coli* K12 (ref. 5).

We now provide evidence that Mu G(−) particles are viable and have a different host specificity from G(+) particles.

Propagation in *Citrobacter freundii*

It has been reported that Mu can be propagated in cells of *C. freundii* but that the organism seemed to have, besides a restriction system directed against foreign DNA in general, a second restriction system specifically directed against phage Mu, because Mu plated with a low efficiency on *C. freundii* r$^-$ strains[6]. However, the presence of such a specific restriction system seems unlikely. Another explanation is that *C. freundii* cells are not sensitive to the Mu G(+) phages, which are the predominant product of lytic growth on *E. coli* K12, but to the G(−) form. To test this, the efficiencies of plating (e.o.p.) of different Mu phage preparations were determined on *E. coli* K12 and *Citrobacter* hosts. It seems that the lytically propagated Mu phage Mu*c*2000, a clear plaque mutant of Mu c^+, has an extremely low e.o.p. of 2.5×10^{-9} on the r$^-$ strain of *Citrobacter* (Table 1, line 1) whereas the e.o.p. of a Mu*cts* lysate obtained by induction is the same on *E. coli* K12 as on *C. freundii* (Table 1, line 2). This simple experiment strongly suggests that *C. freundii* is sensitive for Mu G(−) phages. (The nine log difference found between the e.o.p. of lytic Mu and induced Mu on *C. freundii* is much larger than could be expected from the e.o.p. data obtained by De Graaf *et al.*[6]. This difference is a result of the way the Mu phage was prepared by these authors: a spontaneous induction lysate of a Muc^+ lysogen with $\sim 10^5$ plaque-forming units (PFU) per ml^{-1} consisting of 50% G(+) and 50% G(−) particles was

0028-0836/80/290218-05$01.00

directly used to make confluent lysis plates on *E. coli* K12. The lysate of ~10^9 PFU ml^{-1} obtained in this way still contained 10^5 G(−) particles which led to an e.o.p. of nearly 10^{-4} on the *C. freundii* r^- strain.) That the orientation of the G area is involved in this phenomenon follows also from the behaviour of induced Mu*ctsgin*[3] phages. In this Mu mutant G is fixed in the + orientation and consequently the phages form no plaques on the *Citrobacter* host (Table 1, line 3).

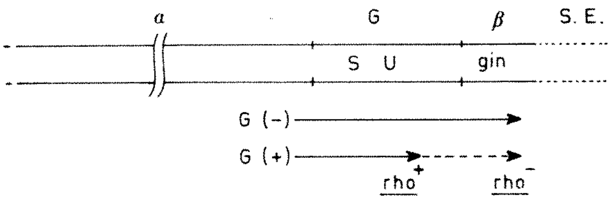

Fig. 1 A model for the expression of *gin* during lytic development of Mu G(+) and Mu (G−) phages.

G inversion during lytic development

When Mu*c*2000 was propagated lytically on *C. freundii* and titrated on different hosts it was found that the e.o.p. on an *E. coli* K12 r^- host was much higher (factor of 10^6) than when lytically propagated Mu on *E. coli* K12 was plated on *Citrobacter* (compare lines 1 and 5, Table 1). Apparently, G inversion is more frequent during lytic development of G(−) phages than of G(+) phages. A likely explanation for this is that the expression of *gin* is dependent on the orientation of the G area. In the + orientation the G area might act as a transcription barrier for *gin* expression, if the *gin* promoter is located in the α region of Mu (Fig. 1). This idea is supported by the following result: when Mu*c*2000 is propagated on an *E. coli* K12 *suA* strain, which is defective in the transcription termination factor ρ (ref. 7), the relative number of G(−) phages in a G(+) lysate is much enhanced (Table 1, line 4). In the prophage state expression of *gin* leads to a randomization of the orientation of the G region. However, our experiments show that Mu phages propagated lytically on *E. coli* K12 normally contain very few G(−) phages. This suggests that in the prophage state *gin* is expressed from a different promoter and that this promoter is shut off during lytic development.

Propagation on other hosts

Other *E. coli* strains and bacterial species were tested for sensitivity to Mu G(+) and G(−) phages. With induced Mu*cts*62 phage we found plaques on lawns of *E. coli* C and of *Shigella sonnei*. Two *Klebsiella* strains, *Salmonella typhimurium*, an *Aerobacter* strain, and *E. coli* B were found to be Mu resistant.

Mu*c*2000 G(−) phages propagated on *C. freundii* form plaques on lawns of *E. coli* C and *S. sonnei* with an efficiency approximately a factor 10^7 higher in comparison with Mu*c*2000 G(+) propagated on *E. coli* K12 (Table 1, lines 1 and 5). This suggests that *S. sonnei* and *E. coli* C are also sensitive to Mu G(−) phages.

However, there are some complications. As *E. coli* C is deficient in restriction functions the e.o.p. of induced Mu*cts* on *E. coli* C should be 1. In fact the e.o.p. on *E. coli* C and on *S. sonnei* is much lower than 1 and, moreover, is difficult to determine accurately. Besides the few normal plaques found, a large number of extremely faint plaques were seen. This is probably due to a poor adsorption of Mu*cts*62 to *E. coli* C and *S. sonnei* which is not related to G inversion. Phage Mu*c*2000, which compared to Mu*cts*62 adsorbs better to *E. coli* K12, also forms uniform clear plaques on *E. coli* C and *S. sonnei*. However, when these phages are propagated on *E. coli* C or *S. sonnei* and plated on *Citrobacter* or vice versa (Table 1, lines 5 and 7) still mutual differences in the e.o.p. of a factor 10–30 are observed. The reason for these differences is not yet known and was not further investigated.

Restriction enzyme analysis

The orientation of the G region is easily determined using restriction enzymes such as *Hpa*I, which cut asymmetrically in the G region[8]. Figure 2 shows the analysis of different DNAs treated with *Hpa*I. The *Hpa*I digest of Mu DNA derived from phage lysates prepared on *E. coli* K12 is shown in lane *b*. The *Hpa*I–E fragment of about 3,500 base pairs contains part of the G region. Mu*cts*62 DNA obtained from an induced phage lysate contains an additional *Hpa*I fragment of ~3,800 base pairs derived from the 50% G(−) molecules (Fig. 2, lane *c*). Of these two *Hpa*I fragments only the 3,800 base pair fragment is present in the DNA of Mu phage propagated in *C. freundii* (lane *d*). The G region must be almost exclusively in the G(−) orientation in this DNA because the fragment present in the Mu G(+) has disappeared. Mu DNA from phage propagated on *C. freundii*, *E. coli* C and *S. sonnei* (lanes *d–f*) gave the same restriction pattern.

Genes in the G region

Amber mutations in the genes *S* and *U* have been mapped inside the G region[9]. The G(−) phage cannot infect cells of *E. coli* K12 which might indicate that the *S* and *U* gene products are not made during lytic development of G(−) phages. A likely explanation for this is that *S* and *U* genes are expressed from a promoter located outside the G region in the α part of Mu (see Fig. 1). The expression of these genes from such a promoter will then be blocked after G inversion. To test whether the *S* and *U* gene products are essential for Mu G(−) phages we made induced lysates from an *E. coli* K12 strain lysogenic for Mu*ctsSam* and another which is lysogenic for Mu*ctsUam* and determined the titres on different strains lacking nonsense suppressors. Normal titres were found on the

Table 1 Plating efficiencies of Mu phage lysates on different hosts

	Phage	Mode of propagation	Host	Efficiencies of plating

All lytically propagated phage were made by the confluent lysis method. When the phage is propagated on a particular strain and titrated on the same strain, the efficiency of plating (e.o.p.) is arbitrarily set at 1. The e.o.p. values for induced Mu*cts*62 on *S. sonnei* and *E. coli* C (line 2) are given in parentheses as these values were extremely variable and dependent on plating conditions. All titrations were on 1.8% agar plates containing 1% Difco trypton broth; 0.8% NaCl and 0.5% Difco yeast extract.

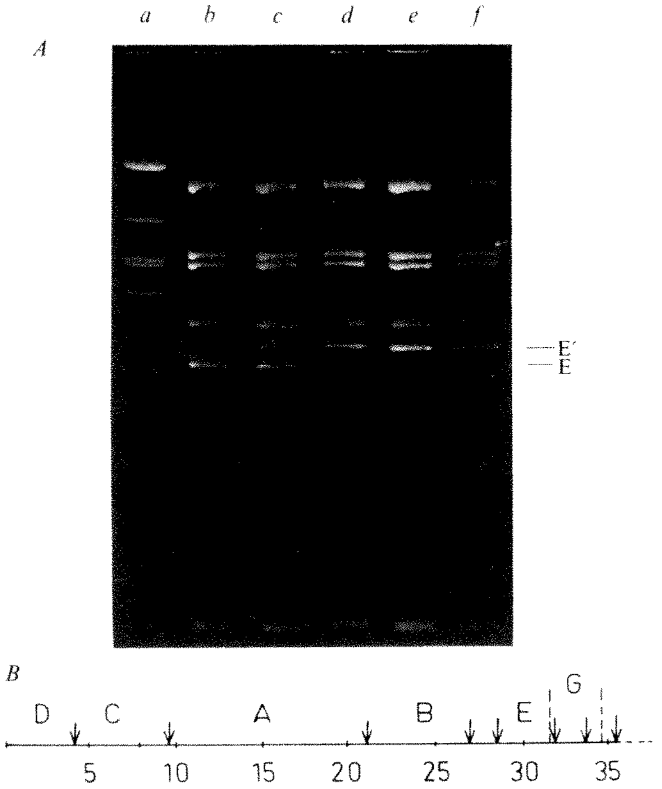

Fig. 2 *A*, DNA fragment patterns obtained from *Hpa*I digests of DNA derived from Mu lytically grown in *E. coli* K12 (*b*). Mu grown by induction of a Mu*cts*62 lysogen (*c*), Mu grown lytically in *C. freundii* (*d*), *S. sonnei* (*e*) and *E. coli* C (*f*). λDNA digested with *Eco*RI (*a*). Mu DNA was prepared by phenol extraction of phage, purified by equilibrium centrifugation in CsCl. *Hpa*I (a gift from Dr van Ormond) reactions were carried out in 20 mM Tris-HCl *p*H 7.4, 7 mM $MgCl_2$, 60 mM NaCl and 7 mM β-mercaptoethanol for 1 h at 37 °C. The digested DNA was subjected to electrophoresis on a 1% agarose slab gel. Electrophoresis buffer contained 89 mM Tris, 89 mM boric acid, 2.5 mM Na_2EDTA, *p*H 8.3 (TEB). After electrophoresis at room temperature at 1.5 V cm^{-1}, the gel was soaked in TEB containing 5 μg ml^{-1} ethidium bromide. The DNA bands were visualized under UV light and photographed with a polaroid camera. The *Hpa*I-E fragment of the G(+) and the E′ fragment of the G(−) orientation are indicated. *B*, the *Hpa*I restriction map of the Mu DNA is slightly different from the one described by Allet *et al.*[8].

C. freundii strain and no plaques were found on the *E. coli* K12 strain with the *Sam* lysate and very few with the *Uam* lysate (Table 2). These results indicate that the *S* and *U* gene products are not essential for Mu G(−) phages. (The non-permissiveness of *C. freundii* for nonsense mutations was tested with an induced *Bam* lysate (Table 2, line 1).)

The *S* protein has a molecular weight (MW) of 56,000 (ref. 10) for which a coding capacity of 1,500 base pairs is needed. We have looked at the structural proteins in Mu virions, propagated lytically in *E. coli* K12 and in *S. sonnei* (see Fig. 3). It seems that the 56,000-MW polypeptide, the product of gene *S*, is absent from phages propagated on *Shigella*. We see instead a polypeptide of MW 48,000. A gene coding for this size polypeptide would be about 1,300 base pairs long and would fit nicely into that part of the G region that can be deleted in Mu G(+) DNA. We propose that the 48,000-MW polypeptide is analogous to the *S* protein and shall refer to it as *S*′.

Table 2 Number of PFU per ml of Mu amber induction lysates on *C. freundii* and *E. coli* strains

Lysogen	Indicator strains *E. coli* K12, *supE*	 *E. coli* K12 su^-	 *C. freundii* r^-su^-
E. coli K12, *supE*::(Mu*cts*62*Bam*)	1.4×10^9	< 10	< 10
E. coli K12, su^-::(Mu*ctsSam*)*	1.1×10^5	< 10	2.4×10^8
E. coli K12, *supE*::(Mu*ctsUam*)*	5.2×10^7	2.1×10^2	4.5×10^8

For plating conditions see Table 1 legend. *The difference in the genetic background (su^- and *supE*, respectively) of the *Sam* and *Uam* lysogens was a coincidence and has no influence on the interpretation of the data.

A 21,000-MW structural protein present in phage propagated on *E. coli* K12 is absent from phage propagated on *S. sonnei*. Instead we see a 26,000-MW polypeptide (Fig. 3). The 21,000-MW polypeptide is a good candidate for the *U* product and 26,000-MW for the analogous *U*′. Support for the identification of the *U* gene product with a 21,000-MW protein comes from the work of Magazin *et al.*[11] who reported that the λ-pMu hybrid 82-573, that contains β and the G region, codes for a 41,500 and 20,500-MW protein.

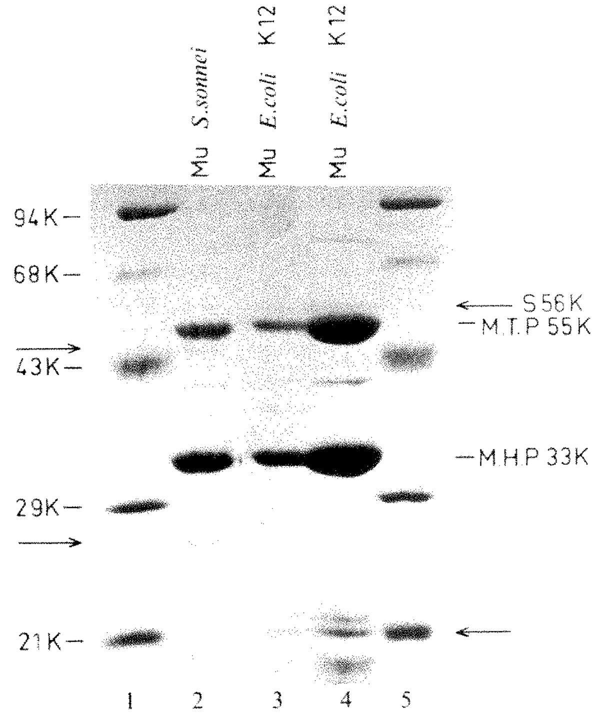

Fig. 3 Electrophoretic separation of the polypeptides of Mu G(+) (two different concentrations) and Mu G(−) phage particles. The molecular weight standards (Biorad; MW range 10,000 to 100,000) were electrophorised in lanes 1 and 5. Mu lysates were obtained by confluent lysis on *E. coli* K12 G(+) or *S. sonnei* G(−). Purified phages were obtained by banding in CsCl and dialysing against 0.01 M Tris-HCl *p*H 7.0; 0.01 M $MgCl_2$. The phages were precipitated in 5% trichloroacetic acid at 0 °C for 2 h and were centrifuged for 30 min at 45,000 r.p.m. in a SW 50.1 rotor. The pellets were solubilized in Laemmli sample buffer[19] and the *p*H adjusted to 6.8. The proteins were desaggregated by heating the samples at 100 °C for 3 min. Polypeptides were separated by electrophoresis through a 20-cm long linear 12.5–20% polyacrylamide gradient slab gel in the presence of SDS at 150 V for 18 h. Polypeptide bands were visualized by staining with Coomassie brilliant blue.

Aspects of regulation

These experiments provide evidence for a new type of regulation of gene expression. This is achieved by the inversion of a stretch of DNA which contains structural genes. We have shown that in bacteriophage Mu inversion of a 3,000 base-pair DNA region, the G region, results in a different host specificity of the phage. This inversion gives new adsorption properties and an extension of the host range of phage Mu. A second regulatory aspect of the inversion phenomenon is that the frequency of inversion during lytic development of the phage seems to be regulated by the invertible region itself. In one orientation the region acts as a ρ-dependent transcription

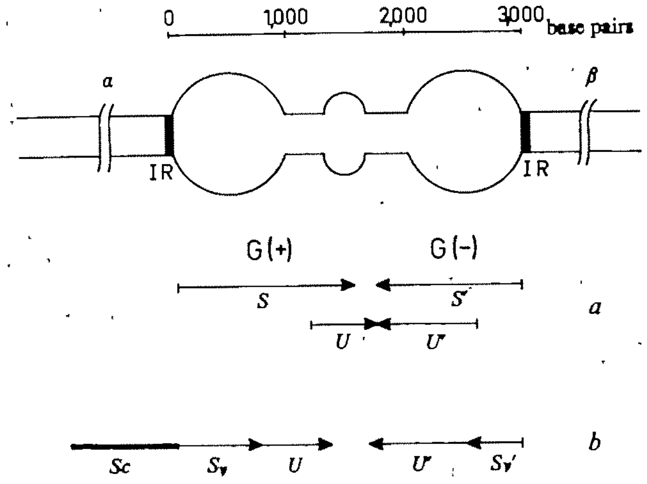

Fig. 4 Two models for the organization of the G region of bacteriophage Mu In model *a*, gene *S* is completely inside the G region based on the observation that no *S* ambers were found to map outside the G region[9] The position of gene *U* is drawn as far as possible to the right taking into account that the rightmost 1,300 base pairs of the G region are non-essential for Mu G(+) phages[3] Gene *U* could also be located completely inside gene *S* The presence of separate genes *S'* and *U'* for Mu G(−) phages is supposed because the *S* and *U* gene products are non-essential for Mu G(−) particles The sizes are based on the appearance of two new polypeptides in Mu G(−) virions instead of the *S* and *U* gene products which have disappeared (Fig 3). The drawing of the heteroduplex structure of G is according to the EM measurements of Chow *et al.*[13]. In model *b*, the *S* and *U* genes do not overlap and there is a common part of *S* and *S'* indicated with Sc outside the G region The genes *S* and *S'* differ from each other in the part located inside G, indicated with S_v and S'_v respectively.

barrier for the expression of a gene *gin*. The *gin* gene is situated outside the invertible region in the β part of Mu and is needed for the inversion of the G area[3]. It is also of interest that the gene *mom* is located adjacent to *gin* (A. Toussaint, personal communication) and might be coordinately expressed with *gin*. The *mom* gene codes for a modification function of a general nature[12]. If the function of G inversion is to prepare the phage for entering new hosts it will be extremely advantageous for the phage if a modification function is expressed simultaneously with *gin* to protect the phage DNA against foreign restriction enzymes.

Organization of the invertible region

All amber mutations in the genes *S* and *U* have been mapped inside the invertible region G. *S* codes for a 56,000-MW protein while *U* probably codes for a 21,000-MW polypeptide[10]. We have shown that these two gene products are only essential for Mu G(+) phages as *S* and *U* amber mutants plate on *C. freundii*, which is sensitive to Mu G(−) phages. Therefore, we postulate that two other genes which we indicate as *S'* and *U'* are also situated in the G region and are expressed in Mu G(−) phages instead of the *S* and *U* genes. We have some experimental evidence for the existence of *S'* and *U'*. The *S* and *U* gene products are present in Mu virions propagated in *E. coli* K12 which is sensitive to Mu G(+). However, these proteins are absent in Mu G(−) virions and are replaced by two new polypeptides with molecular weights of 48,000 (presumably S') and 26,000 (presumably U'). More recently, we have isolated amber mutants of Mu G(−) phages which are likely candidates for mutants in the genes *S'* and *U'*. Three of these amber mutants seem to behave as non-ambers in *E. coli* K12. They fall in two complementation groups and are rescued by λ-pMu hybrid phages containing the β and G regions of Mu.

As some 4,100 base pairs are needed to code for *S*, *S'*, *U* and *U'* their genes have to partially overlap if they are to be accommodated in the G region. Probably, *S* and *U* overlap each other as only 1,700 base pairs of DNA are available to code for *S* and *U*. This follows from the fact that 1,300 base pairs of the right part of G can be deleted in Mu G(+) phages without loss of viability[3]. We propose that *S'* and *U'* genes are situated in the 1,300 base pairs that can be deleted in the Mu G(+) phages. Such a model is presented in Fig. 4*a*. However, if *S* is situated partially outside the G region, it is not necessary to postulate overlapping genes (see Fig. 4*b*). The presence of G-like structures in P_1 and P_7 (refs 13, 14) supports model *a*. It is tempting to suggest that G is a unit involved in adsorption which has or had in the past the capacity to transpose itself to other DNA molecules. In fact the G region shows similarities with transposable elements as this region is bordered by inverted repeats and a *recA* independent recombination system (gin) acts on these repeats. If model *b* is correct then a striking analogy exists with immunoglobulins. The polypeptide chains in an immunoglobulin molecule have a constant region and a variable region coded for by separate genes which are fused, probably by a deletion, a transposition or an inversion[15,16]. According to Fig. 4*b*, *S* and *S'* would also consist of a constant common part coded for by a region outside the G area and a variable part located inside G. A more precise determination of the position of *S* and analysis of the four proteins will reveal whether model *a* or *b* is correct.

It is important to consider how a structure like the G region was created: it contains two pairs of genes, one pair being silent while the other is expressed. From electron microscopic studies it seems that the middle part of the G region, about 1,000 base pairs, shows an inverted homology except for a small part around the centre (see also Fig. 4). This suggests a rather extensive homology between *S* and *U* on one hand and *S'* and *U'* on the other hand. Such an extensive homology within G could be explained if G has evolved from a tandem duplication of *S* and *U* followed by an inversion of one duplicate. Subsequently one duplicate could have changed in such a way that adsorption to other hosts became possible. The nature of these changes is not yet known but apparently involves at least the sizes of the structural tail fibre proteins (S' <S and U'>U). It is of interest that we have found mutants of Mu that make slightly larger or smaller *S* proteins. These were found during the screening in minicells of amber mutants of Mu unrelated to *S*, indicating that changes in *S* might occur with a rather high frequency. In this way Mu might maintain a high degree of flexibility to adapt to changes in the environment in respect to the availability of host receptor sites.

Analogies with G inversion

Several other organisms exhibit regulatory mechanisms analogous to G inversion in Mu in that gene expression is controlled by genetic rearrangement. One example is the phase variation observed in *Salmonella typhimurium*[17]. This organism produces two types of flagella encoded by two different genes. The orientation of a promoter situated on an invertible region of 800 base pairs adjacent to one of the structural genes determines which of the two genes is expressed. Another analogy is with the regulation of the different mating type elements in yeast, a and α, which are expressed only after transposition from a silent position in the chromosome to the mating locus (cassette model[18]). In this type of mechanism, structural genes (genetic 'cassettes') are moved and thus activated. G inversion in Mu has aspects of both types of mechanism: like phase variation, host range switching in Mu involves inversion; like mating type inversion, the structural genes themselves move.

We thank Dr Jan van der Embden whose observations on G-like structures in *S. aureus* phages stimulated the initiation of our experiments, and Dr Ira Herskowitz for interesting discussions on cassette-type controls. This work was supported by Euratom grant 194-76 Bian to M.G.G.

A mouse α-globin-related pseudogene lacking intervening sequences

Elio F. Vanin, Gregory I. Goldberg, Philip W. Tucker* & Oliver Smithies

Laboratory of Genetics, University of Wisconsin, Madison, Wisconsin 53706

A mouse α-globin-related pseudogene ($\psi\alpha30.5$) completely lacks intervening sequences, and could not code for a functional globin polypeptide because of frameshifts. The widespread occurrence of globin pseudogenes in other species suggests that they are not 'dead' genes but may be important in controlling globin expression.

INTERVENING SEQUENCES (introns) interrupt many eukaryotic genes[1–5]. In productive globin genes, that is, those producing functional globin polypeptides, these sequences are transcribed but are removed from the primary nuclear transcripts before the resulting mRNA is translated in the cytoplasm (reviewed in refs 6, 7). The functions of intervening sequences are not known.

The mouse genome has at least seven non-allelic globin genes: two adult β genes (β^{maj} and β^{min}), two β-type embryonic genes (y and z), two adult α genes and an α-type embryonic gene (x). An adult α and two adult β genes have been cloned and sequenced[8–13]. Each of the two β-globin genes has at the same position in the coding region a small 116-base pair intervening sequence[11,13] which has only three nucleotide differences between the two genes[13]. A second larger intervening sequence, 650 base pairs long in β^{maj} and 628 base pairs in β^{min}, differs considerably in sequence between these two genes[13], although it is in the same position in both. Intervening sequences have been found in the coding regions of all productive β-type globin genes described to date, including the adult β-type genes from rabbit[4,14], chicken[15] and man[16], and the human fetal β-type globin genes, $^{G}\gamma$ and $^{A}\gamma$ (ref. 17). An adult α-globin gene[9] from BALB/c mouse has also been shown to contain two intervening sequences, 122 and 134 base pairs long, which occur in positions analogous to those of the β-type globins. A human adult α-globin gene has comparable intervening sequences (ref. 18, and S. Liebhaber and Y. W. Kan, personal communication).

We describe here the nucleotide sequence of an α-globin 'pseudogene', which we call $\psi\alpha30.5$, previously isolated[19,20] from the DNA of outbred CD1 Swiss mice (Charles River Mouse Farms). $\psi\alpha30.5$ is clearly related to the productive mouse α-globin gene, but it lacks the two intervening sequences found in the productive gene; the intervening sequences are as cleanly missing as in fully processed mRNA. This unusual gene also has several additions and deletions, from 1 to 12 base pairs long, relative to the sequenced productive mouse α-globin gene[9]. These additions and deletions introduce frameshifts which would prevent $\psi\alpha30.5$ from producing a functional α-globin polypeptide; this is why we refer to it as an α-globin pseudogene.

Nishioka, Leder and Leder (personal communication) have recently isolated and sequenced the gene equivalent to $\psi\alpha30.5$ from BALB/c mice, and we have found that AKR/J and SWR/J mice have an *Eco*RI fragment of DNA in their genomes comparable in size and hybridization properties to the $\psi\alpha30.5$ fragment. Globin pseudogenes are also found in other species[18,21–23], and this widespread occurrence raises many questions about their evolution and function.

Restriction map of $\psi\alpha30.5$ and sequencing strategy

The α-globin pseudogene 30.5 was isolated, as clone Charon3AMm30.5 (refs 19, 20), from a random collection of recombinant bacteriophages containing *Eco*RI fragments of liver DNA from the Swiss mice. Figure 1*a* shows the restriction enzyme map of the 4.7-kilobase pair *Eco*RI

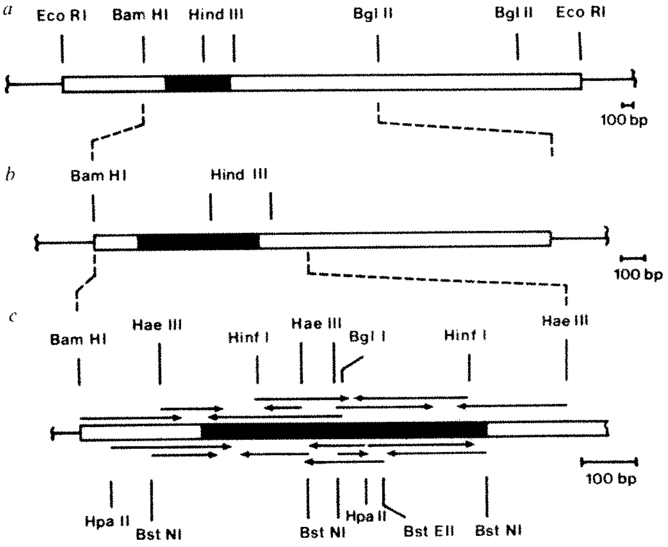

Fig. 1 Restriction maps and sequencing strategy for $\psi\alpha30.5$. *a*, Map of the 4.7-kilobase pair *Eco*RI fragment of mouse DNA in clone Charon3AMm30.5 (refs 19, 20). *b*, The *Bam*HI/*Bgl*II fragment subcloned into the *Bam*HI site of pBR322 before sequencing. *c*, The strategy used in sequencing $\psi\alpha30.5$. The black areas show the region of the cloned DNA which is homologous to mouse α-globin mRNA. The horizontal arrows show the directions of sequencing. ^{32}P-end-labelling and DNA sequencing were by the Maxam and Gilbert procedures[42] modified as described by Slightom *et al.*[17]. Other experimental procedures were essentially as described elsewhere[17]. bp, Base pairs.

0028-0836/80/290222-05$01.00

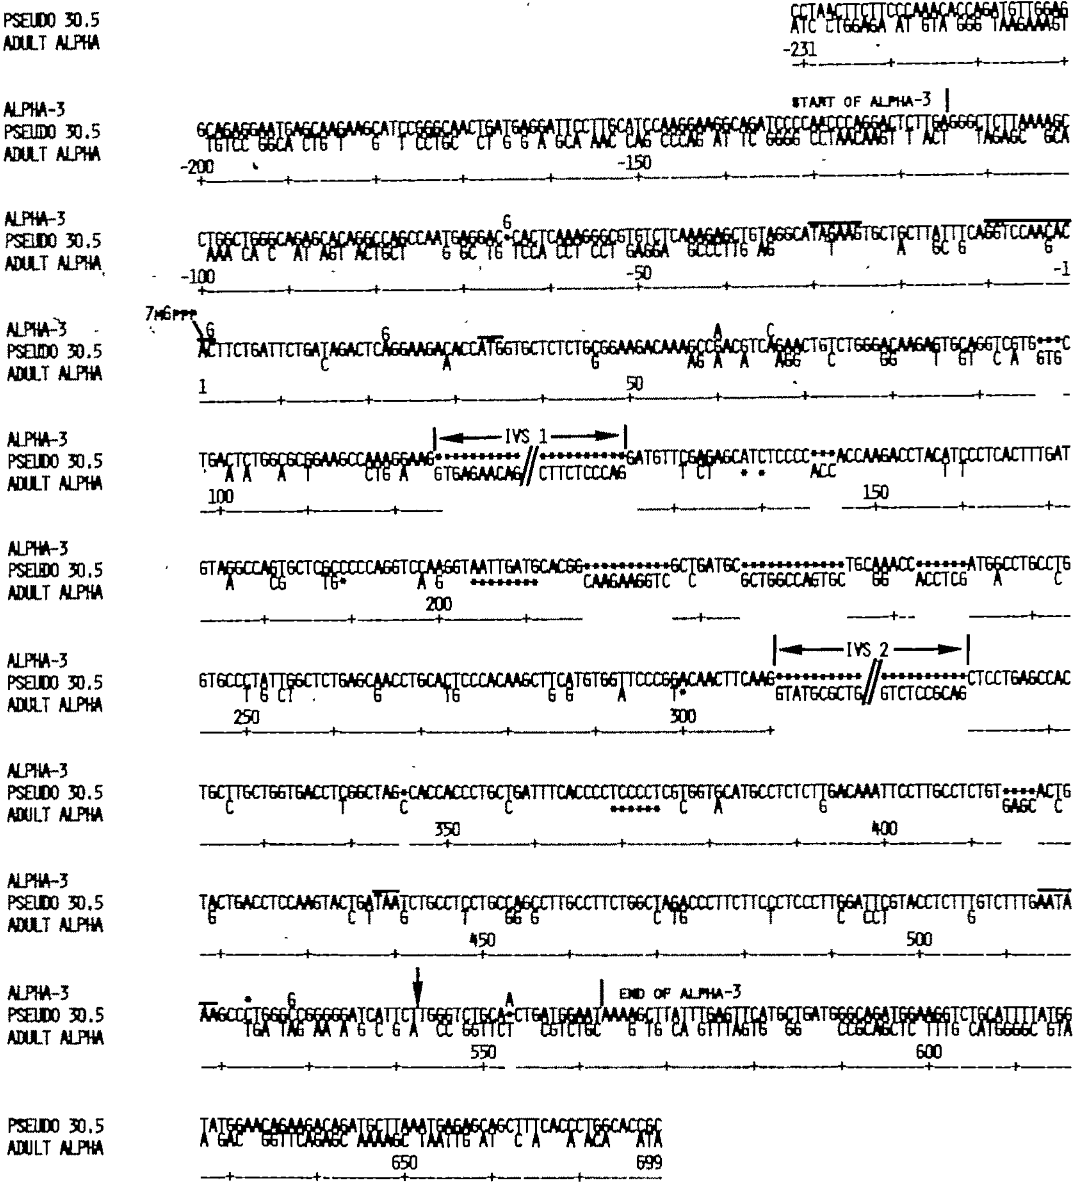

Fig. 2 The nucleotide sequence of the α-globin pseudogene, $\psi\alpha30.5$. The nucleotide sequence of $\psi\alpha30.5$ (pseudo 30.5, middle lines) is compared with the sequence of a productive adult α-globin gene[9] (adult alpha, lower lines), and to the sequence of an equivalent pseudogene (alpha-3, upper lines) isolated from BALB/c mice and sequenced by Nishioka, Leder and Leder (personal communication). The sequence of $\psi\alpha30.5$ is listed in full. Where either of the other sequences differs from $\psi\alpha30.5$ the differing bases are shown; where they are identical only the sequence of $\psi\alpha30.5$ is shown. Asterisks indicate that no bases are present at the indicated positions. The numbering system on the counting scale refers to $\psi\alpha30.5$, with number 1 corresponding to the nucleotide homologous to the first nucleotide of α-globin mRNA. The intervening sequences, IVS 1 and IVS 2, of the adult α-globin gene are shown. Potentially important signals are overlined (see text). 7mGppp shows the position of the cap of adult α-globin mRNA. The arrow after nucleotide position 541 indicates the probable 3′ end of α-globin mRNA (G. N. Pavlakis and J. N. Vournakis, personal communication). Note that the α3 sequence data do not cover nucleotide positions before −115 and after +561.

fragment in Charon3AMm30.5. Figure 1*b* shows the region subcloned into pBR322 before nucleotide sequencing, and Fig. 1*c* outlines the strategy used for nucleotide sequencing.

$\psi\alpha30.5$ is related to an adult α-globin gene

Figures 2 and 3 present the nucleotide sequence for $\psi\alpha30.5$ and compare it with the sequence of a productive α-globin gene from BALB/c mice[9]. The sequence of the equivalent pseudogene, α3, from BALB/c mice (Y. Nishioka, P. Leder and A. Leder, personal communication) is also given in Fig. 2. The nucleotide numbering system used refers to $\psi\alpha30.5$ and assigns number 1 to the nucleotide in $\psi\alpha30.5$ which is homologous to the first nucleotide of α-globin mRNA. The schematic comparison of the nucleotide sequences of $\psi\alpha30.5$ and of the productive α-globin gene presented in Fig. 3 indicates where the two sequences are identical (dark areas) and at the same time emphasizes where they differ in length (triangles above and below the horizontal lines). The points where α-globin mRNA begins and ends are indicated by vertical arrows.

The first feature revealed by the sequence data of Fig. 2 and the schematic comparison of Fig. 3 is that $\psi\alpha30.5$ is very closely related to the productive mouse α-globin gene. If we disregard additions and deletions, $\psi\alpha30.5$ is identical in sequence to the mouse α-globin gene in 84% of the region coding for mRNA. When $\psi\alpha30.5$ is compared with the nucleotide sequence of the mouse β^{maj} globin gene[11] there is only 54% identity, which is not significantly different from the 58% identity found when the sequences of mouse α- and β^{maj}-globin genes are compared with each other. These comparisons show that $\psi\alpha30.5$ is a member of the α-globin family rather than the β-globin family, which confirms our previous hybridization data[20]. Also, $\psi\alpha30.5$ seems more like the mouse adult α-globin gene than the mouse embryonic α-type globin gene, *x*; the nucelotide sequence of $\psi\alpha30.5$ has codons corresponding to an adult α-globin amino acid sequence rather than to the embryonic globin sequence[24] in nine discriminating positions which can be compared. Comparisons of the nucleotide sequence of $\psi\alpha30.5$ with the sequences of the coding regions of all the adult α-globin genes for which sequence data are available show that $\psi\alpha30.5$ is more closely related to the mouse adult α-globin gene[9] (84% identity) than to either the human adult α-globin gene (74%) (S. Liebhaber and Y. W. Kan, personal communication) or the rabbit adult α-globin gene[25] (72%).

$\psi\alpha30.5$ lacks both intervening sequences

The second feature revealed by the data presented in Figs 2 and 3 is that $\psi\alpha30.5$ completely lacks the two intervening sequences characteristic of productive globin genes. The absence of the intervening sequences in $\psi\alpha30.5$ is clean, in that the nucleotide sequence immediately 5′ and 3′ to the intervening sequences in the adult α-globin gene[9] are contiguous in ψα30.5; the nucleotide sequence in these regions of ψα30.5 is exactly the same as that seen in fully processed mouse α-globin mRNA (ref. 26, our unpublished observations, and G. N. Pavlakis and J. N. Vournakis, personal communication). It is as if the intervening sequences had never been there or had been perfectly excized.

ψα30.5 is an α-globin pseudogene

Inspection of the nucleotide sequence of ψα30.5 shows that it has several signals which might be expected in a productive α-globin gene. There is a sequence (TAGAAG) at nucleotide positions −30 to −25 comparable to the version of the Pribnow-like box[27] found in the productive α-globin gene (TATAAG) and thought to be important in the initiation of transcription[9]. There is a sequence (GGTCCAACACAC) at the nucleotide positions −10 to +2 comparable to the (GTTCGTCCTCAC) sequence postulated by Ziff and Evans[28] to be important in the 'capping' of mRNA. The expected translation initiation codon (ATG) and chain terminator codon (TAA) occur at the appropriate nucleotide positions (33–35 and 438–440). Finally, there is a sequence (AATAAA) at positions 514–519 which is identical to the so-called poly(A) addition signal (AATAAA) of Proudfoot and Brownlee[29]. We do not know whether these regions could provide adequate signals for all stages of normal transcription and translation, as the absolute requirements of these signals are not known. However, it is quite remarkable that, although the region of strong homology between ψα30.5 and the productive α-globin gene is extensive enough to include all these potential signals, beyond the outside signals the homology is virtually non-existent (see Figs 2, 3). Thus, on the 5′ (upstream) side of the two genes, the strong homology extends to nucleotide position −34, a few bases upstream from the Pribnow-like box[27]. On the 3′ (downstream) side of the two genes, the strong homology ends at nucleotide position 522, a few bases downstream from the Proudfoot–Brownlee sequence[29]. The strong homology does not extend to the 3′ end of α-globin mRNA, which is close to nucleotide position 541 (G. N. Pavlakis and J. W. Vournakis, personal communication).

Even if ψα30.5 could be transcribed into RNA which was then processed to yield a functional message, it could not code for a functional α-globin polypeptide. Figure 4 shows the amino acid sequence which corresponds to the nucleotide sequence of ψα30.5 on the assumption that it is translated in the same reading frame as the productive α-globin gene. The first 34 of these amino acid residues are very similar to those found in α globins[30], but a frameshift after amino acid residue 34, due to the addition in ψα30.5 of two bases, results in three chain terminator codons (one of each variety) shortly thereafter, and also causes the coded amino acid sequence to become unrelated (in italics) to α globin. Other frameshifts, due to the addition or deletion of non-integral triplets of nucleotides, occur elsewhere in the sequence of ψα30.5, and restore it to the α-globin reading frame briefly from residues 53 to 56 and again from residues 134 to 140.

Because ψα30.5 is clearly related in nucleotide sequence to an adult α-globin gene (Figs 2, 3), but could not code for a functional α-globin polypeptide (Fig. 4), we call it an α-globin pseudogene. This terminology does not exclude the possibility that ψα30.5 codes for a non-globin polypeptide. For example, it is conceivable (although unlikely) that ψα30.5 codes for a polypeptide homologous to α globin in its N-terminal and C-terminal regions but shorter because of the excision of a currently unrecognized intervening sequence covering the chain terminators caused by the frame shifts.

The α-globin pseudogenes in two mouse strains are almost identical

Comparison of the nucleotide sequences of ψα30.5 and the equivalent gene, α3, from BALB/c mice (Y. Nishioka, P. Leder and A. Leder, personal communication) shows (Fig. 2) that they are almost identical (>99% identity excluding deletions and additions). Both lack the two intervening sequences, and both are pseudogenes in the sense that frameshifts would prevent them from producing functional globin polypeptides. The number of differences between the α-globin pseudogenes from the two strains is close to the level attributable to errors in sequencing; thus, relative to ψα30.5, the BALB/c pseudogene has five base substitutions and three single base additions or deletions

How did the α-globin pseudogene ψα30.5 evolve?

Any evolutionary history of the α-globin pseudogene, ψα30.5, must take into account the following key observations: (1) all characterized productive globin genes of both α- and β-type have two intervening sequences at homologous places in their coding regions; (2) ψα30.5 lacks the intervening sequences cleanly; (3) ψα30.5 is much more closely related to an adult α-globin gene than to the β-type genes, and more to the mouse than to the human or rabbit adult α-globin genes; (4) ψα30.5 could not code for a functional globin polypeptide.

The first of these key observations has led to the suggestion by Leder *et al.*[8] that two intervening sequences became evolutionarily fixed in primitive globin genes before the α- and β-type genes diverged. If this is correct, three general types of evolutionary history can be suggested for ψα30.5. Each has problems, and we have no means of excluding any of them, although we favour the second.

First, ψα30.5 could be the present-day descendant of an old duplicate of a primitive globin gene which had never had intervening sequences. In this case, there are two important residual problems. Why did the pseudogene persist for so long, especially after it became unable to produce a functional globin chain? What mechanism or selective pressures caused it to co-evolve with the productive globins genes to the extent that it is recognizably related to an α-globin gene and particularly to a mouse adult α-globin gene? The simplest explanation for the evolutionary persistence of pseudogenes is

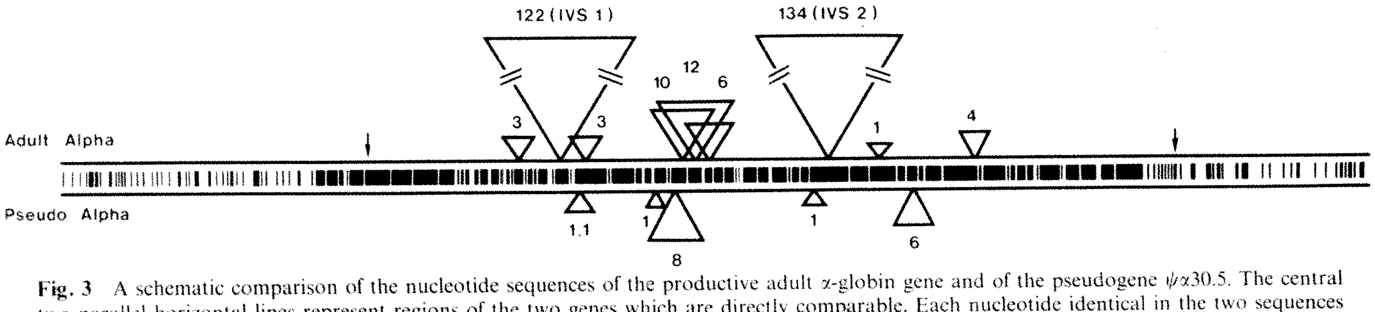

Fig. 3 A schematic comparison of the nucleotide sequences of the productive adult α-globin gene and of the pseudogene ψα30.5. The central two parallel horizontal lines represent regions of the two genes which are directly comparable. Each nucleotide identical in the two sequences is represented by a vertical stroke between these two horizontal lines; therefore, dark regions represent segments of extensive nucleotide homology. The triangles show places where the two genes differ in their lengths, and indicate the number of nucleotides in each length difference. (The triangle labelled 1,1 represents two single base additions separated by one base.) Triangles are drawn above the parallel lines when the adult α gene is longer, and below the lines when pseudogene ψα30.5 is longer. Two vertical arrows show where α-globin mRNA begins and ends.

Fig. 4 The amino acid sequence corresponding to the nucleotide sequence of $\psi\alpha30.5$ on the assumption that it is translated in the same reading frame and from the same initiator codon as the productive α-globin gene. The numbered scales show amino acid residue numbers in α globins. In frame α-globin amino acids are underlined. Amino acids in a different reading frame from α globin, or that have never been seen in an α globin, are italicized. Asterisks indicate chain terminator codons.

that they serve some important function, even though they are unable to code for globin polypeptides. The similarities between $\psi\alpha30.5$ and the adult α gene might then be a consequence of strong selective pressures keeping their sequences from diverging, or it might be due to the existence of mechanisms other than selection for maintaining similarities between related genes within a species. Recent nucleotide sequence data from our laboratory suggest that the human $^{G}\gamma$ and $^{A}\gamma$ fetal globin genes have remained very similar as a result of intergenic exchanges of DNA occurring during recombinational events comparable to gene conversion[17].

Second, $\psi\alpha30.5$ could be the descendant of a much more recent duplicate of a mouse adult α-type globin gene which had both intervening sequences. In this case, the important residual problem is explaining how they were then lost so exactly. The exact loss of both intervening sequences by random deletions at the DNA level would require an improbable series of events the selective advantages of which are individually difficult to imagine. It is easier to imagine that a molecular mechanism exists able to remove intervening sequences exactly from DNA in a fashion comparable to that used at the RNA level. Evidence in support of such a mechanism is provided by recent data on the preproinsulin genes of chicken[31], rat[9,32] and human[33]. All three species have a preproinsulin gene, with two intervening sequences in homologous positions. However, the rat, unlike the chicken and human, has an additional functional preproinsulin gene containing only the smaller first intervening sequence. Bell *et al.*[33] and Perler *et al.*[31] postulate that the two rat genes arose from a duplication, after which the larger intervening sequence was eliminated from one of the genes.

Third, a completely different type of evolutionary scheme can be imagined whereby $\psi\alpha30.5$ was recently derived from mouse adult α-globin mRNA. It is conceivable that a reverse transcript of a mouse α-globin mRNA was reintroduced into the genome, perhaps by recombination with a pre-existing α-globin gene. We know of no precedents for this type of mechanism except those related to the retroviruses, although the general concept was strongly advocated by Temin[34] in his protovirus hypothesis. This type of evolutionary scheme faces a major problem in accounting for the introduction of the reverse transcript into the germ line, because globin mRNA is normally produced in erythropoietic cells belonging to a cell lineage that is developmentally and temporally separated from the germ-cell lineage. Although the reverse transcript scheme is in general compatible with the sequence data for $\psi\alpha30.5$, special explanations would be required to account for the fact that the extent of the homology between the $\psi\alpha$ and α genes does not coincide exactly with the mRNA boundaries.

Have globin pseudogenes any function?

$\psi\alpha30.5$ is not unique in being a globin pseudogene. Maniatis and his collaborators have isolated several globin-related DNA sequences which cannot be identified with known globin polypeptides. In rabbits a gene, designated β_2, is found 5′ to the productive adult β gene[21]; it has limited sequence homology to adult and embryonic β-globin probes, it lacks a detectable mRNA transcript in the erythroid tissues examined (anaemic blood and bone marrow), and its larger intervening sequence does not hybridize to the larger intervening sequence of the productive adult β-globin gene[22]. Similar sequences ($\psi\beta_1$ and $\psi\beta_2$) which do not correspond to any of the β-type globin polypeptides have been identified in humans[23]. $\psi\beta_1$ is on the 5′ side of the productive adult β-type genes, and $\psi\beta_2$ is on the 5′ side of the embryonic ε gene. A gene, $\psi\alpha_1$, which does not code for any known globin polypeptide, has also been identified on the 5′ side of the two productive human adult genes[18]. Thus, each of these unusual genes is located in a comparable position on the 5′ side of productive globin genes. (Note, however, that the position of $\psi\alpha30.5$ in the mouse genome is not yet known.)

Although the human sequences $\psi\beta_1$ and $\psi\beta_2$ have not been studied in detail, the nucleotide sequences of both the rabbit gene β_2 (E. Lacy and T. Maniatis, personal communication) and the human gene $\psi\alpha_1$ (N. Proudfoot and T. Maniatis, personal communication) have been found to differ from the sequences of the corresponding productive globin genes in several ways which would make them incapable of coding for functional globin polypeptides. They are consequently also pseudogenes, although they differ from the pseudogene $\psi\alpha30.5$ in having intervening sequences. However, their intervening sequences are unusual in ways which would be expected to prevent them from being spliced out in the normal manner (E. Lacy, N. Proudfoot and T. Maniatis, personal communication). Thus, there are pseudogenes having unusual (or absent) intervening sequences associated with productive α- and β-type globin genes in all species for which detailed information is available. This leads us to conclude that they are probably important, and it is attractive to consider them as controlling, in some fashion, the productive globin genes. We think it unlikely that the globin pseudogenes are dead genes without function.

How might pseudogenes control productive genes?

We are investigating the possibility that pseudogenes might be 'diverting genes' able to modulate the expression of productive genes by diverting transcription into a degradative pathway. This possible mode of action of pseudogenes has two prerequisites: first, that each globin pseudogene and its related productive genes are members of the same transcriptional unit, although not necessarily of the same transcript; second, that a mechanism exists to select which portion of this unit is used. If the pseudogene portion is selected for transcription from the unit, the transcript would be degraded because the pseudogene lacks normal intervening sequences. If a productive gene portion is selected, processing of the transcript, transport out of the nucleus and translation could occur normally. Examples of processes similar to those envisaged here can be found in the literature: in adenovirus type 2, different portions of the late transcript are used in different mRNAs[35]; in a globin-SV40 system, transcripts not associated with normal intervening sequences do not yield globin polypeptides[36,37].

A second possibility is that $\psi\alpha30.5$ is an 'antigene', by which we mean that $\psi\alpha30.5$ is transcribed from the opposite (complementary) strand of DNA from that used in the productive gene. Such an anti-transcript would have the potential for forming an RNA–RNA heteroduplex with the productive gene transcript in a manner similar to that proposed by Davidson and Britten[38] for the transcripts of some repetitive DNAs. The resulting structure, with a form similar to that shown in Fig. 3, might function as a positive controlling element in erythroid tissues, or as a negative element in non-erythroid tissues. (This idea does not exclude the possibility that pseudogene anti-transcripts form ternary complexes with the transcripts of the corresponding productive genes and the small stable nuclear RNAs recently implicated in RNA processing by Lerner *et al.* and Rogers and Wall[39,40].)

Preliminary experiments aimed at exploring the transcriptional status of the $\psi\alpha30.5$ pseudogene have been done in erythroid tissue. We prepared ^{32}P-end-labelled fragments from $\psi\alpha30.5$ DNA which could be used as specific probes for the 'sense' and 'antisense' transcripts of the $\psi\alpha30.5$ pseudogene. We tested, by the Berk and Sharp procedure[41], the ability of total RNA from mouse fetal liver cells (an erythroid tissue) to form RNA–DNA hybrids capable of protecting these probes from S_1 nuclease. We have been unable in these preliminary experiments to find evidence for significant protection by the fetal liver RNA of either the sense or the antisense probes derived from $\psi\alpha30.5$, using conditions which allow easy detection of globin precursor RNA (A. J. Kinniburgh, personal commmunication). Thus, if the pseudogene is transcribed in erythroid tissues, its available transcript must be at a steady-state level lower than that of globin precursor RNA. This result agrees with that already cited for the rabbit pseudogene β_2 (ref. 22).

The general hypothesis that pseudogenes control the productive genes in some fashion, nevertheless, remains attractive and we are investigating the hypothesis further, including tests in non-erythroid tissues. Certainly, the widespread occurrence of globin pseudogenes argues strongly for their functional importance.

We thank Drs Y. Nishioka, A. Leder, P. Leder, N. Proudfoot and T. Maniatis for sequence data before publication, Natalie Borenstein and John Devereux for technical assistance, Dr J. L. Slightom for advice in the DNA sequencing, and Drs A. J. Kinniburgh and J. Ross for advice and help in the experiments testing for transcription of $\psi\alpha30.5$. This work was supported by NIH grants AM20120 and GM20069 to O.S., and GM21812 to Dr F. R. Blattner, whom we thank for the shared use of laboratory equipment. The recombinant DNA experiments were carried out in accordance with NIH guidelines.

Proximity of mRNA5′-region and 18S rRNA in eukaryotic initiation complexes

Kunio Nakashima*, Edward Darzynkiewicz† & Aaron J. Shatkin

Roche Institute of Molecular Biology, Nutley, New Jersey 07110

Messenger RNA was covalently linked to 18S ribosomal RNA in eukaryotic 40S and 80S initiation complexes by photoreaction with an RNA cross-linking agent, 4′-substituted psoralen. The sites of interaction of the mRNA capped 5′-region included some 3′-ends of 18S rRNA.

An early step in protein synthesis is the binding of mRNA to ribosomal small subunits. The resulting initiation complexes in prokaryotes apparently are stabilized by base pairing between the 3′-terminal sequence of 16S ribosomal RNA,...CCUCCUUA, and a purine-rich nucleotide stretch located in mRNA on the 5′-side of the AUG initiator codon[1-3]. The suggestion that mRNA–rRNA interactions are similarly involved in the initiation of eukaryotic translation[4] has been a topic of considerable speculation[5-9]. Comparative analyses have demonstrated a highly conserved 3′-terminal sequence in the small rRNAs of *Escherichia coli*[1], *Bacillus stearothermophilus*[10] and maize chloroplast[11] as well as in yeast[12], slime mould, wheat, silkworm, mouse[5], rat[13] and rabbit[14] but the CCUCC sequence implicated in prokaryotic initiation is absent from eukaryotic 18S rRNA. Thus, conservation of the 3′ sequence may be related to rRNA processing or events other than initiation of protein synthesis. However, some eukaryotic viral[15] and cellular[16] mRNAs contain within their noncoding 5′ region nucleotide sequences complementary to the 3′ end of 18S rRNA and consequently at least could contribute to stable initiation complex formation.

Psoralens are tricyclic photoreactive compounds that intercalate into nucleic acids. Irradiation of polynucleotide-bound psoralen with long wavelength UV light produces adducts with pyrimidine bases. Because psoralens are bifunctional agents, they can also form cross-links between interacting pyrimidine-containing nucleotide sequences[17]. 4′-Substituted derivatives of psoralen with improved

photoreactivity have been synthesized recently and have already proved useful for investigating genome structure–function relationships in RNA viruses[18]. For example, photoreaction of reovirus with 4′-aminomethyl-4,5′,8-trimethylpsoralen (AMT) produced RNA–RNA cross-links between the two complementary strands comprising the viral genome and inactivated its template function for the virion-associated RNA polymerase[19]. These findings suggested that AMT photoreaction would be useful for probing other types of nucleoprotein complexes, such as those formed between mRNA and ribosomes during initiation of protein synthesis.

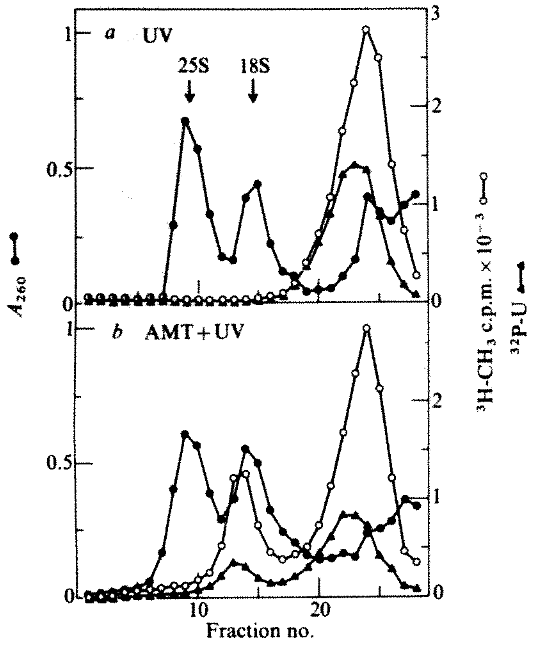

Fig. 1 Cross-linking of reovirus mRNA to 18S rRNA in wheat germ 40S initiation complexes. Reovirus mRNA radiolabelled with ^{3}H-methyl in the 5′-terminal cap, m^{7}GpppG^m and internally with ^{32}P-UMP was synthesized *in vitro* as described previously[43]. The viral mRNA was nicked to fragments sedimenting at 4–6S by incubation in 50 mM NH$_4$HCO$_3$, *p*H 10, at 98 °C for 3 min. The fragments were used to form 40S initiation complexes by incubation in wheat germ translating extracts in the presence of 0.2 mM sparsomycin to block elongation and 0.4 mM guanosine-5′-(β,γ-methylene)triphosphate to decrease 60S subunit joining to 40S–mRNA complexes[23]. Complexes were isolated by centrifugation for 4 h and 189,000*g* in the SW40 rotor in 10–30% glycerol gradients containing 10 mM Tris-HCl (*p*H 7.4), 0.75 mM Mg acetate and 70 mM KCl[20]. Fractions containing 40S initiation complexes (which also included free 60S subunits) were combined and irradiated with long wavelength UV light for 20 min at 0 °C in the absence (*a*) and presence (*b*) of 2.8 × 10^{-4} M 4′-aminomethyl-4,5′,8-trimethylpsoralen (AMT) as described previously[44]. The irradiated mixtures were incubated at 37 °C for 1 h with proteinase K (1 mg ml^{-1}) and 0.5% SDS, and the RNA was extracted with water-saturated phenol and analysed by centrifugation (SW-41, 131,000*g*, 16 h, 5 °C) in 10–30% glycerol gradients containing 50 mM Tris-HCl, *p*H 7.4, 150 mM NaCl and 1 mM EDTA. Fraction aliquots were counted in Aquasol (NEN) after determining the $A_{260\,\mathrm{nm}}$.

We have used this approach to look for RNA–RNA interactions between the ends of radiolabelled mRNA and rRNA in eukaryotic initiation complexes.

Cross-linking of reovirus mRNA and 18S rRNA in wheat germ 40S and 80S initiation complexes

Most eukaryotic mRNAs are monocistronic. During initiation of translation ribosomes bind to mRNA at or near the 5′ cap and re-position, perhaps by a scanning mechanism, at the 5′-proximal AUG codon to start polypeptide synthesis[6]. Previous studies with reovirus mRNA and mRNA fragments labelled with ^{3}H-methyl in the 5′ cap, m^{7}GpppG^m, and at internal sites with ^{32}P have demonstrated that capped molecules are selectively bound to ribosomes[20–22]. Thus when ^{3}H-methyl, ^{32}P-UMP labelled, alkali-fragmented reovirus mRNA (chain length ~200 nucleotides) was incubated in wheat germ cell-free translating extract in conditions of 40S initiation complex formation, 32% of the ^{3}H and 4% of the ^{32}P was bound to ribosomal small subunits and sedimented in a glycerol gradient in a position close to 40S subunits; similar results have been described previously[23,24]. To determine whether mRNA and rRNA were closely apposed in these complexes, pooled fractions from the 40–60S region of the gradient were irradiated at $\lambda_{352\,\mathrm{nm}}$ in the presence and absence of the RNA cross-linking agent, AMT, and the RNA was extracted from the initiation complexes and analysed by gradient sedimentation. As shown in Fig. 1*a*, initiation complexes irradiated in the absence of AMT yielded labelled mRNA

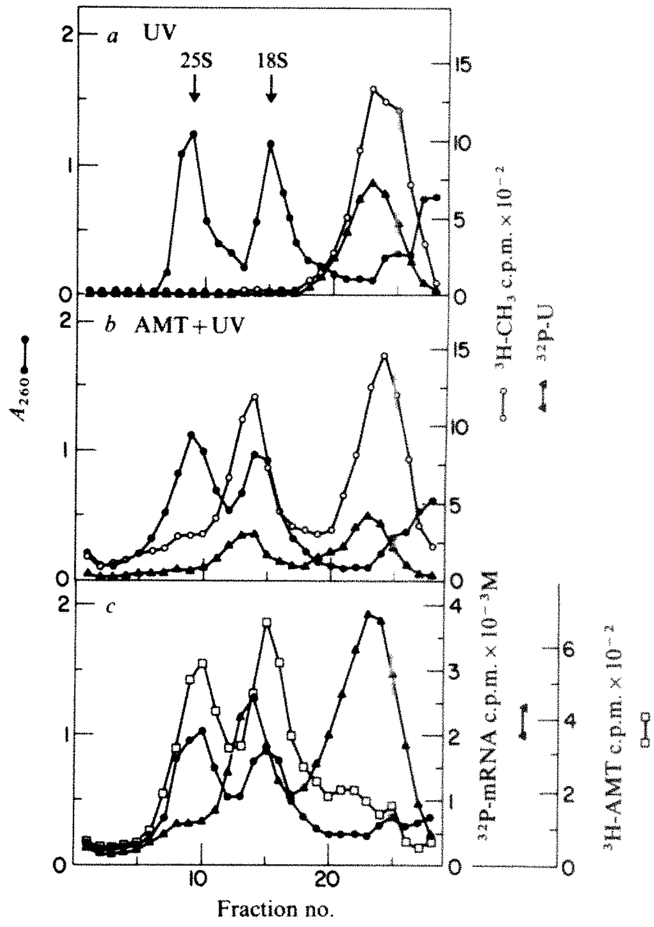

Fig. 2 Cross-linking of reovirus mRNA to 18S rRNA and covalent binding of ^{3}H-AMT to rRNAs in wheat germ 80S initiation complexes. Radiolabelled reovirus mRNA fragments were incubated as in Fig. 1 except that mixtures contained 0.2 mM GTP in place of guanosine-5′-(β,γ-methylene)triphosphate to obtain 80S complexes. Complexes containing double-labelled fragments were isolated by glycerol gradient centrifugation and UV-irradiated in the absence (*a*) or presence (*b*) of 2.8 × 10^{-4} M AMT. For *c*, fragments were prepared from mRNA synthesized in the presence of all four [α-^{32}P]labelled ribonucleoside triphosphates and unlabelled S-adenosylmethionine, and the incubation mixture, rather than isolated initiation complexes, was irradiated for 20 min in 1.4 × 10^{-4} M ^{3}H-labelled AMT (specific activity 1.4 × 10^5 c.p.m. μg^{-1}. RNA was extracted and analysed by glycerol gradient centrifugation as described in the legend to Fig. 1.

fragments that sedimented at the top of the gradient, well-separated from the rRNAs. By contrast, complexes that were irradiated in the presence of AMT yielded a significant portion of both the ^3H (28%) and ^{32}P (25%) sedimenting in a position slightly faster than the small ribosomal RNA (Fig. 1*b*).

Like 40S initiation complexes, 80S complexes irradiated with AMT also yielded a large fraction (38%) of the radioactive mRNA fragments cross-linked to 18S rRNA (Fig. 2*a*, *b*). Apparently there was little interaction of mRNA fragments with the large rRNA in initiation complexes. However, the rRNAs in both ribosomal subunits were accessible to psoralen photoreaction. As shown in Fig. 2*c*, in conditions which resulted in cross-linking of ^{32}P-labelled mRNA fragments to 18S rRNA, both rRNAs formed ^3H-labelled AMT adducts; psoralen average molar ratios were 0.8 and 1.5 for the small and large rRNAs, respectively.

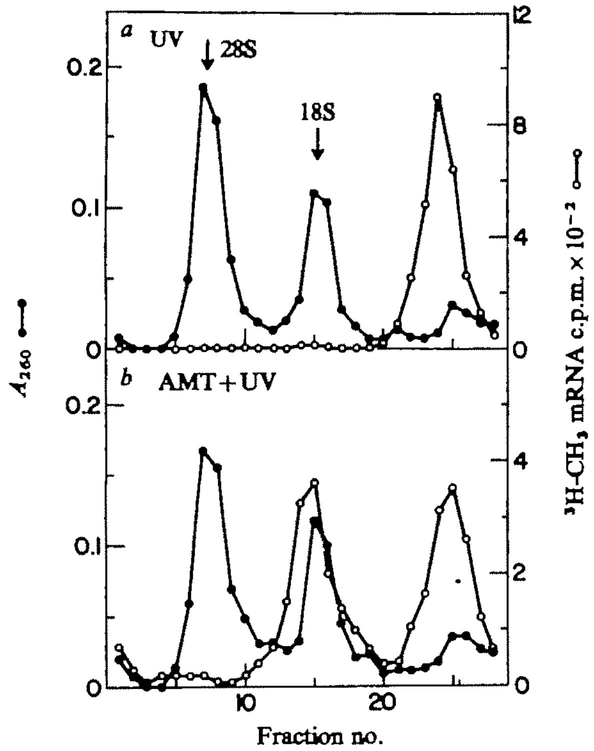

Fig. 3 Cross-linking of vesicular stomatitis virus mRNA to 18S rRNA in reticulocyte 80S initiation complexes. ^3H-methyl-labelled viral mRNA containing all radioactivity in the 5′-terminal cap, m^7GpppA^m was synthesized *in vitro* in the presence of 2 μM *S*-adenosyl-L-[Me-^3H]methionine (specific activity 70 Ci $mmol^{-1}$)[45]. Rabbit reticulocyte lysates (treated with haemin)[46] were used to form 80S initiation complexes as in Fig. 2. Gradient fractions containing complexes were combined, irradiated in the absence (*a*) or presence (*b*) of 2.8×10^{-4} M AMT, and the extracted RNA analysed as described for Fig. 1.

Results essentially the same as those in Figs 1 and 2 were obtained with intact mRNA and when sedimentation analyses were done in denaturing conditions in 99% Me_2SO-sucrose gradients, although the ribosomal and mRNAs were less well resolved. With either intact mRNA or fragments, interaction with 18S rRNA was dependent on initiation complex formation. Cross-linked hybrid molecules were not obtained by AMT photoreaction of a mixture of mRNA and purified rRNAs. Furthermore, cross-linking of ^3H-methyl, ^{32}P-AMP-labelled mRNA to rRNA was not observed following AMT photoreaction of incubation mixtures that were complete except for the absence of ATP which is required for mRNA binding to ribosomes[25,26].

Interaction of 18S rRNA with other mRNAs in rabbit reticulocyte and wheat germ initiation complexes

Various other 5′-terminally labelled viral mRNAs including *in vitro* transcripts synthesized by the virion-associated RNA polymerases of vesicular stomatitis (VSV), influenza and cytoplasmic polyhedrosis (CPV) viruses and genome RNAs of tobacco mosaic (TMV) and satellite tobacco necrosis (STNV) viruses were tested. Each of these RNAs interacted with the 18S rRNA in wheat germ initiation complexes as detected by AMT photoreaction (data not shown). In addition, 40S and 80S initiation complexes formed in rabbit reticulocyte lysates gave results similar to those obtained in the wheat germ system. For example, when initiation complexes of reticulocyte 80S ribosomes and fragmented VSV mRNA containing 5′-terminal ^3H-methyl-labelled m^7GpppA^m were photoreacted with AMT, 47% of the ribosome-bound radioactivity cross-linked to, and sedimented with the 18S rRNA (Fig. 3).

Capped ribopolymers, synthesized by incubating polynucleotide phosphorylase, ribonucleoside diphosphates and ^3H-methyl-m^7GpppG^m-C in primer-dependent conditions, have proved useful for studies of structural and compositional effects on mRNA binding to ribosomes[27]. Capped poly(U) forms only 40S initiation complexes with wheat germ ribosomes while capped poly(A, U) associates with 80S monosomes[27]. However, as observed with natural mRNA, AMT photoreaction of the 40S-capped poly(U) complexes or of the capped poly(A, U)–40S and 80S complexes resulted in polymer cross-linking to 18S rRNA only (data not shown).

Sites of cross-linking of 18S rRNA to 5′ end of mRNA

Initially we attempted to test whether the 3′ region of 18S rRNA interacts with mRNA during initiation by using prelabelled ribosomes but were unsuccessful in radiolabelling the 3′ terminus of rRNA *in situ* by incubating wheat germ extracts with ^{32}P-pCp and RNA ligase[28]. Instead we used the same technique to label purified, cross-linked hybrids of 18S rRNA and mRNA fragments isolated from AMT-photoreacted wheat germ 80S initiation complexes. They were formed with 5′ ^3H-methyl-labelled reovirus mRNA that had been treated at *p*H 10 before ribosome binding to produce mRNA fragments containing a 3′-terminal phosphate. As a consequence, ^{32}P-pCp-labelling of the cross-linked RNA–RNA complexes was apparently limited to free hydroxyl groups at the 3′ end of the rRNA strands. The radiolabelled sample, which included an excess of 18S rRNA from ribosomes that did not bind mRNA in addition to rRNA–mRNA complexes, was digested with RNase T_1. The resulting oligonucleotide fragments were loaded onto a column of acetylated dihydroxyboryl (DBAE)-cellulose in conditions that result in the selective binding of those oligonucleotides that contain 2′,3′-*cis*-diols[29]. Since the ^{32}P was present as ^{32}P-pCp at the 3′ end of rRNA (and T_1 RNase digestion results in oligonucleotides with a 3′-terminal phosphate), 99% of the ^{32}P-labelled fragments did not bind to the resin. The ^3H radioactivity, however, bound to the extent of 78% as expected for mRNA fragments containing 5′-terminal $m^7G^{5'}ppp^{5'}G^m$, that is, a 2′,3′-*cis*-diol in the 5′-linked m^7G (ref. 30). The bound oligonucleotides were eluted and rechromatographed on DBAE-cellulose. There was quantitative binding of the ^3H-labelled material, and more than 70% of the ^{32}P-labelled oligonucleotides were retained on the resin in the second pass (Fig. 4*a*), presumably due to cross-linking to capped mRNA fragments since in the absence of AMT photoreaction there was little ^{32}P rebinding.

The DBAE-bound sample was eluted and analysed by electrophoresis in a 20% polyacrylamide gel in denaturing conditions in 7 M urea. Although the capped oligonucleotides released from at least six of the reovirus mRNA species by RNase T_1 digestion are 8 to 10 nucleotides long[31], the ^3H-labelled cross-linked sample migrated as a broad peak of chain length ~15 to ~35 nucleotides as estimated from the position of marker dyes, bromophenol blue and xylene cyanol (Fig. 4*b*). The ^{32}P-labelled oligonucleotides were resolved into a fraction that co-migrated with the peak of ^{3}H and a larger, more heterogeneous component near the xylene cyanol dye. On the basis of the known 3′- and 5′-terminal sequences of rRNA and reovirus mRNAs, RNase T_1 treatment would release from 3′-^{32}P-pCp-labelled wheat germ 18S rRNA[5] the radioactive oligonucleotide, AUCAUUG-^{32}P and from a mixture of ^{3}H-methyl-labelled reovirus mRNAs, several 5′-capped A,U-rich oligonucleotides of chain length 8–10 nucleotides[31]. Cross-linking by AMT of the rRNA 3′ end to mRNA 5′ fragments would result in hybrids of minimum size ~15–17 nucleotides, a value corresponding reasonably well to the double-labelled peak at fractions 46–47 in Fig. 4*b*. The formation of cross-links involving pyrimidine residues distal to the 3′ end T_1 fragment of rRNA might have two related effects consistent with the higher ^{32}P/^{3}H ratio in the longer oligonucleotides: increased accessibility of the 3′ end for ^{32}P-pCp addition by RNA ligase and decreased susceptibility for complete cleavage by RNase T_1. Alternatively the radioactivity profiles may reflect cross-linking of some mRNA 5′ ends to other sites in the 18S rRNA. Results similar to those in Fig. 4 were obtained with reovirus mRNA–18S rRNA cross-linked fragments from wheat 40S and rabbit 80S initiation complexes.

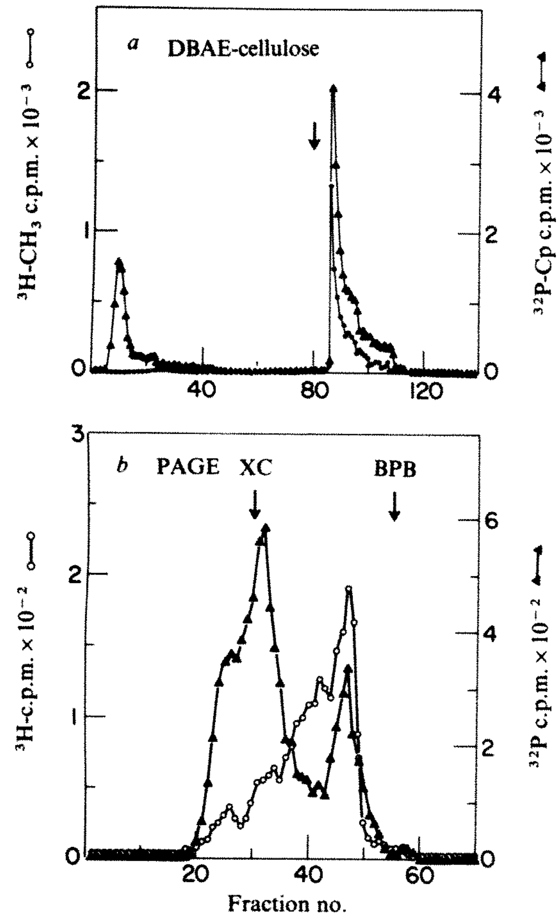

Fig. 4 Analysis of RNase T_1 digest of 5′ ^{3}H-methyl labelled reovirus mRNA cross-linked to 3′-^{32}P-labelled 18S rRNA. Wheat germ 80S initiation complexes were isolated, photoreacted with AMT and the cross-linked complexes of mRNA fragments with 18S rRNA were obtained as in Fig. 1. rRNA in the complexes was radiolabelled at the 3′ end by incubation with ^{32}P-pCp and T_4 RNA ligase[28]. After digestion with RNase T_1 (200 μg RNA, 100 units T_1 in 0.5 ml 20 mM Tris-HCl buffer *p*H 8 containing 0.1 mM EDTA) at 37 °C for 1 h, the digest was added to 2 ml of buffer A[30] and applied to a column (0.6 × 5 cm) of acetylated dihydroxyboryl-substituted cellulose (DBAE-cellulose). After extensive washing with buffer A, bound material was eluted with 1 M sorbitol in buffer A and precipitated by addition of 3 volumes of ethanol and standing overnight at −20 °C. The precipitated RNA was recovered by centrifugation and rechromatographed on DBAE-cellulose (*a*). Aliquots of fractions were counted in Aquasol. The RNA in fractions 85–115 (arrow indicates start of sorbitol elution) was recovered by ethanol precipitation and analysed by electrophoresis in a 20% polyacrylamide gel in the presence of 7 M urea. The 0.6 × 10 cm cylindrical gel was fractionated into 1 mm slices that were dissolved in 18% H_2O_2 before counting in Aquasol (*b*). XC, xylene cyanol dye; BPB, bromophenol blue dye.

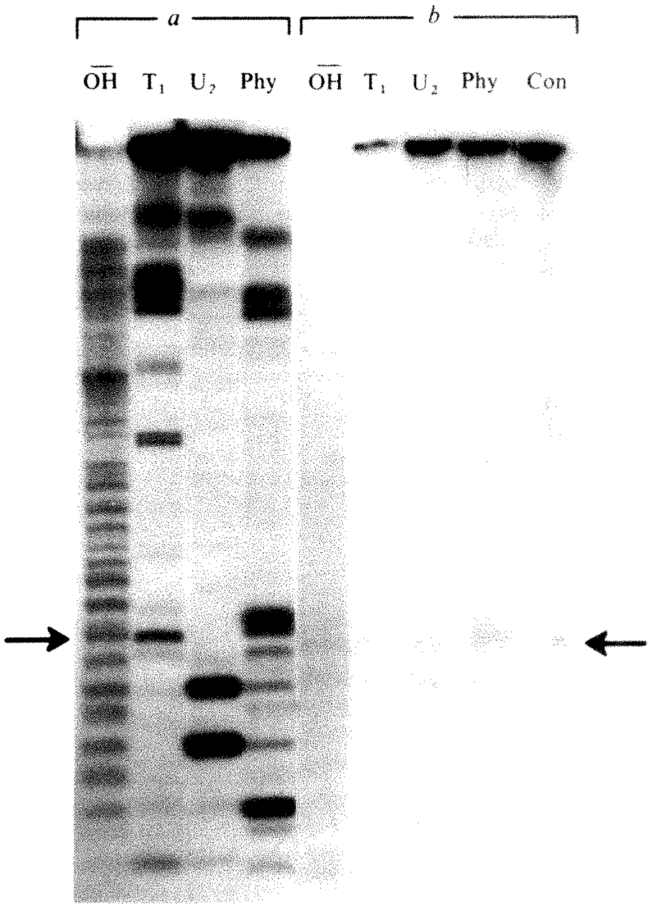

Fig. 5 Nucleotide sequence analyses of 18S rRNA and mRNA–rRNA complexes. AMT cross-linked complexes of mRNA and 18S rRNA that had been 3′-end labelled with ^{32}P-pCp, RNase T_1 digested and selectively bound to DBAE-cellulose two times (fractions 85–115 in Fig. 4*a*) were recovered by ethanol precipitation and irradiated with short wavelength UV light (254 nm) for 2 h at 0 °C in conditions that photoreverse AMT cross-links[32]. After photoreversal, the ^{32}P-labelled fragments were analysed by partial enzymatic digestion and polyacrylamide gel electrophoresis[33] in comparison with 3′-terminally ^{32}P-labelled 18S rRNA. *a*, Wheat germ 18S rRNA labelled at the 3′ end with ^{32}P-pCp; *b*, RNase T_1 fragment from photoreversed rRNA–mRNA complexes. Arrows indicate 18S rRNA 3′-terminal T_1 oligonucleotide. $\overline{\text{OH}}$, alkaline hydrolysate; T_1, U_2 and Phy, the respective RNase digests using conditions described previously[47]; Con, RNase T_1 fragments from photoreversed complexes not further digested.

To confirm that the DBAE-bound, ^{32}P-labelled oligonucleotides included 3′ ends of 18S rRNA, the cross-linked, double-labelled fragments eluted from the resin were irradiated at a wavelength of 254 nm to photoreverse the AMT cross-links[32]. The photoreversed sample was analysed in a polyacrylamide sequencing gel in comparison with 3′-^{32}P-labelled wheat germ 18S rRNA[33]. Partial enzymatic digests of the rRNA in non-denaturing conditions yielded patterns consistent with the published 3′ sequence[5] including a nuclease-resistant, presumptive hairpin structure extending from about residue 10 to 30 (Fig. 5*a*). Although some of the radioactivity in the irradiated oligonucleotide sample remained near the gel origin, the released ^{32}P-labelled material migrated in a position corresponding to the T_1 limit oligonucleotide of rRNA (Fig. 5*b*, Con, arrows). This oligonucleotide yielded a series of shorter products on digestion with alkali (OH). RNase T_1 treatment released some radioactivity which migrated near position 1 as in T_1 digests of rRNA, but most of the oligonucleotide remained undegraded (T_1). It was also relatively resistant to *Physarum* RNase I in these partial digestion conditions (Phy). RNase U_2 treatment yielded two additional bands that corresponded in position to oligonucleotides obtained from rRNA by U_2 digestion (U_2). These results indicate that the DBAE-selected, cross-linked fragments included some of the ^{32}P-pCp-labelled 3′-terminal T_1 oligonucleotide from 18S rRNA.

Role of base pairing

Several lines of evidence[2,3,34–36] support the early suggestion that initiation codon selection in prokaryotic mRNAs is influenced by base pairing between the 3′ sequence of 16S rRNA and a polypurine region about 10 nucleotides to the 5′ side of the initiator triplet. Similar kinds of experiment in eukaryotes have not been reported, but sequences complementary to the conserved 3′ end of 18S rRNA occur in the 5′ noncoding regions of many eukaryotic mRNAs. In some cases the complementarity is striking, with calculated stabilities for the potential mRNA–rRNA base-paired structures in the same range as prokaryotic initiator regions[15,37,38], and in polyoma virus mRNA the 5′ leader contains multiple copies of such a sequence[39]. In other functional eukaryotic mRNAs, including species of reovirus[31] and VSV mRNA[40], the potential for stable base pairing between 5′ ends and 18S rRNA 3′-termini is so low as to suggest that it could have at most a minor influence on initiation, indicating that this type of base pairing is not obligatory for eukaryotic protein synthesis. The observation that the translation of prokaryotic virus mRNAs in wheat germ extract is strongly enhanced after enzymatic addition of a 5′ cap supports this conclusion[41].

In an effort to test experimentally whether mRNAs interact with rRNAs during eukaryotic initiation, we have used photochemical reaction with the RNA–RNA cross-linking agent, AMT. By using ^{3}H-methyl-labelled capped mRNA and ^{32}P-pCp-labelling of rRNA, we detected cross-linking between mRNA 5′ fragments and 18S rRNA 3′ sequences in both 40S and 80S initiation complexes. It is not clear if cross-linking occurs at many sites in the 18S rRNA or is restricted to the 3′ end. Although the findings indicate that the opposite ends of mRNA and 18S rRNA are proximally located at least in some initiation complexes, the interaction clearly is not strictly homologous to 'Shine and Dalgarno' base-paired structures. One obvious difference noted previously[5] is the variation among eukaryotic mRNAs in the position of the rRNA complementary sequences relative to the initiator AUG, compared with the fixed position in prokaryotic mRNAs. However, since different 5′ leaders precede the initiator codon in eukaryotic mRNAs and ribosomes apparently re-position at the 5′-proximal AUG after attaching near the cap[6], 18S rRNA 3′-complementary sequences with functional effects on initiation could occur at different places within the 5′ noncoding region of various mRNAs. Another consideration is that some mRNAs, and particularly synthetic ribopolymers such as capped poly(U), contain too few 5′-proximal nucleotides complementary to the 3′ sequence of 18S rRNA to form a stable base-paired structure of the prokaryotic type. By the cross-linking method capped poly(U), as well as mRNAs like adenovirus hexon mRNA which can form a stable base-paired structure between 5′ leader sequences and 18S rRNA 3′ ends[15], would be fixed to 18S rRNA by the formation of AMT diadducts between pyrimidines that are even transiently juxtaposed. In some cases cross-linking presumably could also occur without base-pairing by the sequential reaction of AMT with two pyrimidines.

It is important to emphasize that although initiation-dependent interactions, perhaps base-pairing, between mRNA 5′-terminal regions and 18S rRNA can be detected by AMT cross-linking, their functional role if any in eukaryotic protein synthesis remains to be established. However, a stable interaction compatible with base-pairing has been demonstrated between 18S rRNA and globlin mRNA in 40S initiation complexes formed in a reconstituted mammalian cell-free protein synthesizing system (B. Erni and T. Staehelin, personal communication). It may be possible to test whether this interaction has a function in translation by using cloned rDNA including specific fragments complementary to the 3′ end of 18S rRNA[34,35,42].

We thank Alba LaFiandra and Maureen Morgan for assistance, Drs M. Kozak and Y. Furuichi for discussion, Dr J. Hearst for ^{3}H-AMT, and the following for gifts of virus or viral mRNA: Drs A. Marcus (TMV), J. Clark (STNV), Y. Furuichi (CPV), A. Banerjee (VSV) and R. Krug (influenza virus).

Note added in proof: Recent studies indicate that mRNA cross-linking is mainly within the ribosome-protected region.

Monoclonal antibodies which recognize different cell types in the rat retina

Colin J. Barnstable

Department of Neurobiology, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115

Seven monoclonal antibodies have been produced against a membrane preparation from adult rat retina. Three antibodies reacted with particular regions of rat photoreceptor cell surfaces: RET-P1 labelled the cell bodies, outer and inner segments (rods but not cones), RET-P2 labelled only outer segments and RET-P3 labelled only the cell bodies. Three antibodies reacted with glial cells; RET-G2 and RET-G3 were specific for Müller cells, RET-G1 also labelled glia elsewhere in brain. The seventh antibody (RET-N1) reacted with many types of neuronal cells.

It is widely believed that differences between classes of neural cells are expressed in part by distinct patterns of cell-surface molecules[1-3]. Cell-surface molecules such as transmitter receptors and ion channels are basic to the function of the nervous system[4,5]. These and other surface molecules may be important in determining the exquisite specificity of synaptic connections.

Antibodies are almost uniquely suited for the detection of such cell-surface molecules since they can be used in histochemical assays to resolve single cells in mixed cell populations; they can be used in quantitative biochemical assays to determine the amount, molecular nature and tissue distribution of the antigens recognized; and perhaps most importantly, they can be raised against essentially any antigen or cell type of interest. Progress in producing antibodies against any but the broadest classes of neural cell types has, until recently, been hindered by the heterogeneity of the immune response generated against the available antigens[6-9]. The technique introduced by Milstein and co-workers[10,11], whereby antibodies are produced by cloned cell lines, has overcome many of these difficulties. Such monoclonal antibodies have already been of great value in biochemical, functional and genetic analyses of cell surface molecules[12-15].

We have chosen the visual system, and particularly the retina, as a model system in which to study the differences in cell-surface molecules of different subclasses of neural cells. This system has the advantage that many of the cells involved in the transmission of visual information from the photoreceptors to the primary visual cortex have been identified and reasonably well characterized with respect to their physiological responses and synaptic interactions[16-18]. The retina has the additional advantages that it is readily accessible, it has only seven basic neural cell types, its layered structure generally allows assignment of cell type from position alone[19], and it is a region of the vertebrate central nervous system (CNS) from which single dissociated cells have been isolated and successfully used in physiological[20] and biochemical studies[21,22].

This article describes initial observations on seven monoclonal antibodies that recognize cell-surface molecules of rat retina. Three of these antibodies react with photoreceptors, although each stains subregions of the cell surface in a distinct way. Three antibodies react with Müller cells, the main glial cell type of retina, and the seventh reacts with many classes of neuronal cells throughout the brain.

Production and immunological characterization of antibodies

Retinas were dissociated from adult CD rats (Charles River Breeding Laboratories) and a crude membrane pellet prepared as described by Barclay *et al.*[23]. Female BALB/c mice were given two intraperitoneal injections of 200 μg of membrane protein in Freund's adjuvant 3 weeks apart. Three weeks after the second injection mice were given an intravenous injection of 100 μg of membrane protein in saline. Four days later spleens were removed and used for fusions. Spleen cells were fused with either P3-NS1/1-Ag4-1 or 8653 myeloma cells (gifts of C. Milstein and P. Goodfellow, respectively), and hybrid cultures selected and cloned as described previously[15,24].

Hybrid- and clone-culture supernatants were tested for antibody activity using an indirect trace radioactive binding assay as described by Williams[25]. Target particles consisted of adult rat retina that had been lightly homogenized and fixed with 0.5% paraformaldehyde[26]. Bound mouse immunoglobulin was detected using a ^{125}I-labelled F(ab$'$)$_2$ fragment of an affinity-purified rabbit anti-mouse IgG antibody.

The seven antibodies described here have been selected from the products of four separate fusions. All seven antibodies were found to be of the IgG1 subclass when tested by Ouchterlony double diffusion against subclass-specific sera.

The antibodies were initially selected for study because the early culture supernatants did not react in a binding assay with rat thymocytes or by immunofluorescence with a fibroblast cell line grown out from newborn rat lung (data not shown). Thus they seemed to recognize antigens that were not expressed by all rat tissues. To study the antigen expression by different tissues in a more quantitative way, each antibody was absorbed with crude membrane preparations from retina, cerebral cortex and cerebellum, with liver as a control non-neural tissue. The amount of membrane needed to inhibit antibody-binding activity by 50% was determined (see Table 1 legend) and was used as a measure of the level of antigen expression of that particular tissue (Table 1). Because these

Table 1 Tissue distribution of antigens recognized by anti-retina antibodies

Antibody	Antigenic activity of membrane			
	Retina	Cortex	Cerebellum	Liver
RET-P1	50	<1	<1	<1
RET-P2	2,326	<1	<1	<1
RET-P3	15	<1	<1	<1
RET-G1	238	1,724	600	<1
RET-G2	87	<1	1.3	7
RET-G3	100	<1	5	8
RET-N1	312	91	161	<1

Crude membrane fractions[23] were prepared from each tissue. Aliquots of monoclonal antibody solution, at a dilution chosen so as to be limiting in the assay, were incubated with varying concentrations of membranes for 2 h at 4 °C. The residual antibody activity was then measured using a trace radioactive binding assay. At least 10 dilutions of each membrane preparation were used with each antibody. The antigenic activity is defined as the dilution of a 20 mg membrane protein per ml solution necessary to give 50% inhibition of the binding activity of an equal volume of antibody solution. The values given in the table are taken from inhibition curves, the points of which were each the mean of two separate inhibitions each assayed in duplicate.

0028-0836/80/290231-05$01.00

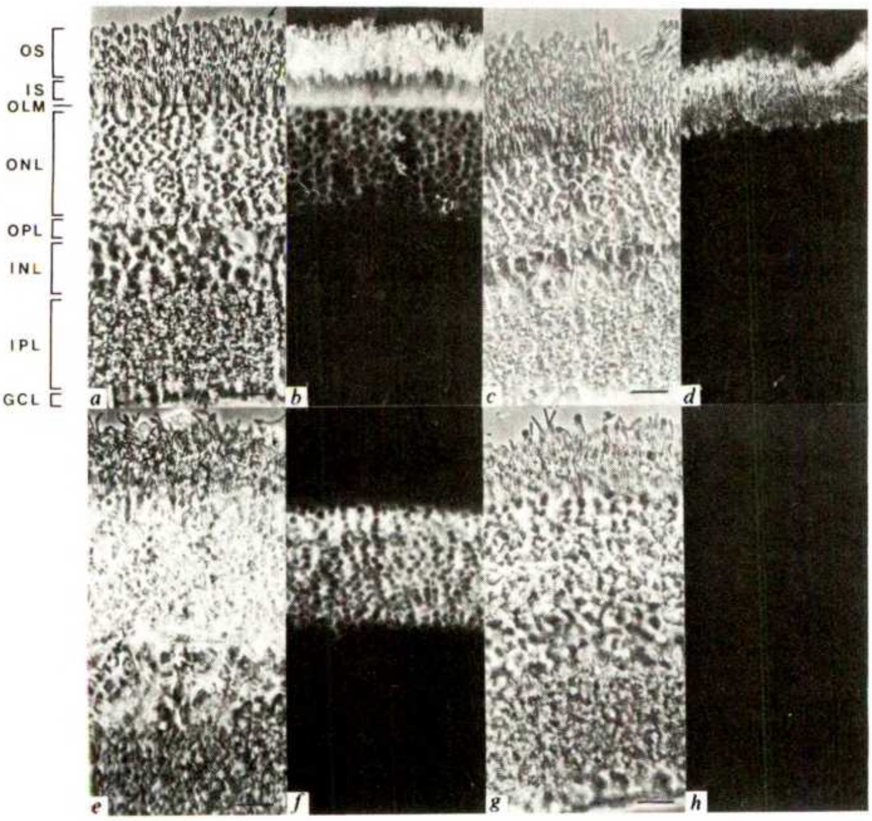

Fig. 1 Immunofluorescent labelling of sections of adult rat retina by antibodies RET-P1, RET-P2 and RET-P3. Rats were killed by cervical dislocation and the retinas rapidly dissected. They were fixed for 1 h at 4 °C in 1% parafomaldehyde, 0.1% glutaraldehyde in 0.1 M sodium phosphate buffer *p*H 7.6. After fixation the retinas were soaked in 30% (w/v) sucrose overnight. Sections (15 μ) were cut on a freezing microtome and dried onto subbed slides. Sections were preincubated with 5% (w/v) bovine serum albumin (BSA) in phosphate buffer for 1 h at 4 °C and then with the primary antibody for 18 h at 4 °C. The slides were washed in two changes of a large excess of phosphate buffer for 10 min each at 4 °C. Sections were then treated with a rhodamine-conjugated goat anti-mouse IgG preparation (Cappell) which was diluted in a solution of equal parts of 5% BSA in phosphate buffer and normal rabbit serum. Before use, the rabbit serum was passed over a column of mouse IgG coupled to Sepharose 4B to remove any heterophile anti-mouse IgG antibodies. After incubation for 45 min at room temperature the slides were again washed with two changes of phosphate buffer and then a coverslip applied using 50% glycerol in phosphate buffer as mounting medium. Slides were examined with a Zeiss ICM35 microscope. White light photographs were taken with phase contrast optics. Fluorescence photographs were taken using epi-illumination and excitation–barrier filter and reflector combination 48-77 15-9902. Photographs were taken on H & W Control film with 2 min exposures for fluorescence and an automatic light meter for phase contrast photographs. *a, b*, RET-P1 antibody; *c, d*, RET-P2 antibody; *e, f*, RET-P3 antibody; g, *h*, control using a monoclonal antibody against a human cell-surface glycoprotein. *a, c, e*, g, Phase contrast; *b, d, f, h*, fluorescence. The arrow at the top right corner of *a* indicates the only outer segment that can be detected as unlabelled in *b*. OS, outer segments; IS, inner segments; OLM, outer limiting membrane; ONL, outer nuclear layer; OPL, outer pelxiform layer; INL, inner nucelar layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar represents 20 μ.

values are functions of both quantity of antigen and antibody affinity, only comparisons between different tissues for the same antibody are meaningful. From Table 1 it can be seen that RET-P1, RET-P2 and RET-P3 antigens were predominantly if not exclusively localized in retina because only retina membrane was able to give measurable inhibition of antibody binding activity. RET-G2 and RET-G3 antigens were expressed strongly by retina, weakly by cerebellum and liver and not detectably by cortex. Neither antigen was detectable by immunofluorescent staining of cerebellum or liver sections (data not shown) so that it is not yet possible to ascribe the absorption to the presence of a few cells with high levels of antigen expression, many cells with low levels of antigen expression or even some nonspecific absorption that affects these two antibodies but not the others. RET-G1 and RET-N1 antigens were strongly expressed by all three brain regions but were not detectable on liver. Although the absorption has the advantage of being quantitative, it cannot be used to determine which cell types in a tissue are expressing the antigen. For this, immunofluorescent staining of tissue sections was carried out.

Antibodies RET-P1, RET-P2 and RET-P3 specifically label photoreceptors

The immunofluorescent staining of sections of adult rat retina given by RET-P1 is shown in Fig. 1*a* and *b*. With the exception of the outer plexiform layer, the whole of the photoreceptor layer was labelled. Clear ring fluorescence was found around almost all of the photoreceptor cell bodies. The packing between the cell bodies appeared looser towards the outer limiting membrane and the intervening spaces often showed fluorescence. This was probably due to the fibres which connect the cell bodies with their inner segments[27]. The photoreceptor inner segments were labelled at about the same intensity as the cell bodies but the outer segments had a much brighter fluorescence. These differences presumably represented differences in antigen density which supports previous observations that the composition of the outer segment membrane is different from that of the rest of the cell[28,29]. This was much more decisively demonstrated by the staining pattern given by antibodies RET-P2 (Fig. 1*c*, *d*) and RET-P3 (Fig. 1*e*, *f*). Within the limitations of the fluorescence assay, RET-P2 antigen was located exclusively on the outer segments and RET-P3 antigen was located exclusively on the photoreceptor cell bodies. These differences in labelling patterns seen with these three antibodies suggest that some photoreceptor membrane molecules are common to all regions of the cell while others are restricted to discrete areas of the cell. It is not yet known whether this restriction is caused by some form of anchorage of particular molecules in a fluid membrane to submembranous or extracellular elements or by localized areas of insertion of newly synthesized molecules in a non-fluid membrane.

Experiments are now under way to determine the chemical nature of the RET-P1, RET-P2 and RET-P3 antigens to see whether both membrane proteins and lipids are restricted in their localization. In addition, production of other antibodies that label specific regions of photoreceptors will allow an estimate of the number of compartments into which the photoreceptor cell membrane is divided.

Although RET-P2 antibody was not absorbed by cerebellum membrane, immunofluorescent labelling of cerebellum sections showed that it reacted with structures at the level of the initial segment of the Purkinje cell (data not shown). The exact nature of the labelled structures and their relationship to the photoreceptor outer segments have yet to be determined. Neither RET-P1 nor RET-P3 stained any cerebellar structures.

The rat retina consists almost entirely of rods[30], so that judging whether or not the three antibodies reacted with both rods and cones was almost impossible. To investigate this, the three antibodies were tested on a number of different species to see whether or not any of them reacted with a retina containing a higher proportion of cones. RET-P2 and RET-P3 seem to be specific for rat but RET-P1 reacted with several species (including BALB/c mice from which the antibody-producing spleen cell was derived). A group of photoreceptors in a section of retina from the tiger salamander (*Ambystoma tigrinum*) is shown in Fig. 2. Cells 1, 3 and 5 are rods although the outer segment of cell 3 was removed during dissection. All three cells stain throughout their length with the most intense fluorescence being in the outer segment. The bright band at the junction of the inner and outer segments was probably due to labelling of the deep membrane invaginations at this region. These invaginations have been shown to represent the initial stage of pinching off of the disks of the outer segment[31]. Cells 2 and 4 have the morphology of cones, that is, narrower cell bodies, narrower but longer inner segments and slender outer segments. The outer segments of cells 2 and 4 are almost certainly damaged but there is no trace of fluorescence on any part of the cell. This would indicate that antigen RET-P1 is restricted to rods. As can also be seen in Fig. 2, the axons and synaptic pedicles of the rods were labelled. In several cases fine labelled processes were found to be given off from the thick pedicles. The lack of staining of the outer plexiform layer in the rat retina found with this antibody may simply be because such staining was below the threshold for visualization or alternatively may be real and may represent a difference in antigen compartmentalization between the two species.

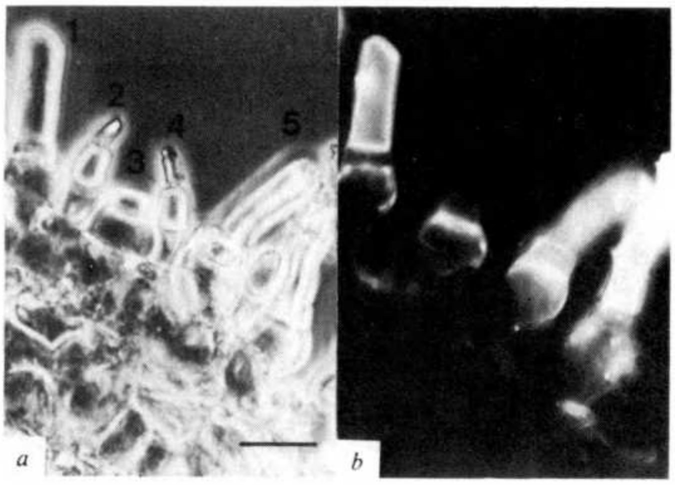

Fig. 2 Immunofluorescent labelling of tiger salamander photoreceptors by antibody RET-P1. Sections were prepared and treated as described in Fig. 1 legend except that the animals were dark-adapted for 4 h before being killed. *a*, Phase contrast; *b*, fluorescence. Scale bar represents 20 μ.

One obvious candidate for a photoreceptor-specific marker is the light-sensitive molecule rhodopsin. A rabbit antiserum raised against bovine rhodopsin stained both the outer and inner segments of frog photoreceptors[32]. This pattern was not given by any of the three antibodies described here. In addition, the anti-rhodopsin serum stained both rods and cones. None of these antibodies was inhibited by a partially purified preparation of bovine rhodopsin (a gift of Dr E. A. Schwartz) used at concentrations where whole retina membrane gave complete inhibition (data not shown). Thus, it is unlikely that any of these three antibodies recognize rhodopsin but final resolution of this must await a chemical analysis of the respective antigens.

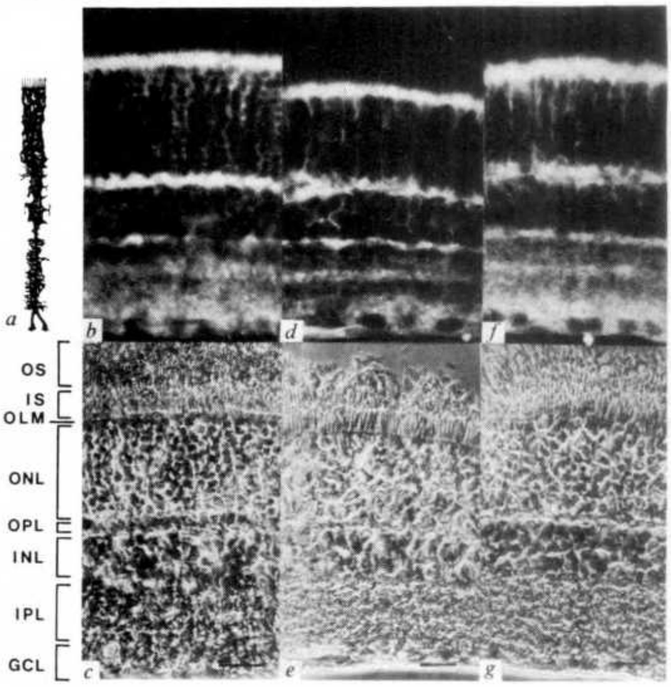

Fig. 3 Immunofluorescent labelling of sections of adult rat retina by antibodies RET-G1, RET-G2 and RET-G3. Sections were prepared and treated as described in Fig. 1 legend. *a*, A Müller cell taken from Golgi-stained retina as drawn by S. R. Cajal (ref. 35, p. 298); *b*, *c*, RET-G1 antibody; *d*, *e*, RET-G2 antibody; *f*, g, RET-G3 antibody. *b*, *d*, *f*, Fluorescence; *c*, *e*, g, phase contrast. Designation of retinal layers is described in Fig. 1 legend. Scale bar represents 20 μ.

Antibodies RET-G1, RET-G2 and RET-G3 specifically label Müller cells

Müller cells have a unique morphology in that they are the only cell type to extend radially across the retina from the outer limiting membrane to the inner limiting membrane[33,34]. The essential features of their structure, as shown in the Golgi-stained cell (Fig. 3*a*), were clearly picked out in the immunofluorescent labelling of sections of adult rat retina given by antibodies RET-G1 (Fig. 3*b*, *c*), RET-G2 (Fig. 3*d*, *e*) and RET-G3 (Fig. 3*f*, g). At the outer limiting membrane, each antibody labelled the fine finger-like Müller cell processes that extend up between the inner half of the photoreceptor inner segments. Thick radial processes passing through the outer nuclear layer were also labelled although the single focal plane shown in the photographs was not always adequate to show a single process traversing the whole width of that layer. Such fibres could frequently be followed visually. Virtually no tangential labelling was seen in the outer nuclear layer, indicating that the photoreceptor cell bodies had not reacted with the antibodies. The labelling in the inner nuclear layer was harder to interpret but probably represented Müller fibres following the contours of the cell bodies in this region on their way to the inner plexiform layer.

In very few cases was it possible to see a clear ring of fluorescence around a cell body as would have been expected if the neuronal cell bodies had been labelled. Those few cell bodies that were labelled had the position expected for Müller cell bodies. The radial Müller fibres give off fine tangential processes in the plexiform layers causing both plexiform layers to be labelled. The labelling of the inner plexiform layer showed three bands of higher intensity. One band was located at the junction of the inner nuclear and inner plexiform layers, one band was about half way through the inner plexiform layer and the other thick band was at the junction of the inner plexiform and ganglion cell layers and was continuous with the labelling of the bulbous feet that surround the ganglion cell bodies and optic fibres and end at the inner limiting membrane. This banded appearance of the inner plexiform layer, which probably reflects the density of tangential glial projections, was closely similar to the autoradiographic staining of Müller cells seen following uptake of radioactive GABA *in vitro* (refs 36, 37 and unpublished observations with R. W. Baughman).

As a further demonstration that antibody RET-G1 was reacting with Müller cells, immunofluorescent labelling of enzymatically dissociated adult rat retina cells[38] was carried out. The results (Fig. 4) clearly show that this antibody labelled cells with the morphology characteristic of Müller cells. Cells with the morphology of bipolar cells and a variety of amacrous cells were not labelled in these preparations.

Müller cells and astrocytes have a number of structural and functional features in common, such as close apposition to neuronal processes[39], potassium ion transport[40], and γ-aminobutyric acid transport[41]. Thus it was not surprising to find an antibody, RET-G1, that reacted with glial cells in all regions of brain. The results in Table 1 show that cerebral cortex and cerebellum express more RET-G1 per mg membrane protein than retina although the differences provide no information about the relative amounts expressed per cell.

In cerebellum, the cells expressing this antigen were found in all layers. The area illustrated in Fig. 5*c* shows labelled cell bodies in the granular layer and processes passing up through the unlabelled Purkinje cell layer to the molecular layer. Further studies will be necessary to determine whether this antigen is also on oligodendrocytes and glia of the peripheral nervous system. RET-G2 and RET-G3 antigens were expressed by Müller cells but not to a significant extent by other glia. The nature and function of these two 'Müller-cell specific' antigens are unknown. The two can be distinguished by their fluorescent labelling pattern on adult retina. RET-G2 antibody gave a relatively even labelling but RET-G3 antibody gave a highly punctate pattern of labelling in the inner plexiform layer. Studies at the electron microscope level will show whether these areas of increased labelling are related in any way to other structures in the inner plexiform layer, such as areas of glial processes close to synapses.

Antibody RET-N1 recognizes a neurone-specific antigen

Antibody RET-N1 labelled several cell types in sections of adult rat retina (Fig. 5*a*). It labelled the whole length of the photoreceptor inner segments but not the outer segments or cell bodies although some very faint labelling was found over the outer nuclear layer. Both plexiform layers were stained and many cell bodies in the outer half of the inner nuclear layer could be recognized. Axons of bipolar cells could be seen leaving some of these cells and passing through to the inner plexiform layer. There seemed to be fewer labelled cells in the inner half of the inner nuclear layer which may indicate that some amacrine cells were unlabelled. The ganglion cells were labelled. No traces of the characteristic glial labelling pattern—radial fibres in the outer nuclear layer and glial feet around the ganglion cells—were found. The absorption results (Table 1) indicated that RET-N1 antibody reacted with cortex and cerebellum. In agreement with this, the antibody was found to label cells at all levels in the cerebral cortex (data not shown). In cerebellum it also labelled several cell types. In the portion shown (Fig. 5*b*) it labelled Purkinje cells and brightly labelled pinceaux of basket cell terminals around the Purkinje cell initial segment. Many other cell bodies in the granular layer and processes in the molecular layer were also labelled, although in a pattern different from that given by antibody RET-G1. Thus antigen RET-N1 may be a marker for most if not all neurones of the CNS although further work will be necessary to show whether or not it cross-reacts with types of glial cells not found in the retina such as oligodendrocytes. It will also be of interest to determine whether antibodies RET-G1 and RET-N1 label glia and neurones, respectively, of the peripheral nervous system as these are of neural crest rather than neural tube embryonic origin. Experiments to investigate this are under way.

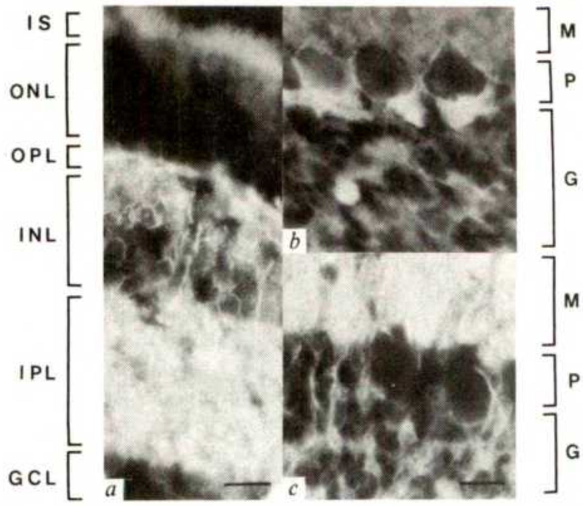

Fig. 5 *a*, Immunofluorescent labelling of adult rat retina by antibody RET-N1. The section preparation, labelling and the designation of retinal layers is as in the legend to Fig. 1. *b*, Immunofluorescent labelling of adult rat cerebellum by antibody RET-N1. *c*, Immunofluorescent labelling of adult rat cerebellum by antibody RET-G1. For *b* and *c* animals were anaesthetised with Nembutal and perfused through the ventricle with 2% paraformaldehyde in phosphate buffer. Cerebella were then dissected and treated as for retina. M, molecular layer; P, Purkinje cell layer; G, granular layer. Scale bar represents 20 μ.

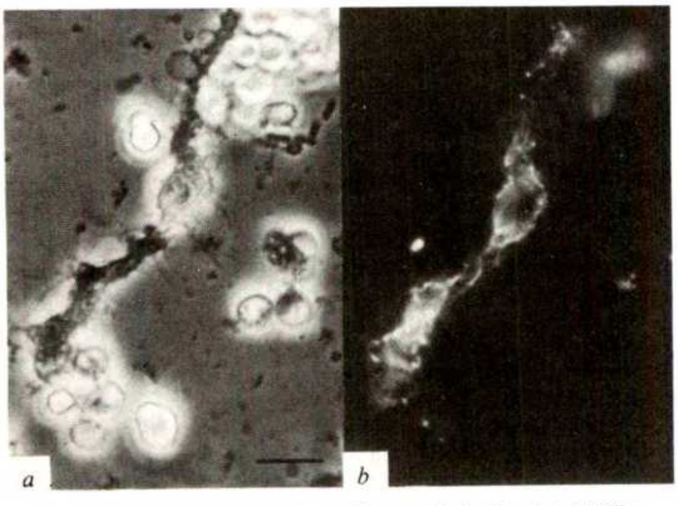

Fig. 4 Immunofluorescent labelling of enzymatically dissociated Müller cells by RET-G1 antibody. Retinas were dissected from adult rats and cells dissociated using published procedures[38]. The cell suspension was allowed to settle to the bottom of Petri dishes and the labelling carried out using 1-h incubations at room temperature for primary and fluorescent antibodies. Three rinses with HEPES-buffered Hank's salts solutions were carried out after each antibody incubation, care being taken not to disturb the cells. Scale bar represents 10 μ.

Discussion

The results presented above show clearly that monoclonal antibodies can be produced against subclasses of neural cells. It has yet to be shown formally that each antibody interacts with an integral cell-surface molecule rather than extracellular matrix or intracellular membrane material, but this seems likely. Fixation by itself is not an efficient way of allowing visualization of internal antigens in tissue sections. Addition of detergent to sections similar to those illustrated neither changed nor enhanced the labelling pattern, suggesting that external rather than internal antigens were recognized. Final demonstration of the cell-surface location of the antigens will be achieved by a combination of electron microscopic immunocytochemistry, biochemistry and studies in tissue culture on living cells.

The antibodies described here will be valuable for several studies. For example, they will be useful for studying the topography and development of particular cell types in the intact organism. Preliminary experiments have established that RET-P1, RET-P2 and RET-P3 are expressed at different stages of photoreceptor development and RET-G1, RET-G2 and RET-G3 are expressed at different stages of Müller cell development. Thus they are markers not only for adult cells but also for immature cells at discrete stages of development. Whether such stages are intrinsic to neural cells after the initial step of determination or whether they require distinct environmental triggers is not known. Experiments are in progress to test these alternatives by following cell maturation in defined *in vitro* culture systems.

Another use of antibodies such as those described above, and others now being characterized, will be for the separation of cells and subcellular fractions from adult and developing tissue for a variety of physiological and biochemical studies.

There is also the additional hope that production of antibodies that recognize particular neural cell subclasses may lead to the identification of cell-surface molecules that mediate functions specific to those subclasses and may, therefore, aid in an understanding of the molecular and genetic basis of neural cell development and function.

I thank Torsten Wiesel for his continuing encouragement and support of this work, Peter MacLeish for help with the salamander retina, Robert Baughman, Ed Furshpan, Peter Parham and Elio Raviola for their comments on the manuscript, Lynn Mangini, Karl Reich and Jane Soukup for technical assistance, and Cathy Cross for photography. This work was supported by grant EY006C6 from the National Eye Institute, NIH, and fellowship DRG-242 from the Damon Runyon–Walter Winchell Cancer Fund.

Pressure balance and pressure distribution along the dayside ionopause of Venus

The pressure distribution within the magnetic barrier just outside the ionopause of Venus is shown here to be similar to expected solar wind pressure variation provided the more realistic shape of the ionopause is taken into account. The ionospheric pressure just below the magnetic barrier is about equal to the solar wind pressure while magnetic field pressure within the magnetic barrier amounts to about two-thirds of both ionospheric and solar wind pressures. So we can expect that one-third of magnetic barrier pressure is accounted for by the hot plasma contribution.

The existence of a bow shock near Venus was established during the Mariner 5 fly-by mission[1] and Venera 4 lander mission[2] in 1968. The close location of this shock to the planet demonstrated that Venus does not have a significant internal magnetic field and that the ionosphere of the planet is capable of deflecting a major part of the incoming solar wind plasma.

The Venera 9 and Venera 10 mission in 1975–76 made detailed studies of the shock and the wake region of Venus[3–5]. Recently the Pioneer Venus Orbiter (PVO) performed important measurements of the structure of the venusian ionosphere and its interaction with the solar wind[6,7]. Above 200 km the dayside ionosphere is in a state of diffusive equilibrium with the O^+ ions as the main constituent. The elevated electron and ion temperatures in the ionosphere together with the number density below the ionopause provide, in most cases, enough pressure to sustain the solar wind dynamic pressure. The height of the ionopause is strongly influenced by the solar wind pressure[8–12].

The magnetic field measurements from the PVO show that the magnetic pressure within the ionosphere is in most cases negligible, but that above the ionopause there is a region of increased magnetic field where the magnetic field pressure approximately equals the solar wind dynamic pressure. This region of increased magnetic field presumably transfers solar wind pressure to the ionosphere[10,13–16].

Joint data on the solar wind, magnetic field and ionosphere are available only for the first period of PVO observations in December 1978 when the region of solar zenith angle (SZA) $\geq 61.5°$ was studied. It is frequently assumed that external pressure exerted on the venusian ionopause changes as a simple newtonian law of specular reflection, $\cos^2 \psi$ (where ψ is the SZA). But the deviations of the ionopause shape from that of a spherical surface should give rise to significant deviations from the $\cos^2$ law for large SZA. Further improvement may be

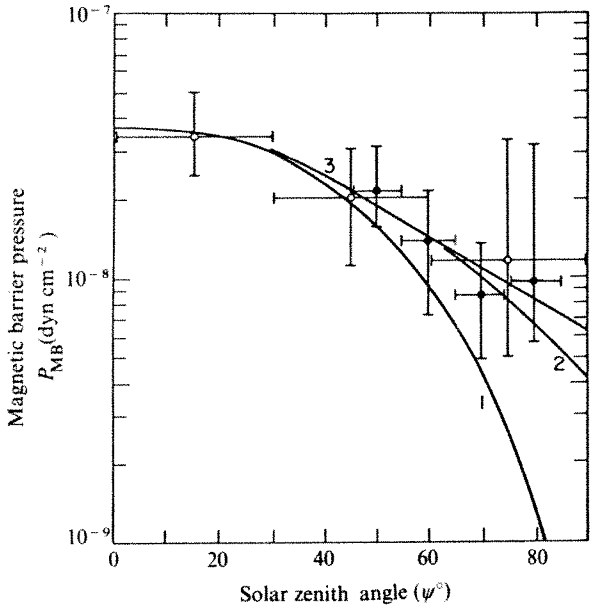

Fig. 1 Dependence of magnetic field pressure in the magnetic barrier on solar zenith angle. ●, From ref. 19; ○, from ref. 16. Curves are: 1, $\cos^2 \psi°$; 2, $\cos^2 \chi°$, with χ equal to expected angle between normal to ionopause and solar wind flow direction; and 3, hydrodynamic pressure variation along the boundary[17,18]. Curves are normalized to subsolar pressure value 3.7×10^{-8} dyn cm^{-2}.

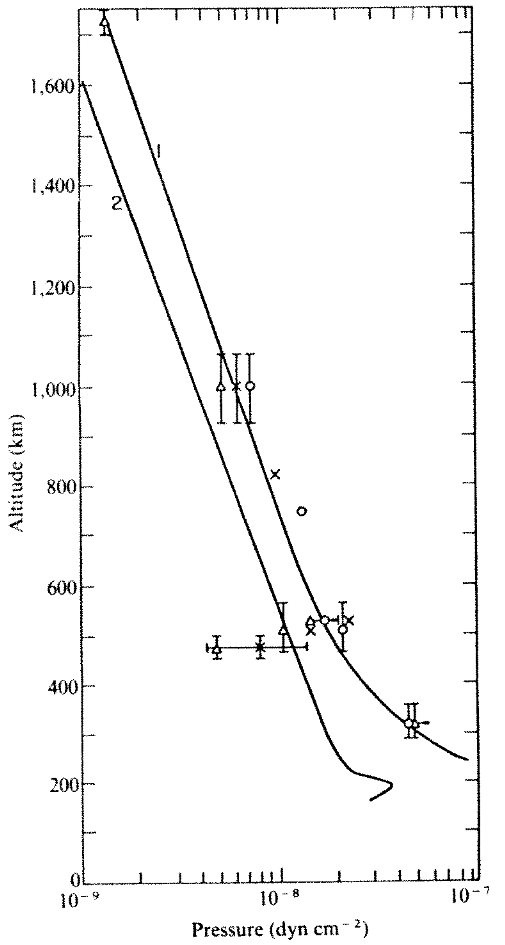

Fig. 2 Solar wind pressure (P_{SW}), magnetic barrier pressure (P_{MB}), increased by a factor of 1.5, and total (kinetic and magnetic) pressure of the ionosphere (P_I) below the ionopause plotted against observed ionopause altitudes on first orbits of PVO. Line 1 is drawn to show the change of pressure values at the ionopause with altitude for SZA range 65°–75°. Mean ionospheric pressure model, line 2, obtained from means of measured number densities and ion and electron temperatures for the same SZA range[6,7]. ○, P_{SW}; △, P_I; ×, $1.5 \times P_{MB}$.

obtained by taking into account a more realistic approximation of the external pressure. To obtain an estimate of the external pressure variation with SZA we assumed that the surface of the ionopause can be obtained from a simple ionospheric pressure balance[17,18]. The parameter H/r_0, ratio of the ionospheric scale height to planetocentric subsolar dimension of obstacle, defining the approximate shape of the ionopause, was taken equal to 0.07 (ref. 10). Figure 1 shows that the mean magnetic field pressure in the region just outside the ionopause, or in the 'magnetic barrier' closely follows the expected pressure variation along the boundary of the obstacle. The mean magnetic pressure within the magnetic barrier and its variations were taken from refs 16, 19. To fit the observations the pressure curves were normalized to 3.7×10^{-8} dyn cm^{-2} at $\psi = 0$ and this value is representative for mean subsolar magnetic barrier pressure for the PVO period of observations. Data of Fig. 1 confirm that pressure within the magnetic barrier is determined by the pressure of external flow and show that this condition holds up to SZA ~90°.

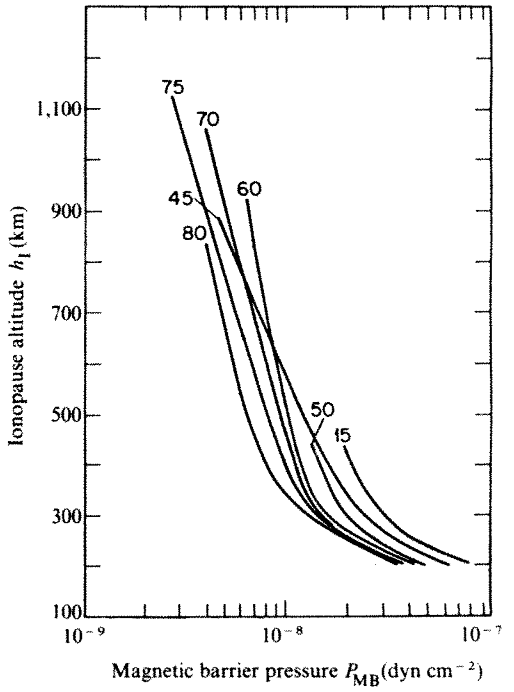

Fig. 3 Magnetic barrier pressure distribution versus height for different solar zenith angles (indicated) obtained according to data of refs 16, 19.

Distribution of measured values of ionospheric pressure just below the ionopause, magnetic pressure within the magnetic barrier, and solar wind pressure versus height of the ionopause for December 1978 are shown in Fig. 2. Data are limited to SZA between 63° and 90°. Solar wind pressure was estimated from the measured ρV^2 value corrected for pressure distribution along the boundary (curve 3, Fig. 1). Magnetic field pressure was multiplied by a factor of 1.5 to fit both the solar wind pressure and ionospheric pressure. Figure 2 shows good agreement between the measured ionospheric pressure below the ionopause and the solar wind pressure corrected for angle of incidence. It shows also that although the magnetic barrier has a major role in the transfer of solar wind pressure to the ionosphere, the plasma pressure within the magnetic barrier may provide up to one-third of the total pressure.

Comparison of the behaviour of the ionospheric pressure just below the ionopause with the mean ionospheric pressure distribution for the same SZA range apparently shows significant differences between these distributions suggesting modification of the subionopause layer due to changing solar wind conditions.

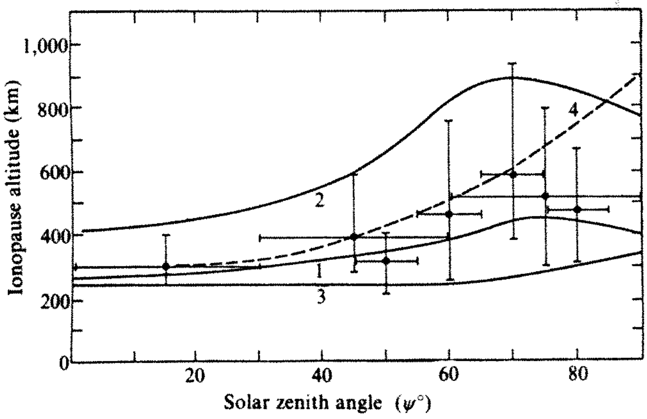

Fig. 4 Observed ionopause altitudes versus solar zenith angle. Expected 'instant' ionopause profiles are shown for close to the mean solar wind ram pressure value (curve 1); one half of it (curve 2); and doubled mean pressure value (curve 3). Dashed line, model ionopause profile for $H/r_0 = 0.07$ and $r_0 = 6{,}350$ km.

The magnetic pressure distribution within the magnetic barrier as a function of the ionopause altitude and as a function of SZA was obtained using data from (refs 16, 19). This distribution, shown in Fig. 3 enables the 'instant' profile of the ionopause to be found for a given solar wind pressure, provided that the hot plasma contribution to the magnetic barrier pressure is taken into account. Assuming that the plasma pressure within the magnetic barrier is one-third everywhere, the shapes of the ionopause for close to the mean solar wind condition, half and double this value were obtained. Figure 4 shows that the behaviour of the model profiles is in reasonable agreement with the observed mean ionopause altitude dependency on SZA and with the observed distribution of ionopause crossings. Also, it can be seen that both the observational data and the ionopause model show that at SZA ~70° the shape of the venusian ionopause differs significantly from the simple hydrostatic equilibrium model of the ionopause (curve 4 in Fig. 4). This implies the important role of solar wind heating of the subsolar ionosphere[15,20,21] and the significant influence of transport processes within the ionosphere at large SZA[12].

. The model of the subionopause pressure distribution with height and with the solar zenith angle seems to represent reasonably the observed behaviour of ionopause crossings at different SZA and allows one to obtain an 'instant' profile of the ionopause for given solar wind pressure.

Hydromagnetic dynamo in the cores of Uranus and Neptune

M. Torbett & R. Smoluchowski

Department of Astronomy, University of Texas, Austin, Texas 78712

The explanation of the origin of a magnetic field of Uranus is difficult because the structure of the planet's interior is not well known and the strong thermal flux, which is associated with the operation of hydromagnetic dynamos in Jupiter and Saturn, seems to be absent or very low. We show here that the composition, physical state and electrical conductivity of the planet's core permits the generation of a magnetic field within the very low observational limits of its heat emission. We also suggest that the higher density and higher pressures in the core of Neptune could explain the suspected absence of a measurable field on that planet even though it is a relatively strong source of heat.

While there are no rigorous theories which would permit us to make quantitative predictions of the magnetic fields of various planets it is usually possible to explain the presence or absence of these fields and sometimes even give a semiempirical estimate of their strengths[1–3]. Observations[4] of 0.5-MHz pulses analogous to jovian emission suggested that Uranus has a magnetic field but the planet had resisted efforts to explain its field's origin in a satisfactory manner. It now seems that a detailed consideration of convection and electrical conductivity in the planet's core indicates the presence of a thermally driven hydromagnetic dynamo.

The generation of magnetic fields in planets, whether by a thermally or precessionally driven dynamo, is very sensitive to details of the models of their interiors. The development of a satisfactory model of Uranus has been hampered by the availability of only approximate values of some of the important parameters, by the lack of good equations of state and by the difficulty in fitting, within reasonable limits, what is known about the chemical composition and evolution of the outer planets. In particular there is still an uncertainty of about a factor of two in the rotational velocity of the planet[5,6]. This velocity strongly affects the structure of the outer parts of the planet and, to a much smaller degree, the size of the core. We have shown previously[7] that a two-layer model of Uranus could account for the presence of a magnetic field only if the planet had a layer of metallic hydrogen or of a metallically conducting molecular hydrogen and even then probably only if the dynamo were precessionally driven by Miranda. This conclusion was forced by the fact that in this model the core turned out to be solid while the layer containing liquid H_2O, NH_3 and so on had much too low an ionic electrical conductivity even though, as shown by experiment (W. J. Nellis, A. C. Mitchell, R. S. Hawke and R. K. Keeler, personal communication), the water would be pressure dissociated but not yet metallic. The above result was independent of the rate of rotation of the planet within the limits mentioned above.

The new three-layer model of Uranus of Hubbard and MacFarlane[8] led us to review the situation as the model uses new equations of state and, within a wide range of rotational velocities, it seems to fit better the observational parameters as well as the chemical constraints. First, the model excludes the presence of a metallic or of a suitably conducting molecular hydrogen layer. Second, just as in the two-layer model, the liquid 'ice' layer has too low an ionic conductivity to permit the operation of a magnetic dynamo although a thin layer of 'metallic' H_2O could appear right at the core boundary. It remains then to analyse the planet's core which has a radius of 7,700 km

0028–0836/80/290237—03$01.00

($r_c/R_u \sim 0.3$), and contains 38, 25, 25 and 12% of SiO_2, MgO, FeS and FeO respectively. The melting temperatures of these compounds as a function of radius in the core were calculated using the same method as in our previous paper (assuming the Grüneisen parameter to be the same for FeO and FeS) and the densities at which these compounds should become metallic were estimated using Herzfeld's molar refractivity criterion[9]. The results are shown in Figs 1 and 2. It seems that in an isothermal core FeS and FeO are always liquid, MgO is always solid while SiO_2 is solid in the inner part of the core. FeO and FeS are metallic throughout the core, the sulphide being known to change from a low gap semiconductor to a metal at pressures of the order of kilobars[10]. MgO and SiO_2 are metallic up to ~85% of the radius of the core.

It can be shown that initial gravitational condensation and radioactive heating led to a temperature of the interior of Uranus which was probably in excess of that required to keep the core metallic and entirely liquid. The outward flow of this heat produced convection which kept the core well mixed during this early high temperature phase. As the core cooled, however, large differences in the density of its constituents produced gravitational, diffusion controlled, separation between the heavy iron compounds and other lighter constituents which led to a significant evolution of additional heat. Further cooling of the core resulted in the formation of solid MgO which floated towards the surface of the core thereby releasing energy which in turn slowed down the cooling and the segregation. This self-regulating aspect of the process, reminiscent of that proposed[11] for the H–He system in the giant planets and necessary to explain the present magnetism and excess luminosity of Saturn[12], may be still active because the theory is certainly not rigorous enough to ensure that the melting temperature of MgO near the surface of the core is indeed 1,000 K higher than the calculated temperature at this radius. It seems reasonable, therefore, to conclude that even now the core of Uranus is not isothermal but adiabatic. Unfortunately, lack of knowledge of the phase diagram of the multicomponent alloy and especially of mutual solubilities of the components in the early stages of the evolution of the planet makes a quantitative prediction of the rate of heat generation in the core almost impossible. The total energy available from gravitational interchange in the core can be estimated, however, to be $\sim 10^{39}$ erg which distributed over a time scale of 10^{10} yr yields an average flux of the order of 40 erg cm^{-2} s^{-1} at the surface of the planet, a value compatible with the observational[13] upper limit for Uranus of about 10^2 erg cm^{-2} s^{-1}. The total original primordial energy of the planet was probably not less than 10^{40} erg. The range of possible compositions of cores of the giant planets introduces an uncertainty of about a factor of two into the above estimates.

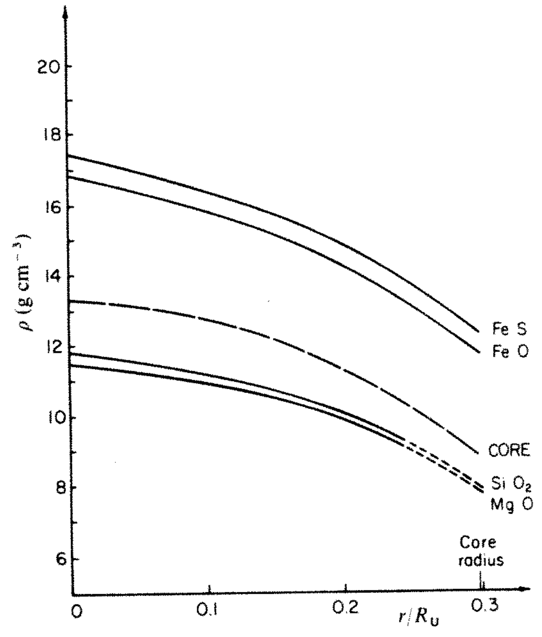

Fig. 1 Density profiles of the core and of its constituents: solid line, metallic; dashed line, non-metallic. R_U is the radius of the planet.

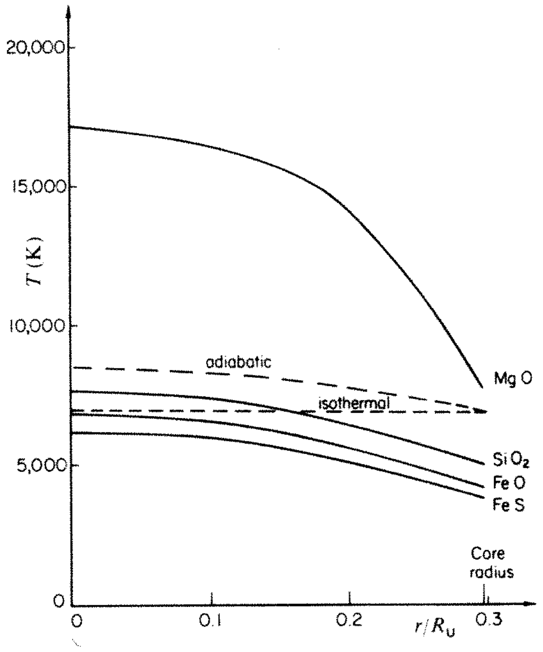

Fig. 2 Melting temperature profiles of the constituents of the core (solid line) and the temperature gradients in the core (dashed lines). R_U is the radius of the planet.

Assuming a superadiabaticity of $\nabla - \nabla_s = 10^{-6}$, a thermal expansion coefficient of the order of 10^{-6} and a mixing length $l \sim 10^{-3} r_c$ one obtains for the convective velocity in the core $v \sim 10^{-1}$ cm s^{-1}. In view of the highly heterogeneous chemistry of the core it seems reasonable to put electrical conductivity $\sigma = 10^{-5}$ e.m.u. which is typical of low conductivity metals. With these values for v and σ, the necessary condition for the operation of a thermally driven hydromagnetic dynamo—the magnetic Reynolds number, $R = \sigma \mu L v$ where μ is the permeability and L is the size of the core, has to be greater than 10—is amply satisfied. The heat flux carried by this convection, as estimated using the expression $\Phi = \rho C_p v l T\ (\nabla - \nabla_s)\ (2H_p)^{-1}$ (Scalo, personal communication) is about 10 erg cm^{-2} s^{-1} at the surface of the planet. Here H_p is the pressure scale height and C_p is the specific heat, about 5×10^6 erg g^{-1} deg^{-1}.

The presence of an internal heat source in the core implies, of course, that the central temperature of the planet is somewhat higher than in the original model[9], but this does not significantly affect the model's other features because the presence of a comparable flux is already taken into account and the thermal pressure is negligible. The approximate adiabatic gradient is also indicated in Fig. 2 showing that, except for MgO, all constituents of the core are liquid. One may add that Busse's semi-empirical rule[2] applied to Uranus' core leads to a surface field of the order of 10^{-1} G.

Applying the same kind of reasoning to the three-layer model of Neptune[8] one concludes that because of higher densities and pressure nearly half of the volume of its core is solid as compared to about one-third on Uranus. Thus one may expect the differentiation, the heat evolution, the rate of convection and the magnetic field of the core to be much lower than on Uranus. On Neptune, just as on Uranus, the ionic conductivity of the liquid 'ice' layer is too low and the probable layer of 'metallic' H_2O at the core boundary too thin to permit the operation of a hydromagnetic dynamo even in the presence[14] of the high heat flux.

It seems, therefore, that a slightly modified three-layer model of Uranus explains in a natural way the presence of a magnetic field on this planet and does not require making rather problematic assumptions which were necessary for the two-layer model. Application of a similar analysis to the three-layer model of Neptune explains its very low, if any, magnetic field in spite of the high thermal flux.

Solar cycle changes in the polar solar wind

Although the 11-yr cycle of solar activity was first recognized in 1843 (ref. 1) and was subsequently traced back to the seventeenth century[2–4], it is still only poorly understood. The most obvious indicators of the activity cycle are sunspots, flares, plages, and so on. The corona as seen during an eclipse also reflects the cycle, appearing flattened at the poles near solar minimum and almost spherical near the solar maximum. All such phenomena are intimately linked to the solar magnetic fields, which exhibit complex but systematic variations. Whereas there are satisfactory qualitative models (see refs 5, 6) for the magnetic variations, the underlying physics is still obscure. The solar cycle also influences the Earth causing, for example, changes in geomagnetic activity, the magnetosphere and aurorae, the ionosphere, the flux of galactic cosmic rays and possibly the weather. These modulations are not well understood but must be transmitted by one or more of the following: electromagnetic radiation; solar wind thermal plasma and its magnetic field; energetic particles. We here present new observations on the changing three-dimensional form of the solar wind, which helps to relate some of the modulations.

The solar wind also shows the effects of the solar cycle, but changes observed by ecliptic spacecraft are minor compared with the dramatic changes observed in the corona for example. Two processes are apparent in the observations of 1962–74 (ref. 7). First, at sunspot maximum, there is an increase in flare-associated transient disturbances in the solar wind. Second the quasi-static structures of the solar wind such as magnetic sectors and high speed streams are much more evident and stable during the declining and minimum years of activity. In fact the dominance of the high speed streams during the declining phase of the cycle is the most obvious change in the ecliptic solar wind. We show that an understanding of the three-dimensional wind structure explains the occurrence of such streams.

Direct spacecraft observations have reached ±16° in latitude although most are confined to ±10°. These show very high latitude gradients of velocity during streams[8,9], and they have helped to clarify the magnetic sector structure[34] but they are obviously limited in defining the overall latitude structure. However, the indirect techniques of interplanetary scintillation (IPS) (refs 10–13) and comet-tail observations[14] can cover essentially all latitudes albeit with reduced precision. IPS observations from 1971 to 1979 show that the solar wind does respond dramatically to the solar activity cycle but the primary effects are in the polar regions.

The IPS method, pioneered by Dennison and Hewish[15] relies on three spaced antennas to record signals from a small diameter radio source. The scintillations in the strength of the signals at each antenna are caused by inhomogeneities in the solar wind; the signals are cross-correlated to yield time offsets, from which the speed of the scintillation pattern can be deduced.

The UCSD observatory, which operates at 74 MHz, and the methods of data analysis have been described elsewhere[16,17]. A careful comparison of ecliptic IPS observations with spacecraft observations[18] has 'calibrated' the IPS method. From this work we conclude that the IPS-observed speed is within ±50 km s^{-1} of the solar wind speed at the point where the radio-wave scattering is strongest. We thus adopt the simplified interpretation that the IPS speed gives an estimate of the solar wind speed at that single point in space. We make IPS observations of eight radio sources daily, from which we typically obtain useful solar wind speed estimates at 3–5 such effective locations. The heliographic latitude of these locations spans 60 °S to 70 °N. However, the coverage is not continuous; northern latitudes (>20°) are observed from March–July and October–November, while southern latitudes (>20°) are observed June–July, each year (see Fig. 1 of ref. 19).

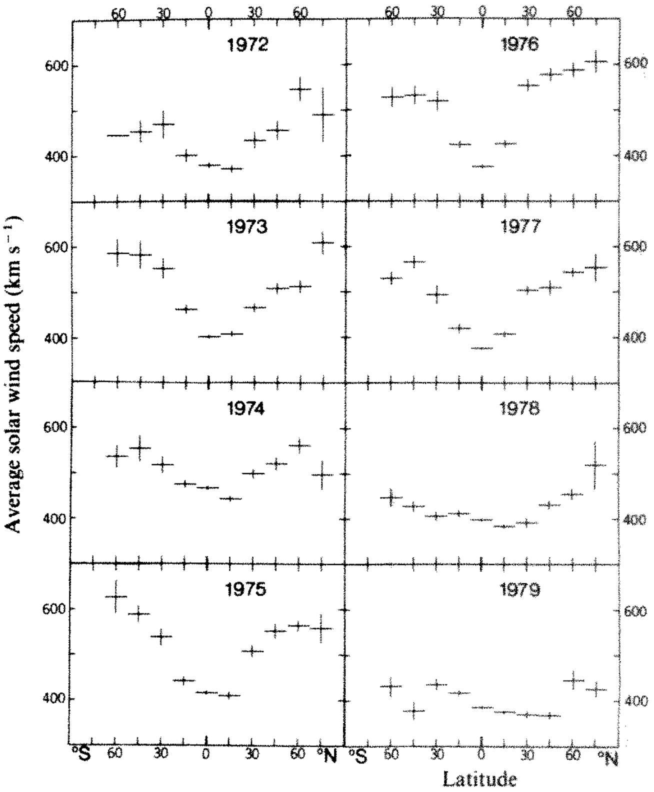

Fig. 1 Solar wind speed measured by IPS averaged into 15° intervals in heliographic latitude for the years 1972–79. The error bars are ± twice the standard deviation in the average.

SCIENCE COLLEGE Upper Circular Road CALCUTTA

Fig. 2 *a*, The average solar wind speed in 15°×15° bins of heliographic latitude and longitude coded by the grey scale as indicated. The IPS data were averaged for Carrington rotations 1612–1617 (March–July 1974). *b*, Coronal holes indicated by a contour of low *K*-coronameter polarization brightness (1.5×10^{-8} pB); the tick marks point towards low brightness, that is towards the holes. Data, supplied by Drs R. and S. Hansen, are averaged for the same period as *a*.

The solar wind speed can be averaged over longitude to provide the speed versus latitude plots of Fig. 1. Their characteristic U-shape shows that the wind speed is on average considerably faster at high latitudes than at the solar equator[20]. This phenomenon is best described as evidence for persistent fast polar streams from the north and south poles. In studying the long-term changes in Fig. 1, we must be aware of the reduced number of observations at high latitudes, with a corresponding increase in the error bars with latitude. Nevertheless, we can identify three phases in the evolution of the polar streams.

First, during the years of declining activity 1973–75, equatorial speeds are somewhat elevated and there is a gradual increase of speed between 0° and ±60°. The distribution of mean wind speed with latitude and longitude averaged over six rotations is shown in Fig. 2*a*. Here it is apparent that the polar streams are tilted from the axis, remaining opposite each other but centred near latitudes of ±50°. These streams are wide enough to reach the ecliptic, where they are seen as two fast streams per rotation and also cause an increase in the mean speed[7]. Figure 2*b* shows that these fast streams come from coronal holes, where the polar holes are shown to be tilted in much the same way.

The second phase, 1976–77 (Fig. 1), shows slower equatorial speeds and a sharp transition from slow to fast between 15° and 30° in both the north and south. This corresponds to a better alignment of the polar streams with the rotation axis, as revealed in latitude–longitude plots[21]. Note that the gradient of the mean speed is greater than 10 km s^{-1} per degree between 15° and 30°. This is comparable with instantaneous measurements of the latitude gradient made with two spacecraft (see refs 8, 9). The polar holes were also wide and axially aligned during these years of solar minimum as shown by *K*-coronameter data[22] and by eclipse photographs which are elongated along the equator due to low densities over the poles[23].

The third phase, 1978–79, shows a flattening of the U-shape curve, that is a dramatic reduction in the wind speed at 30–60 °N and S, implying that the polar streams are much narrower. Note that this change probably occurred at the same phase of the previous cycle. Hewish and Symonds[10] observed higher speeds at north latitudes than at the equator in 1966, but not in 1967. Their restricted data coverage meant they could not draw any strong conclusions, but it is now clear that this is the same change which we see 11 yr later.

The polar holes also contracted during 1977, as the new sunspots emerged at mid-latitudes. This implies that bipolar magnetic regions are dominating the mid-latitudes restricting the extent of the open field regions (polar holes). Figure 3 compares average wind speed at 0, 30° and 60° with the area of the polar holes from 1971 to 1979. Hole area estimates from observations of He 10,830 Å made at Kitt Peak are plotted for 1974–78, together with earlier estimates by various techniques[24]. The areas are given as percentages of 4π sr at the photosphere. The slowing of the wind at 30° and 60° north and south in late 1977 to the present (a narrowing of the polar streams), is closely matched by the shrinking of the polar holes.

The latitude boundary of the polar holes and polar streams are compared in Fig. 4 (assuming axial symmetry). The stream boundary is chosen to be the latitude at which the velocity is 500 km s^{-1}. There are clearly large changes in the width of the polar streams. Between 1974 and early 1977, the polar stream boundaries were near ±30° showing that 50% of 4π sr were occupied by solar wind with an average wind speed > 500 km s^{-1}. By contrast, from late 1977 to the end of 1979, the polar stream boundaries moved up to ±65°, showing that the fast polar wind occupied only 9% of 4π sr.

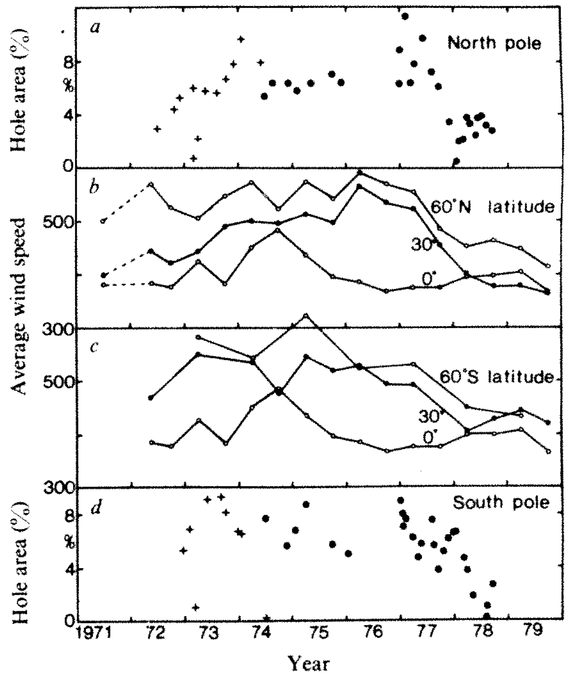

Fig. 3 The solar wind speeds averaged into 15° latitude intervals for six month periods are plotted against time in *b* and *c*. Single rotation estimates of polar coronal hole areas derived from photospheric observations are plotted for the north polar hole in *a* and for the south in *d*. Symbols indicate techniques from ref. 24. The slowing of the wind above ±30° latitude in 1978 is matched by a narrowing of the polar holes.

When these changes in the fast polar streams are compared with changes in the polar coronal holes, it is apparent that the polar hole boundaries do not change as much as the polar stream boundaries. Although there are real variations between rotations, the mean hole boundaries remain at ±60° (13% solid angle) through early 1977, shrinking to ±70° (6% solid angle) in 1978. Data are not yet available for 1979. The ratio of the solid angle for fast polar streams to that for coronal holes defines an expansion factor which characterizes the degree to which the coronal holes open out faster than radial as they become fast streams. This ratio decreased from 3.8 for 1974–77 to 1.5 for 1978. Whereas the numerical value of the ratio cannot be easily related to the areal expansion factor as defined and measured for a northern polar hole[25], the change in the ratio indicates that the areal expansion factor of the polar holes decreased substantially as the holes narrowed. A large expansion factor implies that the solar wind is accelerated to supersonic speeds closer to the base of the corona than for a smaller areal expansion[26].

The agreement with IPS observations in 1967 and 1968, and the agreement with the polar hole variations shows that the changes in the fast polar stream are part of the solar cycle. Studies of polar faculae over many solar cycles[27] suggest that the polar holes narrow for several years at the peak of activity. The polar magnetic field polarity also reverses near solar maximum. Clearly the polar holes; defined as unipolar open field regions, must undergo a major change and disappear altogether when the fields reverse. Eclipse photographs tell a similar story. The flattened images at solar minimum indicate the large low density holes over the polar regions; the circular images at solar maximum indicate no such polar holes. The changing three-dimensional solar wind structure reported here helps explain the solar cycle modulations of several phenomena.

The average level of geomagnetic activity varies with solar cycle but the pattern shows differences from one cycle to the next. Two mechanisms are thought to be responsible[28]: the increase in solar wind transients near the maximum phase of the cycle, and the increase of ecliptic fast streams in the declining phase. Both processes cause enhanced geomagnetic activity index. However, their relative importance change from cycle to cycle, so that the peak index sometimes occurs near the maximum phase, sometimes in the declining phase, or sometimes extends between the two. In particular, it has been suggested[29] that the previous solar cycle (number 20) was unusual in the dominance of ecliptic streams and associated geomagnetic activity during the declining phase. Such cycle-to-cycle variability is easier to understand in the context of the three-dimensional stream structure. The recurrent ecliptic streams are seen when the long-lived polar streams are tilted far enough from the axis to intersect the ecliptic. For obscure reasons, such tilting is greatest in declining solar activity. However, we suggest that the degree of tilt varies from one cycle to the next causing recurrent ecliptic streams and accompanying geomagnetic activity to be more pronounced in some 11-yr cycles than in others.

The average flux of galactic cosmic rays detected at the Earth is also modulated by the sunspot cycle, such that minimum cosmic ray flux occurs at sunspot maximum and vice-versa[30]. The spherically symmetrical diffusion models for this modulation predict an 11-yr variability in the strength of inhomogeneities in the magnetic field and also a radial gradient in the cosmic ray flux, both of which are now contradicted by observations[31]. The present results indicate a need for models where the magnetic geometry in three-dimensions is important (such as those of Jokipii *et al.*,[32]), especially when combined with the recent correlation of polar hole area and cosmic ray flux[33]. We suggest that at solar minimum wide polar holes connect to wide fast polar streams, which are presumably unipolar and may in turn be connected to the interstellar magnetic field, allowing easy access of cosmic rays. At solar maximum the polar holes are constricted by high latitude active regions, causing a narrowing of the polar streams, that is a smaller area of easy access which reduces the cosmic ray flux.

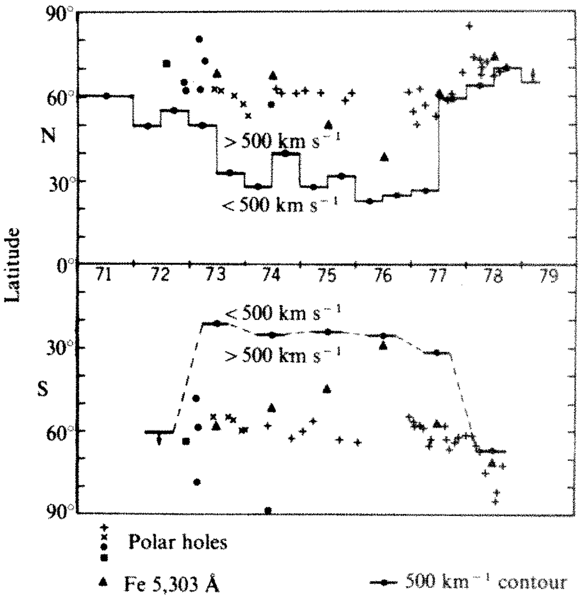

Fig. 4 Solid curve (in the north) and horizontal bars (in the south) indicate the contour of 500km s^{-1} average solar wind speed. The latitude boundaries of the polar holes are indicated by various symbols: +, He 10,830 Å; ×●■, different techniques (see ref. 24); ▲, Fe 5,303 Å (threshold at 1.5×10^{-6} of disk centre brightness, data from Sacramento Peak Observatory).

Fast solar wind streams from the polar coronal holes persist for at least 6 yr but contract as the solar activity cycle approaches maximum. The polar coronal holes are observed to narrow at the same time, presumably in response to the changing solar magnetic field. The link between coronal holes and fast wind streams is thus extended to polar latitudes and to a major fraction of the 11-yr cycle. This picture throws considerable light on the problem of solar cycle modulation of galactic cosmic rays, geomagnetic activity and the presence of fast ecliptic wind streams.

Peninsula method of ULF signal generation

A. C. Fraser-Smith & O. G. Villard Jr

Radioscience Laboratory, Stanford Electronics Laboratories,
Stanford University, Stanford, California 94305

Natural pulsations of the geomagnetic field in the ultra-low-frequency range (ULF; <5 Hz) have been studied for many years, but progress has been limited by the lack of controlled experiments on their generation and propagation. Clearly, a method for producing the pulsations artificially on a controlled basis would contribute greatly to our understanding of their properties. In 1975 we participated in a theoretical study[1] that described a method for generating artificial Pc 1 geomagnetic pulsations (0.2–5 Hz) by driving a large alternating electric current with frequency in the Pc 1 range around a relatively nonconducting peninsula in an enclosed sea or large saline lake. The study predicted that the alternating magnetic field of the current loop in the sea could disturb the lower ionosphere above the peninsula and that hydromagnetic (HM) waves at the Pc 1 frequency would propagate away from the disturbed region to large distances in the ionosphere and magnetosphere. Two important conditions for the generation to take place were that the amplitude of the ULF magnetic field fluctuations should be greater than $\sim$1 nT (refs 2, 3) and that suitable propagation conditions should exist for the HM waves. We report here the results of two experiments on the 'peninsula method' of Pc 1 pulsation generation conducted during 1975–76. Our results, when combined with those from a recent peninsula experiment by Soviet scientists[4,5], strongly support the proposed method of Pc 1 pulsation generation.

Our peninsula experiments used the North Neck Peninsula on Chappaquiddick Island, Massachusetts (Fig. 1), which is located in an enclosed body of seawater (enclosure of the peninsula provides well defined boundary conditions and protection from wave action; it is not a necessary condition for ULF signal generation). During the summer of 1975 we carried out a passive experiment using the seawater around the peninsula as a receiving loop. Two electrodes constructed of thin copper sheet $\sim$0.45 m square were inserted in the water on either side of the peninsula and connected by shielded cables (total length, 300 m; total resistance, $\sim 10\ \Omega$) to an electronics package consisting of a ULF differential amplifier, a timer, a calibrator and a low pass filter with an overall voltage gain of 200 at a frequency of 1 Hz. The resistance of the cable–seawater–cable circuit as seen by the electronics package was $\sim 12\ \Omega$, implying that the resistance between the two electrodes was roughly $2\ \Omega$. The output of this system, which had a flat frequency response over the Pc 1 frequency range, was recorded on a slow-speed analogue magnetic tape recorder.

Measurements of ULF geomagnetic pulsation activity were made each night between 26 August and 5 September, and several well defined Pc 1 events were recorded. A spectrogram of one particularly long-lasting and large-amplitude event is shown in Fig. 2, together with spectrograms of the same event as seen at Roberval, Quebec, and at Stanford, California (see Fig. 3 for locations of the stations). Although this was a preliminary experiment, and some desirable controls were necessarily lacking, it demonstrated that Pc 1 pulsations could be measured across the neck of a peninsula. Further, the high signal-to-noise ratio of the measurements, as shown by the data in Fig. 2, supported the peninsula current loop concept, as a large receiving area would be required to provide the high ratio.

An exploratory small-scale active experiment was conducted during the summer of 1976. Electrodes were installed at roughly the same locations on either side of North Neck Peninsula as during 1975, but this time they were larger and were constructed of galvanized iron pipe. They were spaced $\sim$180 m apart and connected to a ULF current source by heavy-gauge insulated aluminium wire (wire diameter 0.52 cm), and the resistance of the current path was $0.4\ \Omega$, as compared with $12\ \Omega$ the previous year. The ULF current source used four automobile starter relays in a bridge circuit to produce a pseudo sine wave alternating current; it could deliver a maximum current of 60 A into the $0.4\ \Omega$ load, and its frequency was adjustable in the range 0.5–12 Hz. Power was provided by two 12-V automobile batteries connected in series.

There were three parts to this active experiment: (1) a fluxgate magnetometer was used to measure the magnetic field produced on the peninsula and its vicinity; it had a flat frequency response from d.c. to 500 Hz, and its noise level was $\sim$1–2 nT in the 0.2–5 Hz band; (2) a three-axis electric field (or current) probe was constructed and used to measure the ULF currents flowing in the seawater around the peninsula. It had three orthogonal pairs of contacts spaced 0.5 m apart, and each pair fed a preamplifier with a voltage gain of 100 and a bandpass of 0.5–5 Hz. The calibrated outputs from the preamplifiers were separately monitored on a portable chart recorder, and the minimum electric field amplitude that could be measured was about $1\ \mathrm{mV\ m^{-1}}$. (3) Finally, measurements of the magnetic field produced above the peninsula were made with the total field magnetometer on a P-3C Orion aircraft.

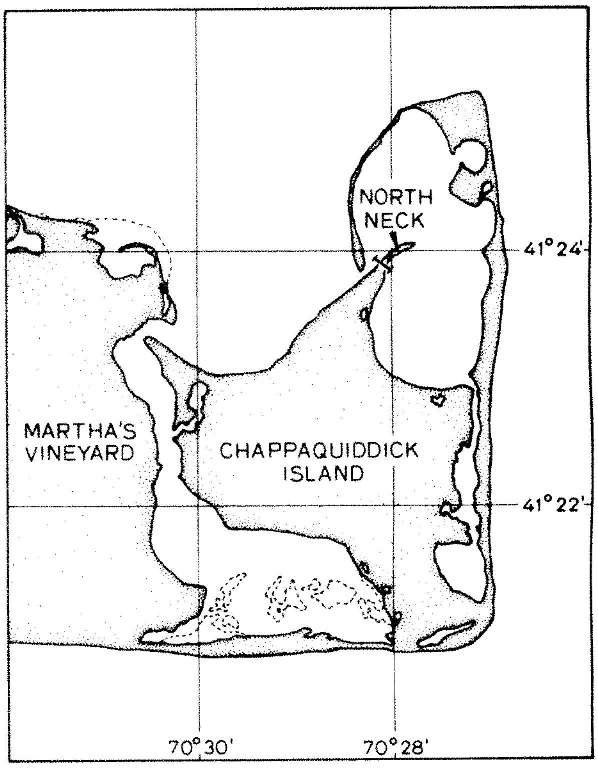

Fig. 1 Map of Chappaquiddick Island, Massachusetts. The experiment was conducted on North Neck, which projects into Cape Poge Bay (upper right), and the location of the electrodes on either side of the Neck is superimposed on the map. The longitude lines are 2.8 km apart.

0028-0836/80/290242—02$01.00

The magnetic field measurements on the peninsula were largely dominated, as expected, by the field of the electrode feed wires. This field was calculated, and it was found that the calculated values were ~20% greater than the measured values. The difference can be attributed to current flow directly through and under the peninsula. Noise caused by boat motion limited the probe measurements to points within ~300 m of the electrodes, and the principal result of these measurements was finding that the current flow was largely radial at all distances where measurements were possible. This finding indicated that some of the current paths would enclose a large area: a necessary condition for a large magnetic moment for the 'peninsula antenna'. Further evidence for this latter condition was provided by the aircraft measurements, which were made during eight passes over the peninsula at altitudes in the range 160–320 m. The sensitivity of the magnetometer was reduced after each pass, and even on the last pass, with minimum sensitivity (measurement range 0–40 nT), the peninsular current loop produced off-scale readings.

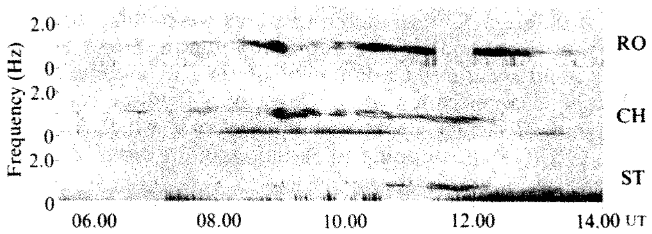

Fig. 2 Spectrograms of a long-lasting Pc 1 geomagnetic pulsation event, as recorded at Roberval, Quebec (RO), Chappaquiddick Island, Massachusetts (CH), and at Stanford, California (ST), on 2 September 1975. The recording at Chappaquiddick Island was made with a 'peninsula antenna'; the other recordings were made with conventional ULF solenoid antennas. A power failure caused the blank interval in the Roberval record.

Although these experiments supported the feasibility of the peninsular current loop concept, they only gave indirect information about the magnetic fields produced in the ionosphere. We therefore computed the amplitude of the magnetic field produced at an altitude of 100 km above the peninsula during our active experiment, using a standard finite difference relaxation method to obtain the electric potentials and current distribution in the seawater and then the Biot–Savart law for the magnetic field. The amplitude obtained was 0.017 ± 0.008 pT. This is about 49 times larger than the field that would be produced by the same total current flowing through a wire laid along the shoreline of the peninsula from one electrode to the other. Assuming a 20% loss of current through the peninsula (as suggested by our magnetic field measurements) the field produced by the peninsula–seawater combination is still ~35–40 times larger than the comparison value. Note that this comparison does not take into account the greater power that would be required to drive the current through the wire outlining the peninsula.

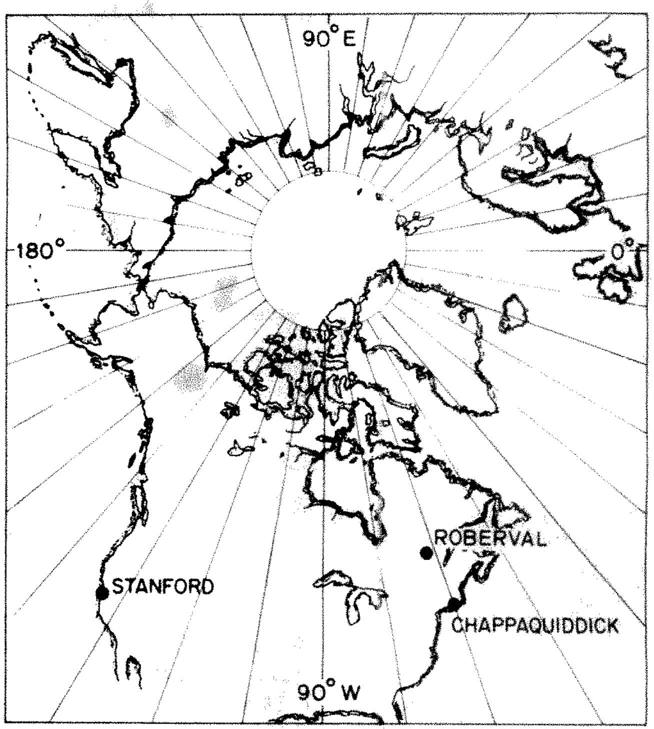

Fig. 3 Map of North America, showing the relative geographic locations of the ULF recording stations at Chappaquiddick, Massachusetts; Roberval, Quebec; and Stanford, California.

An experiment was recently reported by Soviet scientists in which a large current produced by a portable magnetohydrodynamic (MHD) pulse generator was driven through the sea surrounding the Rybachiy Peninsula (69°N, 32.5°E), and the resulting magnetic field was measured over the adjacent Kola Peninsula[4,5]. The maximum duration of the current pulses was ~6 s, and measurements showed that the equivalent magnetic moment of the current loop around the peninsula was 10^{14} A m^2. This loop was reported to take an equivalent area of about 5,000 km^2, implying that the amplitude of the current was 20 kA. As the resistance of the loop was 90 mΩ (this includes the resistance of the cables joining the MHD generator to the sea on either side of the peninsula; these cables weighed 160 tons), a power of about 36 MW was required. Measurements of the magnetic field were made at distances up to 750 km from the peninsula, and at 320 km the electric and magnetic fields had amplitudes of about 0.01 V m^{-1} and 1 nT, respectively.

These results are in good agreement with the predictions of Lipa *et al.*[1]. Note the very small resistance of the peninsula current loop and the resulting large current (and loop magnetic moment) for a moderate power. They imply that a substantial (⩾2 nT) ULF magnetic field can be produced in the lower ionosphere above the peninsula: one of the primary requirements for the artificial generation of Pc 1 pulsations. Unfortunately, the Soviet experiment seems to have been wholly devoted to the deep electromagnetic sounding of the Earth's crust, and no measurements to detect artificially generated Pc 1 pulsations were reported.

We conclude that the proposed 'peninsula method' for ULF signal generation in the ionosphere and magnetosphere[1] is not only feasible but that it is likely to have considerable economic advantages over the use of a large horizontal wire loop on the ground. These advantages include lower construction and running costs and the production of much greater ULF magnetic field amplitudes in the lower ionosphere per unit of input power.

We thank D. M. Bubenik, J. L. Buxton and H. Lewis for assistance, Mr and Mrs G. F. Hodder and the late Mr and Mrs E. Hartell on Chappaquiddick for their co-operation, and also the personnel at the US Naval Air Station at Brunswick, Maine, who made the airborne measurements. This work was supported by the US Defense Advanced Research Projects Agency through an Office of Naval Research Contract and by the Office of Naval Research.

The interactions of 420–500 MeV/c K$^-$ in the 11T hydrogen bubble chamber HYBUC have been used to produce a sample of 120,000 $\Sigma^{\pm}$ decays in flight[1,2]. We describe here how these decays were used to investigate the effects of longitudinal accelerations between 0.5 and $5.0\times10^{15}g$ on particle lifetimes. Any observed effect of acceleration on lifetime would indicate that the Lorentz transformation and/or the dynamics of particle decay is sensitive to acceleration. These data suggest that accelerations which change the Lorentz factor and which can return a relativistic elementary particle clock to rest do not cause any observable change in lifetime. This null result complements earlier measurements of the effects of transverse acceleration on muons[13]. Thus ensembles of elementary particles are ideal clocks which are invariant under intense accelerations.

The momentum range of the $\Sigma^{\pm}$ in the HYBUC sample (200–650 MeV/c) is particularly suited to the study of the effects of acceleration on lifetime, because the proper time for decay in the sigma rest frame is a significant fraction of the stopping time as measured in the laboratory. The mean decay length for a momentum of 200 MeV/c at production is 40% of the particle range for Σ^- and 21% for the Σ^+. The average value of this ratio over the momentum range of this experiment is 10% for the Σ^- sample and 5% for the Σ^+ sample.

The slowing down of the sigmas in hydrogen is an electromagnetic process with forces and accelerations that are large compared with gravity. The average accelerations are of the order of $10^{15}g$. The instantaneous accelerations are much greater than these average values and estimates are model dependent. Impact parameter calculations give instantaneous accelerations as high as $10^{22}g$.

The values of the lifetime $c\tau$ have been determined using the maximum likelihood method with a lifetime function normalized with a finite interval of proper time for each event. The lower limit of these intervals corresponds to cutoffs which eliminate scanning losses due to short sigma tracks (0.4 cm for Σ^+, and 0.6 cm for Σ^-). The upper cutoff is the minimum of: (1) the path length at which the sigma would have left the chamber; (2) the path length at which the sigma would stop; (3) a large proper time cutoff ($c\tau = 15$ cm for Σ^+, 20 cm for Σ^-). To take into account the energy loss in liquid hydrogen, the proper time τ is obtained by integrating the instantaneous momentum over the path length,

$$c\tau = m\int \mathrm{d}x/p(x)$$

where x is the distance travelled in the laboratory and the momentum $p(x)$ is obtained from the range–momentum tables and kinematic fits to the event. Note that this integral assumes the accuracy of special relativity applied to transformations from the laboratory system to the particle rest frame.

As the acceleration which a particle experiences depends on its momentum, we have examined $\Sigma^{\pm}$ lifetimes as a function of both the momentum at production and decay. Using the momentum at production is less subject to bias than at decay. However, if the history of acceleration has any observable effect on an elementary particle, then one could distinguish particles on the basis of this effect and, therefore, the momentum and rate of energy loss at the time of decay are of interest. Nuclear interactions are momentum dependent and could affect the lifetimes as a function of momentum. They, however, are <1% in our sample and the scanning requirement of a clear decay vertex would exclude small angle scattering events[2]. The $\Sigma^{\pm}$ samples were divided into five equal momentum bins as functions of the momentum at both production and at decay. The 20 different lifetime determinations were obtained by a maximum-likelihood method and are plotted in Figs 1 and 2. There is no measured variation of lifetime as a function of longitudinal acceleration at the level of a few per cent and ensembles of sigmas behave as ideal clocks, which are not changed by average stopping accelerations of the order of $10^{16}g$.

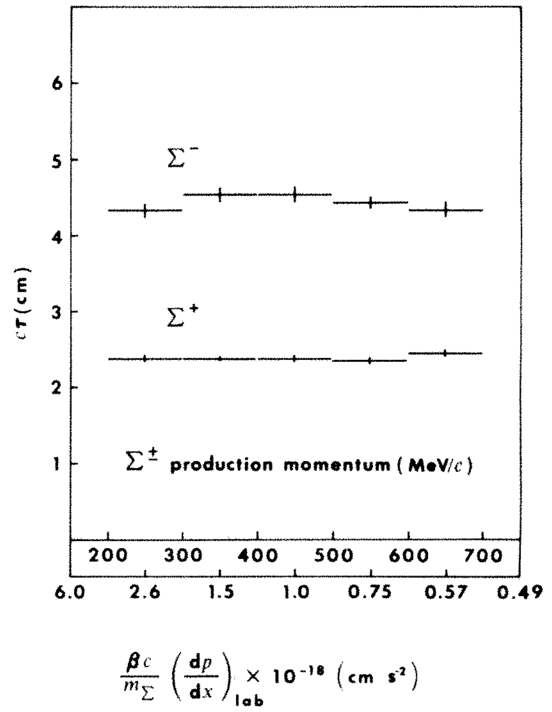

Fig. 1 The $\Sigma^{\pm}$ lifetimes $c\tau$ (cm) as a function of production momentum and rest frame longitudinal acceleration.

Broadening the discussion we note that our mean values of $c\tau$ for the $\Sigma^{\pm}$ are in close agreement with earlier experiments[3]. The particle data tables do not show any observed systematic difference in elementary particle lifetimes as a function of the stopping power of the detector. Sigma lifetimes have been measured in 'free flight'[4] and in nuclear emulsion[5–12] and these measurements are also plotted in Fig. 2. These lifetimes are constant to within a few per cent.

The effect of transverse acceleration on the muon lifetime has been investigated by the $g-2$ muon experiment at CERN[13]. Relativistic muons were held in an orbit by magnetic fields which produced accelerations of $10^{18}g$ perpendicular to the muon's

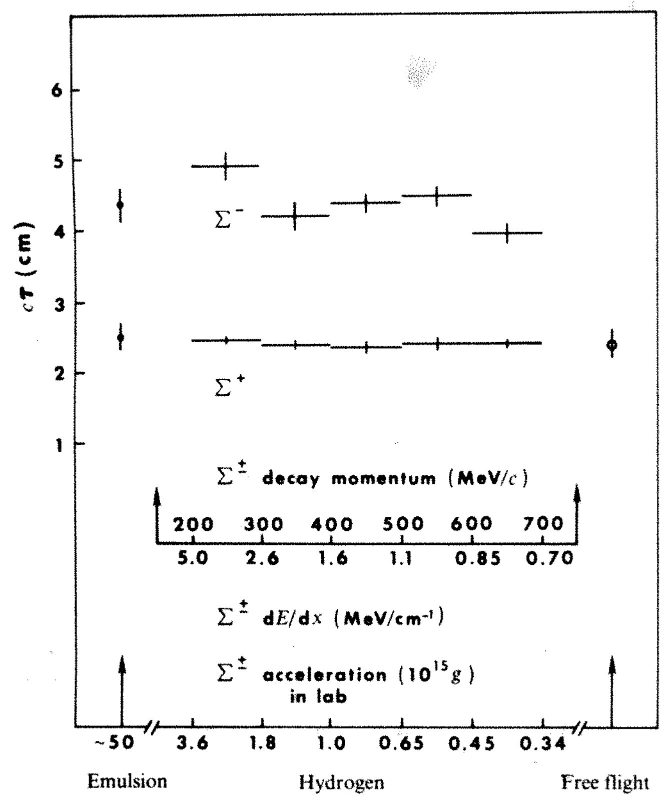

Fig. 2 The $\Sigma^{\pm}$ lifetimes $c\tau$ (cm) as a function of momentum at decay. The longitudinal acceleration depends on the stopping power of the detector. The lifetimes from HYBUC data (hydrogen) are compared with the lifetimes measured with emulsion[5–12] and free flight[4]. The rate of energy loss at minimum ionization is 22 times greater in emulsion than hydrogen.

velocity. The measured values of $c\tau$ for orbiting and free muons were the same to better than 1%. This remarkable result indicates that in the case of transverse acceleration, ensembles of muons can be considered as an ideal clock[13].

Longitudinal acceleration permits us to start two clocks in the laboratory, to accelerate one, return it to rest and then to compare it with the clock that has remained at rest. Transverse accelerations alone would not permit the same experiment. The data indicate that the behaviour of a clock is independent of both longitudinal and transverse accelerations. Arguments that accelerations change the clock are not correct.

We have shown that there is no observed dependence of lifetime on acceleration at the level of a few per cent over the range from 'free flight' to 10^{18}g, and we conclude that the Lorentz transformation gives the correct relationship between clocks subject to acceleration.

We thank Dr J Bell for enjoyable discussions and critical comments. This work was supported by the NSF grant 073-08392 and the Bundesministerium für Forschung und Technologie, FRG.

Time–temperature relations in the magnetization of assemblies of single domain grains

D. Walton*

Department of Physics, McMaster University, Hamilton, Ontario, Canada L8S 4M1

A theory for important magnetization processes such as magnetic viscosity and the production of a moment on cooling in a magnetic field is presented here. The results for viscous phenomena differ from those obtained by others in that the time dependence of the viscosity depends on the size distribution of the magnetic grains. The moment produced on cooling in a magnetic field is calculated for an arbitrary distribution of grains for the first time. The effect of the cooling rate on the moment produced is found not only to be independent of that distribution but also of the temperature dependence of the saturation magnetization.

The moment produced on cooling is affected by the rate of cooling. Cooling rate effects have been considered by York[1], Pullaiah *et al.*[2] and Dodson and McClelland-Brown[3] who all derive results for assemblies of identical grains. They show that the blocking temperature is higher, the higher the cooling rate, and the resultant moment is reduced. In determining palaeointensities, then, a difference in cooling rates will lead to differences in the field intensity deduced. When rocks which are cooled over millions of years are measured using cooling times of minutes the difference can be quite large, and a severe overestimate of the ancient field will result.

Previous authors have only calculated this effect for assemblies of identical grains. However, the magnetization which is observed is an integral over a distribution of grains of different sizes. This integral is found not to be sensitive to the grain size distribution, and the cooling rate effect to be sample dependent only if the magnetic constituents are different.

The calculation of magnetic viscosity presented here uses fewer approximations than generally used, and the time-temperature relation obtained differs from the expressions which can be found in the literature (see ref. 4 for detailed references).

All materials which display viscosity are in disequilibrium. The viscosity is the evolution of the system towards an equilibrium state. Consider an assembly of identical particles, of which n^+ are oriented so that their energy is higher than that of the remaining n^- which are in a ground state. The difference $n = n^+ - n^-$ will tend towards an equilibrium value n_{eq} at a rate given by

$$\frac{dn}{dt} = -\frac{(n - n_{\text{eq}})}{\tau} \tag{1}$$

where τ is a relaxation time.

This equation integrates easily to yield

$$n - n_{\text{eq}} = (n - n_{\text{eq}})_{t=0}\, e^{-t/\tau} \tag{2}$$

Note that although this calculation is for single domain grains, the results apply to all systems which obey equation (1).

If equation (2) is multiplied by the appropriate moment and integrated over all assemblies the change in total magnetization with time is obtained. The moment is JV where J is the saturation magnetization per unit volume.

The relaxation time is given by

$$\tau^{-1} = c\, e^{-KV/kT} \tag{3}$$

Where c is a rate assumed to be constant, K is the anisotropy constant, k is Boltzmann's constant and T the temperature. Only K and V will vary. Thus defining $W_V(K)$ as the probability that a grain of volume V will have a K lying between K and $K+\mathrm{d}K$, similarly that $N(V)$ is the probability that V lies between V and $V+\mathrm{d}V$, and N is the number of grains

$$M(t)=M_{\mathrm{eq}}+N\int\int W_V(K)\,JV(n-n_{\mathrm{eq}})_{t=0} \times\exp[-ct\,\mathrm{e}^{-KV/kT}]N(V)\,\mathrm{d}V\,\mathrm{d}K \qquad (4)$$

where

$$M_{\mathrm{eq}}=N\int\int n_{\mathrm{eq}}JVN(V)W_V(K)\,\mathrm{d}V\,\mathrm{d}K.$$

The first term in the integrand corresponds to viscous decay of the initial magnetization in zero field, the second to the acquisition of a moment from a demagnetized state.

Evaluating the time derivative of equation (4) and assuming that $W(K)$ is independent of V:

$$M'(t)=N\int W(K)\,\mathrm{d}K\int JV\Delta n_0(K,V)[-c\,\mathrm{e}^{-KV/kT}] \times\exp[-ct\,\mathrm{e}^{-KV/kT}]N(V)\,\mathrm{d}V \qquad (5)$$

where $\Delta n_0(K,V)=(n-n_{\mathrm{eq}})_{t=0}$.

As $c\simeq10^{10}\,\mathrm{s}^{-1}$ the integrand is small for small KV. It increases rapidly with KV as KV approaches about 30 kT, reaches a maximum, and decays exponentially as KV increases further due to the term $\mathrm{e}^{-KV/kT}$.

Thus the V integration can be performed using saddle point methods[5]. If V_{B} is the solution of $KV_{\mathrm{B}}=kT\ln ct$

$$tM'(t)=\int_{K_{\min}}^{K_{\max}}\frac{(2\pi)^{1/2}}{e}\Delta n_0(K,V_{\mathrm{B}})N(V_{\mathrm{B}}) \times\frac{kT}{K}JV_{\mathrm{B}}W(K)\,\mathrm{d}K \qquad (6)$$

A suitable average, $\bar{K}$, can always be found such that

$$tM'(t)=\frac{(2\pi)^{1/2}}{e}\Delta n_0\left(\bar{K},\frac{kT}{\bar{K}}\ln ct\right)N\left(\frac{kT}{\bar{K}}\ln ct\right) \times\left(\frac{kT}{\bar{K}}\right)^2(\ln ct)J \qquad (7)$$

$\bar{K}$, of course, is temperature dependent, and must lie between he maximum and minimum possible values of K.

This result leads to three conclusions: first, that the time and emperature dependence are connected through $T/\bar{K}$ and $\ln ct$. Second, that the form of this relationship depends on the previous history of the sample, and it is impossible to draw general conclusions from experimental results unless the initial state has been specified. Third, that it depends on the grain size distribution. This last result differs from Dunlop's[4] who concludes that this distribution is not critically important.

The simplest initial state is probably that in which the sample has been completely demagnetized. Consider then the acquisiton of a viscous moment by a completely demagnetized sample: In this case

$$\Delta n_0=-n_{\mathrm{eq}}=-JV_{\mathrm{B}}H/3kT \qquad (8)$$

and

$$tM'(t)=\frac{(2\pi)^{1/2}}{3\mathrm{e}}\frac{J^2H}{\bar{K}}\left(\frac{kT}{\bar{K}}\ln ct\right)^2N\left(\frac{kT}{\bar{K}}\ln ct\right) \qquad (9)$$

It should be possible to express the distribution as a power series

$$N(V)=\sum_r a_rV^r$$

In the following only one term in the series will be used, but the extension to the general case is obvious.

Thus, assuming $N(V)=AV^r$, and if the anisotropy is due to the shape of the grains, $\bar{K}=aJ^2$, and

$$tM'(t)=BH\left(\frac{kT\ln ct}{J^2}\right)^{2+r} \qquad (10)$$

where B is a constant.

A parameter which is frequently quoted is the viscosity coefficient.

$$S=\frac{\partial M(t)}{\partial\ln t}=tM'(t) \qquad (11)$$

S is often found to be proportional to the temperature[3,4,6]. This is true at low temperatures where J does not change very much, therefore r must be -1. (Note that a log normal distribution yields $r\sim-1$ for the larger grains.) However, equation (10) would suggest that the intervention of the temperature dependence of J would lead to a more complex temperature dependence in general.

Equation (10) is readily integrated to yield

$$M(t)=\frac{BH}{3+r}\left(\frac{kT}{J^2}\right)^{2+r}(\ln ct)^{3+r} \qquad (12)$$

A good way to determine $N(V)$ or r would be to plot $M(t)$ versus T (or T/J^2 if high temperature results are used) for equal values of t.

The expression obtained for the viscous moment differs from those obtained by others.

First, the moment depends on $(\ln ct)^m$ where m is determined by the grain size distribution. In general, however, it will be difficult to observe this experimentally because $(\ln ct)^m\simeq(\ln c)^m+(\ln c)^{m-1}(\ln t)$, and a $\ln t$ dependence will be observed except after very long times.

Second, the simple relationship $M(T_1\ln ct_1)=M(T_2\ln ct_2)$ which is frequently used[7] will not hold in general.

The time and temperature dependence of magnetic viscosity depends on the previous history of the sample. Therefore, unless $N(V)$ at $t=0$ is known an experiment on magnetic viscosity may yield bizarre, but meaningless, results. This is probably most important for experiments on viscous decay. On the other hand, if viscous acquisition is being measured it is probably safest to start with a completely demagnetized sample.

Finally, an interesting comparison of equation (12) with experiment is possible: Pullaiah *et al.*[3] remark that a magnetization acquired by heating a specimen of magnetite at 400 °C for 10 days is not removed before 550 °C if heating steps of 5 min are used. The samples were, in fact, expected to be completely demagnetized by 450 °C if the relationship between time and temperature is the one they derive, namely

$$\frac{T_1\ln ct_1}{[J(T_1)]^2}=\frac{T_2\ln ct_2}{[J(T_2)]^2}$$

However, equation (12) indicates that the relation should be

$$\left(\frac{T_1J^2(T_2)}{T_2J^2(T_1)}\right)^{2+r}=\left(\frac{\ln ct_1}{\ln ct_2}\right)^{3+r}$$

With this result if $r=-1$ (which roughly corresponds to a log normal distribution), the temperature for complete demagnetization becomes 500 °C, and for $r=-1.6$ it is 550 °C.

Similar arguments can be used to explain Pullaiah *et al.*'s observation that unblocking of NRM occurs at temperatures lower than they expected.

Next it is interesting to calculate the moment acquired during cooling.

The solution of equation (1) is complicated by the fact that n_{eq} and T are functions of time. Formally the solution is

$$n=\left\{\exp\left(-\int_0^{t_f}\frac{\mathrm{d}t}{\tau}\right)\right\}\int_0^{t_f}\frac{n_{\mathrm{eq}}(t)}{\tau}\exp\left[+\int_0^{t}\frac{\mathrm{d}t}{\tau}\right]\mathrm{d}t \qquad (13)$$

where t_f is the time at which the moment is measured after the material has cooled. Equation (13) may be rewritten

$$n=\int_0^{t_f}\tau^{-1}n_{\mathrm{eq}}(t)\left\{\exp\left[-\int_t^{t_f}\tau^{-1}\,\mathrm{d}t\right]\mathrm{d}t\right\}\tag{14}$$

For small t, that is initially, the argument of the exponential is large and therefore the integrand is small. It is small again as $t\rightarrow t_f$ because the relaxation time τ becomes very large. Thus, the method of steepest descents is again appropriate, and letting

$$g(t)=-\frac{KV}{kT}-\int_t^{t_f}c\,\mathrm{e}^{-KV/kT}\,\mathrm{d}t\tag{15}$$

the value of n is

$$n=(2\pi)^{1/2}\frac{n_{\mathrm{eq}}(t_c)c}{(|g''(t_c)|]^{1/2}}\exp\left[-\frac{KV}{kT(t_c)}-\int_{t_c}^{t_f}\frac{\mathrm{d}t}{\tau}\right]\tag{16}$$

t_c is obtained from $g'(t_c)=0$. In fact t_c will never be needed explicitly, but the condition $g'(t_c)=0$ gives, if $\mathrm{d}/\mathrm{d}t(K/T)=\alpha$

$$\frac{KV}{kT}=\ln\left(\frac{kc}{V\alpha}\right)\tag{17}$$

This equation may be solved for the temperature; this temperature would then be the blocking temperature. It will be convenient to modify the definition slightly so that the blocking temperature is

$$T_{\mathrm{B}}=\frac{(2\pi)^{1/2}}{e}\,\frac{K_{\mathrm{B}}V}{k\ln(kc/V\alpha)}\tag{18}$$

where K_{B} must be evaluated at the blocking temperature.

Now, returning to equation (16) we can evaluate n by introducing the expression for n_{eq}, equation (8)

and

$$g''(t_c)=-\frac{V}{k}\frac{\mathrm{d}\alpha}{\mathrm{d}t}-\left(\frac{V\alpha}{k}\right)^2\tag{19}$$

In equation (16) the values of J and α, which are temperature-dependent, are evaluated at T_{B}. For single domain grains, where shape anisotropy dominates, K is proportional to J^2 (ref. 8).

The parameter α depends on the particular way in which the material cools and is temperature and time dependent in general. The algebra becomes simpler if α is assumed to be constant. This is a relatively good approximation: it corresponds to a cooling law such that $\mathrm{d}/\mathrm{d}t(1/T)=$ constant. A similar approximation is made in ref. 3. If α is constant

$$\int_{t_c}^{t_b}\tau^{-1}\,\mathrm{d}t=-\frac{k}{\alpha V}\left[\left(\frac{1}{\tau}\right)_{t=t_b}-\left(\frac{1}{\tau}\right)_{t=t_c}\right]=1\tag{20}$$

as

$$(\tau)_{t=t_b}\gg(\tau)_{t=t_c}=\tau_b$$

combined with equations (20) and (21), (16) yields the eminently reasonable result that n is given by the equilibrium expression evaluated at the blocking temperature:

$$n=\frac{J_{\mathrm{B}}VH}{3kT_{\mathrm{B}}}$$

The magnetization is now

$$M=N\iint JV\left[\frac{J_{\mathrm{B}}VH}{3kT_{\mathrm{B}}}\right]N(V)W(K)\,\mathrm{d}V\,\mathrm{d}K\tag{21}$$

K may be replaced by its average as before, however, its temperature dependence must be retained.

Assuming that $N(V)$ obeys a power law $N(V)=AV^r$, equation (21) becomes

$$M=\frac{NJHA}{3k}\int_{V_0}^{V_m}\frac{J_{\mathrm{B}}}{T_{\mathrm{B}}}V^{2+r}\,\mathrm{d}V\tag{22}$$

It is convenient to integrate with respect to either J_{B} or T_{B}. Assuming that $\bar{K}=bJ^p$ and that $J=J_0(1-T/T_c)^{1/n}$, equation (22) yields a hypergeometric function which reduces to

$$M\cong\frac{NAJH}{3kT_c}\,\frac{p}{n}(V_m)^{3+r}\left[\left(\frac{kT_c}{V_m bJ_0^p}\right)\ln\frac{ke}{\alpha V_{\mathrm{eff}}}\right]^{1/p}\tag{23}$$

In obtaining this result $\ln kc/V\alpha$ which varies slowly with V has been assumed to be constant, and taken outside the integral. V_{eff} is an appropriate average V.

V_m is the blocking volume at the highest temperature of interest. Most of the moment is produced in the range from about 50 K below the Curie temperature to room temperature. Therefore V_m will be taken to be the volume of those grains whose blocking temperature is ~50 K below the Curie temperature. V_m is ~30 times V_0, the blocking volume at room temperature.

Note that the grain size distribution only influences the cooling rate effect by possibly affecting V_{eff}, and this is completely negligible. Note also that the cooling rate dependence does not depend on the temperature dependence of J, at least of the order of the approximation used here.

We can now estimate the effect of a change in cooling rate on the resultant moment: $\ln(kc/V_{\mathrm{eff}}\alpha)$ may be estimated as follows, $\alpha=[\Delta(\bar{K}/T)/\Delta t]$ so that in going from the Curie temperature to room temperature $\bar{K}/T$ increases from zero to K_0/T_0 where K_0 and T_0 refer to room temperature, thus

$$\frac{kc}{V_{\mathrm{eff}}\alpha}=\frac{kT_0}{V_{\mathrm{eff}}\mathrm{K}_0}c\Delta\mathrm{t}$$

now $V_{\mathrm{eff}}K_0/kT_0$ is of the order of 30 and if $c\sim3\times10^{10}$

$$\ln\left(\frac{kc}{V_{\mathrm{eff}}^{\alpha}}\right)\cong\ln(10^9\Delta t)$$

If Δt is changed by a factor of 10 the moment should change by about 6% for magnetite. For haematite[4], on the other hand, if $K=aJ^4$ the change should only be about 3%.

These results are in broad agreement with the calculations of Dodson and McClelland-Brown[3], in the sense that the integrated change in moment is in the low range of values obtained by them for an assembly of identical grains.

At present the only experimental results are those of Fox and Aitken[9]: for various samples of pottery they obtain an increase of between 3% and 9% in the moment for a decrease of an order of magnitude in the cooling rate. This agrees with the results obtained above as the carriers of the magnetization in pottery are believed to be monodomain grains of magnetite. It would be desirable, however, to have more precise experimental results.

An approximate expression for the moment produced during cooling from just below the Curie temperature has been obtained. We conclude that: the effect of cooling rate on the resulting moment is not sensitive to the grain size distribution or the temperature dependence of J. But is sensitive to the form of the temperature dependence of K on J; an order of magnitude increase in cooling rate leads to a 6% decrease in moment for magnetite, but only 3% for haematite.

I thank Dr D. J. Dunlop for comments, Dr M. J. Aitken for communicating experimental results before publication. This work was supported by a grant from the Natural Science and Engineering Council of Canada.

Identification and estimation of carbonate minerals at low levels by evolved CO_2 analysis

A. E. Milodowski

Department of Geology, King's College, Strand,
London WC2R 2LS, UK

D. J. Morgan

Institute of Geological Sciences, 64/78 Gray's Inn Road,
London WC1X 8NG, UK

Recent differential thermal analysis (DTA) investigations of carbonate minerals using a flowing CO_2 furnace atmosphere[1,2] have shown that amounts as low as 0.25% (2,500 p.p.m.) may be detected in natural or synthetic mixtures, a significant improvement on that possible using static air DTA or conventional X-ray diffraction techniques. We show here that carbonate minerals can be routinely detected in the hundreds of p.p.m. concentration range using a non-dispersive IR CO_2 detector linked to a DTA furnace and describe modifications to the technique which permit the detection of certain carbonates below 100 p.p.m. The method described gives both an analytical determination of CO_2 and an identification of the mineral species responsible for CO_2 generation. It should be of use in the study of trace constituents in rocks, sediments, soils and ores and as a quality control technique in industrial processes.

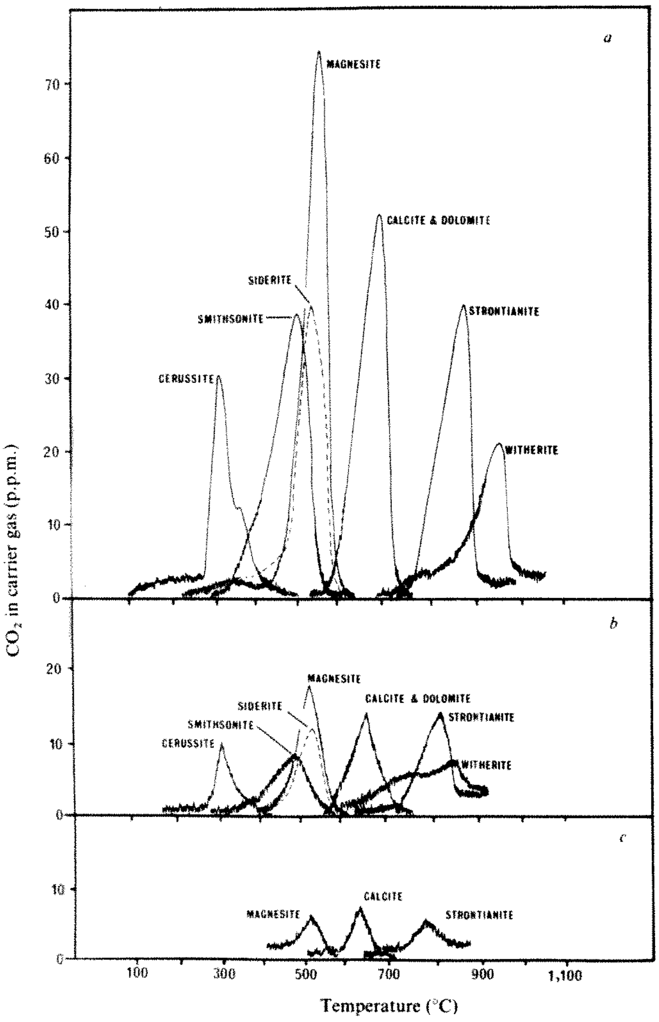

Fig. 1 CO_2 evolution profiles obtained from: *a*, 0.2%; *b*, 500 p.p.m.; and *c*, 50 p.p.m. nominal concentrations of carbonate minerals in alumina. Evolution profiles in *a* and *b* were obtained using a carrier gas flow rate of 300 ml min^{-1} and in *c* with a flow rate of 100 ml min^{-1}.

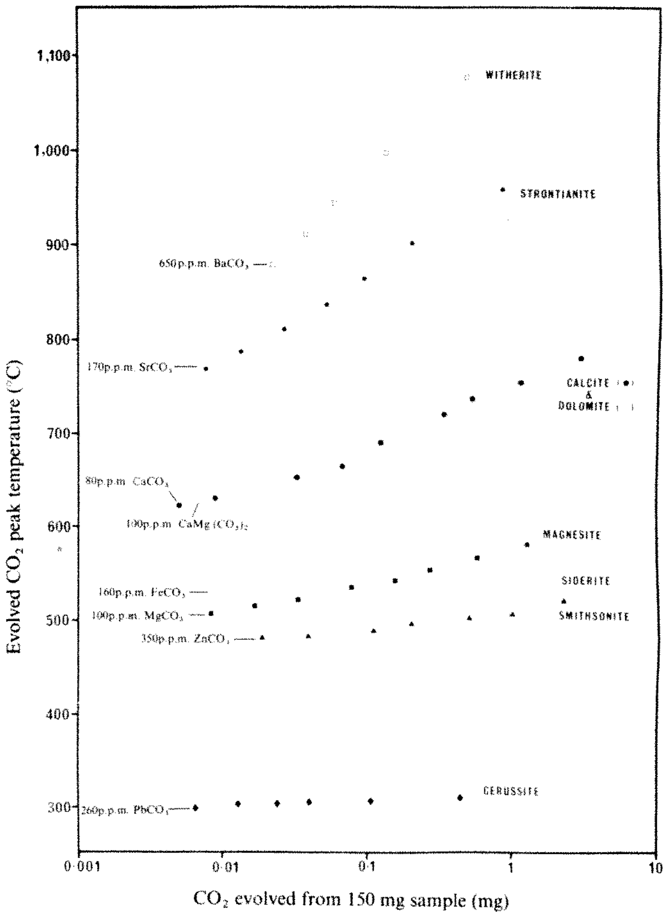

Fig. 2 Plot of evolved CO_2 peak temperature versus log mass of CO_2 evolved for the eight carbonates investigated.

Details of the DTA–EGA (CO_2) system have been given previously[3]. Briefly, this consists of a DTA furnace swept at 300 ml min^{-1} by a carrier gas stream consisting of a 2 : 1 mixture by volume of nitrogen and oxygen and linked by a stainless steel line to a non-dispersive IR CO_2 detector. This has two analysis cells capable of measuring up to 1,000 and 10,000 p.p.m. CO_2 in the carrier gas stream, although for the present study only the most sensitive cell was used. Output signals from the detector are fed into an external chart recorder which also monitors sample temperature. Additional, more sensitive ranges on the chart (0–500 and 0–100 p.p.m. fsd) are obtained through ×2 and ×10 signal amplification switches on the detector.

A standard mass of sample (150 mg) is lightly packed into a dimped Pt-crucible and this placed in the DTA head. A heating rate of 15 °C min^{-1} is used. Areas of the CO_2 evolution profiles on the chart are measured with a planimeter and the amount of CO_2 evolved obtained by calculation[3].

Eight X-ray pure natural anhydrous carbonates were examined: witherite, strontianite, calcite, dolomite, magnesite, siderite, smithsonite and cerussite. Each mineral was ground to pass a 200-mesh sieve and mixed with alumina to give a dilution sequence covering the range 2% to 50 p.p.m. The alumina/carbonate mixtures were placed in glass screw-top bottles and mechanically shaken for 20 min. No precautions were taken to obtain a statistically uniform 150 mg sample for analysis as the amount of carbonate mineral present was determined from the area of the CO_2 evolution profile.

Figure 1*a–c* shows CO_2 evolution profiles given by the eight carbonates at nominal concentrations ranging from 0.2% to 50 p.p.m. At 0.2% (Fig. 1*a*) all the carbonates give sharp peaks

0028–0836/80/290248—02$01.00

with virtually no baseline drift. Areas of the peaks vary in proportion to the CO_2 contents of the minerals which range from 52.2% for magnesite to 16.5% for cerussite. Detection limits are obviously influenced by this factor, although with decreasing concentrations other factors become increasingly important. In the concentration range examined, CO_2 release from witherite is governed more by solid-state reaction with alumina than by simple dissociation[4]. As a result, CO_2 evolution occurs over a relatively large temperature range and the mineral does not give recognizable peaks at concentrations <500 p.p.m. Kinetics of the dissociation are also relevant: cerussite, although containing less than half the CO_2 content of smithsonite, can be detected at lower levels because of its sharp CO_2 evolution profile (Fig. 1*a*, *b*).

Figure 2 summarizes the data obtained for the dilution sequences using a carrier gas flow rate of 300 ml min^{-1}. Values in p.p.m. to the left of the figure represent the lowest concentration at which each mineral gives a well-defined CO_2 peak. Reducing the carrier gas flow rate would be expected to improve detection limits due to the effective increase in CO_2 content of the carrier gas. However, at slower flow rates convection currents in the furnace assume a much greater importance. These are especially noticeable in the 150–450 °C range and cause irregular flushing of the evolved CO_2 and a consequent increase in background noise-to-signal ratio in the detector. Detection limits for cerussite and smithsonite, which dissociate within this temperature range, were not, therefore, significantly improved at slower carrier gas flow rates although satisfactory CO_2 peaks were obtained from magnesite, calcite and strontianite at nominal concentrations of 50 p.p.m. using a carrier gas flow rate of 100 ml min^{-1} (Fig. 1*c*).

Plots of evolved CO_2 peak temperature versus log mass of CO_2 evolved (Fig. 2) are straight lines which become shallow curves in the lower concentration ranges (this curvature is experimental and is a function of the rate of diffusion of CO_2 from the carbonate–alumina mixture). In general, the higher the dissociation temperature of the carbonate, the greater the slope of the line, a similar relationship to that existing between plots of DTA dissociation peak temperature and mass of the various carbonates at higher concentrations[5]. The exception is siderite which shows no variation in CO_2 peak temperature with dilution; note that Warne[6] found that the temperature of the endothermic DTA peak of this mineral was also relatively insensitive to dilution.

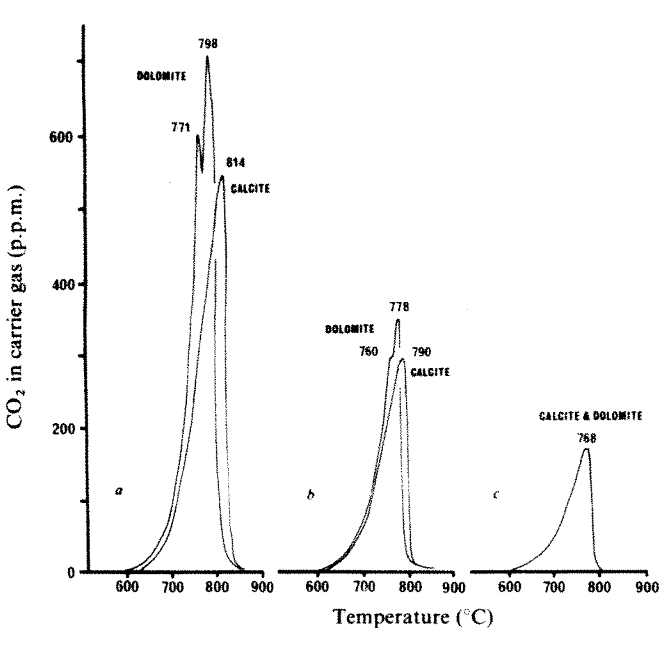

Fig. 3 CO_2 evolution profiles of calcite and dolomite obtained with a porous cap on top of sample crucible. *a*, 2%; *b*, 1%; and *c*, 0.5% nominal concentrations.

The CO_2 peak temperature–concentration relationships presented in Fig. 2 provide the basis for both identification and quantification of individual carbonates present at low levels in natural mixtures although it is apparent that distinction between calcite and dolomite is impossible in the experimental conditions used and some difficulty might be anticipated in differentiating between magnesite, siderite and smithsonite, especially when variations in thermal behaviour of the natural minerals are taken into account. This topic will be discussed in detail elsewhere but note here that placing a porous cap over the Pt-crucible resulted in a marked separation of dolomite and calcite peaks at concentrations of 1% and above (Fig. 3). Evolution of CO_2 from magnesite is also retarded to a much greater extent than from siderite or smithsonite by the porous cap and this mineral is readily distinguishable in 0.5% artificial mixtures with the other two carbonates.

This work was carried out while A.E.M. was in receipt of a Natural Environment Research Council CASE studentship. The paper is published by permission of the Director, Institute of Geological Sciences.

Coral morphology, diversity and reef growth

John Chappell

Department of Biogeography and Geomorphology, Australian National University, Canberra, Australia

The shape of reef corals is affected by light level[1,2] and by wave stress[3,4], leading to the well-known zonation of coral form associations with exposure and depth[3–6]. Growth form also seems to be constrained by geometric factors[2,7,8]. Similarly, coral calcification rate, of importance both for coral form and for net reef growth, is light dependant[9,10], and may be affected by other factors such as wave stress and sediment flux. Here the growth structure of raised Pleistocene reefs in New Guinea, of both fringing and barrier types, is explained in terms of variations of coral framework growth rate across the reef profile. A model for growth rate in terms of wave stress, light level and other variables is outlined, first by examining the effects of these factors on coral form and diversity.

Growth form responses to several factors are outlined in Fig. 1, on the following basis. (1) Light response: Porter's general argument that surface-to-volume ratio should diminish as light increases[7] is contradicted by types which show globose to platy polymorphism[1,2]. A better index, consistent with Porter's argument, is the ratio of polyp-covered surface to the projected surface area seen from above. (2) Hydrodynamic stress response: adaptation will be to increase structural strength as wave/current stress increases[3,11,12]. (3) Sediment flux effect: advantageous forms, where sediment flux is high, would intercept the smallest proportion of settling sediment per unit surface area, for a given polyp size[13]. (4) Subaerial exposure: significant on many reef flats, the best adaptation is likely to be that which maximizes stored water capacity by minimizing surface-to-volume ratio as well as maximizing sideways spreading. Note that Fig. 1, outlining these responses, is not exhaustive and interpolations can be made in any row, for example, types 7 and 8 have similar or lower polyp surface/projected surface ratios than type 1, and can be placed at the left in row 1.

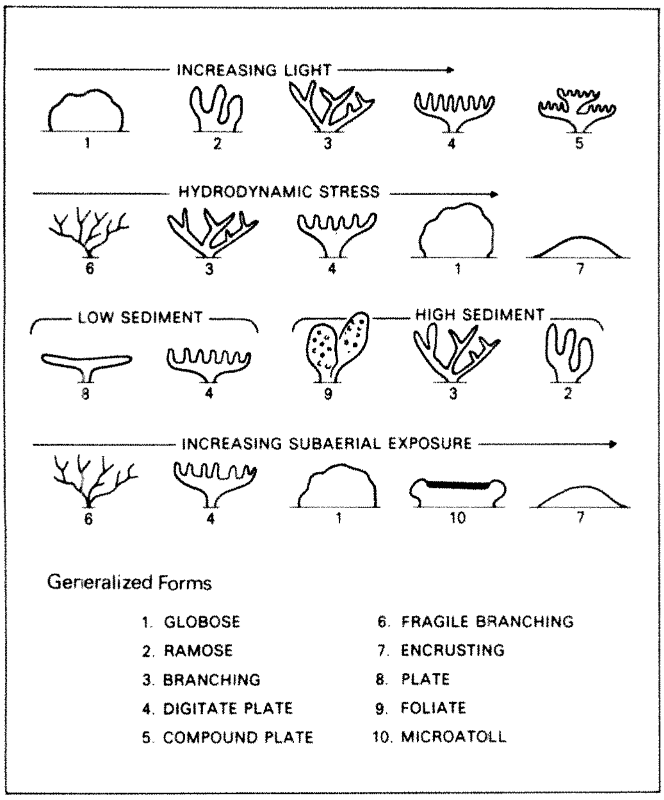

Fig. 1 Coral form responses to environmental stresses.

Net reef growth not only depends on coral calcification rate, but is also affected by the type of framework built by the local assemblage of forms. Figure 1 indicates that form assemblage will vary with the net balance of the four stress factors, which vary with position, as follows. Light diminishes with depth, although it seems not to be stressful until the depth where photo-adaptation (increasing zooxanthellae) ceases to change[1,14]. Wave stress increases with square of wave height and declines negative-exponentially with depth. The stress imposed by settling sediment should increase slowly down the windward forereef; it is significant on the reef flat, and also is high where sediment overspill to the backreef is high. Subaerial exposure on the reef flat increases with height above lowest spring tide level. These variations are shown in Fig. 2 for an idealized reef cross-section. Characteristic coral community forms, projected in Fig. 2 in the light of Fig. 1, are consistent with zonations described by others[3,6,15]. Note that when wave exposure is very high, the encrusting coral zone at the reef margin (shown at '7' in Fig. 2) often is replaced by algal bioherm[3,16].

Hypothetical diversity curves also are shown in Fig. 2, based on net stress (= sum at any point of stresses shown graphically in Fig. 2). Diversity ranges from maximum when environmental stress is small, down to zero when any factor is limiting[17]. Diversity curves in Fig. 2 are based on an assumed inverse-linear relationship between net stress and diversity. The curve for the forereef compares well with Porter's results from a Panama reef[18] when these are smoothed to eliminate variations related to local topographic effects. No account is taken, in compiling Fig. 2, of the 'intermediate disturbance' effect[19] on diversity of events such as cyclones.

Coral morphology and diversity zonation have been accounted for by others in terms of depth variation of wave stress and light[3,4,16,17]. In this regard, the semi-quantitative relationships underlying Fig. 2 are valuable. It is also suggested that growth of coral framework is constrained by the four stress factors in the same way as is diversity in Fig. 2, that is, that growth diminishes as net stress increases until any factor becomes limiting. This is tested by simulating reef growth and comparing the results with known reef growth structures.

A simple computer model to simulate reef development was arranged as follows. Each of the four stress factors was given a range 0–1 and net stress taken as the arithmetic mean at any point on the evolving profile. Growth ceases where any factor

reaches the limiting value of 1. Wave behaviour was modelled as Airy waves outside the breaker line, solitary waves inside it, with standard equations for bed shear, and so on.[20] Energy dissipation at wave break was assumed to be 75%. Maximum possible growth rate was 1 cm yr^{-1}. Light stress was assumed 0–15 m depth and to increase then to become limiting at 40 m. Waves of 2 m at 8 s (800 W m^{-1} of wave crest) were input (assumed not to be limiting). Sediment flux, taken as equivalent to the rate of wave energy loss from bed friction, was assumed limiting when wave power loss reached 100 W m^{-1} per m of wave advance. These values are taken in accordance with my observations of modern and Pleistocene reefs at Huon Peninsula, New Guinea[21], with which model results are compared, below. Variations from these values alters scaling dimensions but not the form of the results.

Reef development is affected by previous topography which developed sub-aerially during Pleistocene low sea levels[22,23]. This is simplified in the model by using a rectilinear initial substrate, which accords with the New Guinea case[21]. The rate of sea-level rise during deglaciation, relative to maximum potential growth rate of framework, is also important for reef growth structure[21], although the extent to which Darwin's hypothesis, that barrier and lagoon structure arises from rising relative sea level (submergence), is debated[22]. Accordingly, Fig. 3 shows three runs of the computer model, with sea-level rise rates of 0.0 cm yr^{-1}, 0.5 cm yr^{-1}, and 1.0 cm yr^{-1} respectively. The first two cases induce formation of a fringing reef; in the third case a barrier and lagoon develops.

The model is compared with late Pleistocene reefs for which the growth history is known, shown in Fig. 4. These developed during sea-level changes centred on the last interglacial period, 135–120 kyr ago, and are now exposed well above sea level through tectonic uplift, at Huon Peninsula, New Guinea[21] (examples 1, 2 in Fig. 4), and at Atauro Island, Timor[24] (example 3). Also shown is the pattern of 'absolute' sea-level change for the period[24,25]. Mean growth rates differ between the Huon and Atauro examples; Huon reef VIIa grew 50 m in <10,000 yr (>0.5 cm yr^{-1}), while the Atauro reef grew 40 m throughout the entire interval of 145–115 kyr (0.13 cm yr^{-1}). The rate difference is not due to uplift rate or substrate slope differences as these are matched in one or the other of the Huon cases (Fig. 4), and is probably caused by clastic sediment flux which is much greater at volcanic Atauro than at Huon Peninsula, where the hinterland is limestone. This is supported by the fact that Huon Peninsula coasts away from the limestone region have a volcanogenetic hinterland, high clastic flux, and only minor reefs. Coral zonation in the Huon reefs, described by Chappell[21], is consistent with Fig. 2 (no major algal bioherm occurs at reef crest on this moderate-energy coast); these zones are simplified to backreef (B), shallow forereef (S), and so on, in Fig. 4. Major facies boundaries trace the course of reef growth.

The structures in Fig. 4 compare well with computer model predictions in Fig. 3 when growth rate–sea-level rise rate relationships are considered. Maximum growth rates in Holocene reefs at Huon Peninsula, which are comparable to the raised Pleistocene reefs, are around 0.8 cm yr^{-1} (ref. 26). Sea-level rise for the NW Huon section slightly exceeded this, at ~1.0 cm yr^{-1} (uplift for this section being only 0.05 cm yr^{-1}), and a barrier–lagoon structure developed (see model case 3 in Fig. 3). Relative sea-level rise rate for the south-east Huon case is lower than maximum potential growth rate, at 0.6 cm yr^{-1}, due to rapid tectonic uplift (0.4 cm yr^{-1} at this section), and a fringing reef formed (see model case 2 in Fig. 3). In the Atauro case the potential reef growth rate seems to have been much lower than

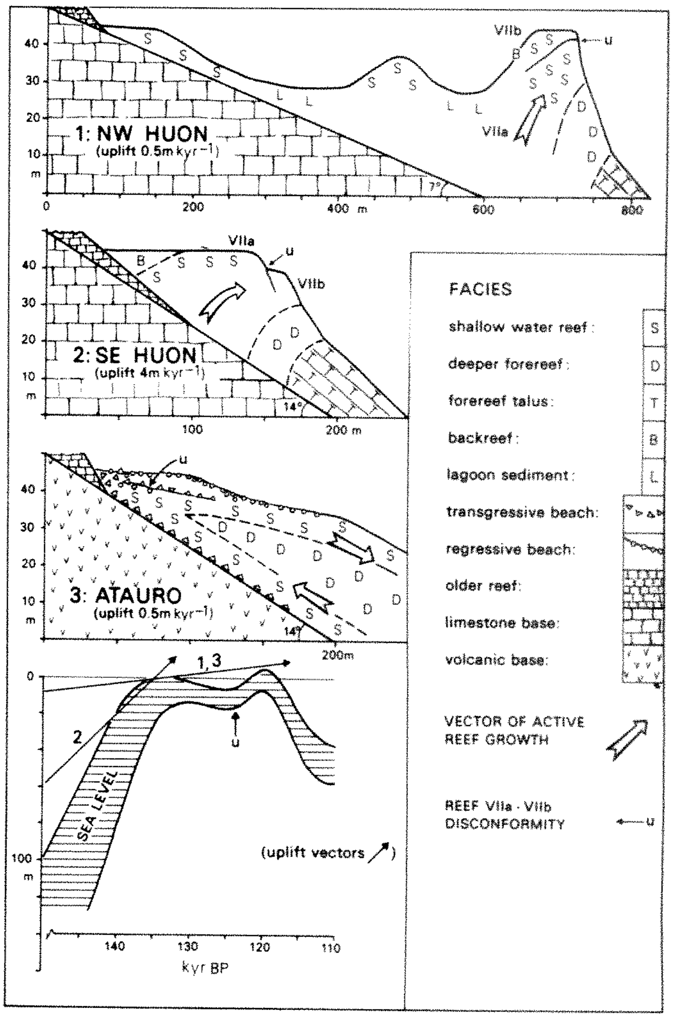

Fig. 4 Mapped cross-sections of late Pleistocene reefs at Huon Peninsula, New Guinea[21], and Atauro Island, Timor[24].

relative sea-level rise rate, resulting in formation of a transgressive shelving reef which continued to grow slowly through the interglacial and into the early phase of the subsequent falling sea level.

In conclusion, raised Pleistocene reefs at Huon Peninsula, where major variations of uplift rate along the coast provide the opportunity for examining reefs formed under different relative rates of sea-level rise, are compatible with a model for reef development which relates growth rate to net environmental stress. As the model is semi-quantitative, its predictions as to growth rates, coral forms and coral diversity, as functions of the four stress factors invoked, are readily testable through further observations.

A water depth model for the evolution of the planktonic Foraminiferida

Malcolm B. Hart

Department of Environmental Sciences, Plymouth Polytechnic,
Drake Circus, Plymouth PL4 8AA, UK

Recent papers on the evolution of the planktonic Foraminiferida have stressed the importance of repeated patterns[1,2] in the Neogene and Palaeogene, as well as in the Cretaceous[1–4]. Most authors have recognized the importance of gross morphological characters (the biocharacters of Steineck and Fleischer[2]) and used them to illustrate the evolution of the superfamily Globigerinacea, as well as a prime tool in classification. Cifelli[1] and Frerichs[4] relate such patterns of evolution to the available palaeotemperature data[5], and while temperature is clearly important I shall show that it is not the complete story. Here the evolution of the planktonic Foraminiferida is reconsidered in the light of recent advances in the understanding of distributional controls of the modern fauna. I suggest that well-known 'iterative' trends indicate successive attempts at colonizing deeper levels in the water column.

In the planktonic environment, and especially in the surface waters where the planktonic Foraminiferida are most abundant, faunas avoid competition by adjusting their regional distributions to the different surface water and temperature regimes and by sometimes seeking different levels in the water column in their adult growth form. Bé[6] has summarized his extensive knowledge of the modern fauna, and confirmed a threefold subdivision of the water column; shallow-water fauna (0–50 m), intermediate-water fauna (generally 50–100 m) and deeper-water fauna (with adults normally below 100 m). This distribution can be identified in the Cretaceous using oxygen isotope data[7] or, more conventional, stratigraphic information[8].

Using planktonic:benthonic ratios (counted on the 500–250 μm grain-size-fraction) a depth curve[8] has been produced for the Albian–Santonian interval of the Cretaceous succession in south-east England. A sample interval of 1 m (or less) was used throughout that study and the reliability of the graphs produced was tested by regional correlation[9,10]. That water depth curve has many major features in common with other postulated depth curves for the same area[11,12], although there are some minor differences[13]. Onto this depth curve Hart and Bailey[8] have reconstructed the evolutionary trends of the mid-Cretaceous planktonic Foraminiferida, placed at their predicted water depth (following the Bé[6] model) and confirmed by their distribution in the shelf seas prevailing over north-west Europe at that time. In all the examples cited, mid-Cretaceous evolution either proceeds horizontally within the same depth zone, or migrates downwards into a lower depth zone. I know of no examples of evolution following a trend up into a higher level in the water column. As indicated by Hart and Bailey[8], the distribution of an individual species and its appearance in time is, therefore, a function of the water depth available over the shelf during any particular interval. Differences in the known stratigraphic ranges of certain species are to be expected when one compares the UK succession with those recorded in the oceans by the Deep Sea Drilling Project[14], or even areas like the Tethyan/Alpine region of Southern Europe[15]. Using this experience of the mid-Cretaceous fauna the central part of Fig. 1 was constructed, and then extended to include both the late Cretaceous/Cenozoic and the Triassic/Jurassic/early Cretaceous, with the aid of data from the literature[1–6]. The depth preferences for each of the biocharacters is given where this is possible (following refs 6, 8), although this is clearly a great approximation the further one goes back through the geological record. There are also some characters that do not appear in all parts of the record, the most obvious being the lack of twin-keeled forms in the Palaeogene and Neogene, and the absence of biserial morphotypes at present.

Throughout the preparation of Fig. 1 the regional distributions of genera and species, together with their palaeoecological associations, have been considered. While the proposed model seems to cover most stratigraphic situations, there are clearly many cases where local palaeo-oceanographic conditions have created apparently anomalous occurences of deeper-water morphotypes in what are regarded as shallow-water sediments (for example, *Globotruncana* spp. in the Campanian/Maastrichtian marginal calcarenites of Scania, S. Sweden; *Rotalipora* spp. in the Lower Middle Cenomanian calcareous sands of south-east Devon[9]; the apparently contradictory distribution of certain spinose/smooth species in parts of the Palaeogene; and the occurrence of some species of *Acarinina* and *Morozovella* in Palaeogene shallow-water sediments). Interesting, and important, as these individual cases may be, they do not negate the longer-term, overall trends outlined here.

Following my experience of mid-Cretaceous planktonic foraminiferal evolution[8], it is possible to consider the complete Triassic to Recent time interval. Figure 1 shows the successive appearance of certain biocharacters exhibited by the whole superfamily Globigerinacea from its benthonic source (fully discussed by Masters[16]) in the Triassic(?). This original, primitive, shallow-water 'globigerinid' form remains virtually unchanged until the mid-Cretaceous (Aptian) when the first evolutionary explosion began. During, and following, the Aptian and Albian there was a very rapid appearance of new morphotypes of planktonic Foraminiferida, and their suggested depth stratification from this time onwards up the geological succession can be enclosed by the dotted line shown in Fig. 1, and contours the repeated conquest of deeper, surface, water habitats. This 'envelope' is also represented in Fig. 2, on which are also indicated the oceanic anoxic events of Schlanger and

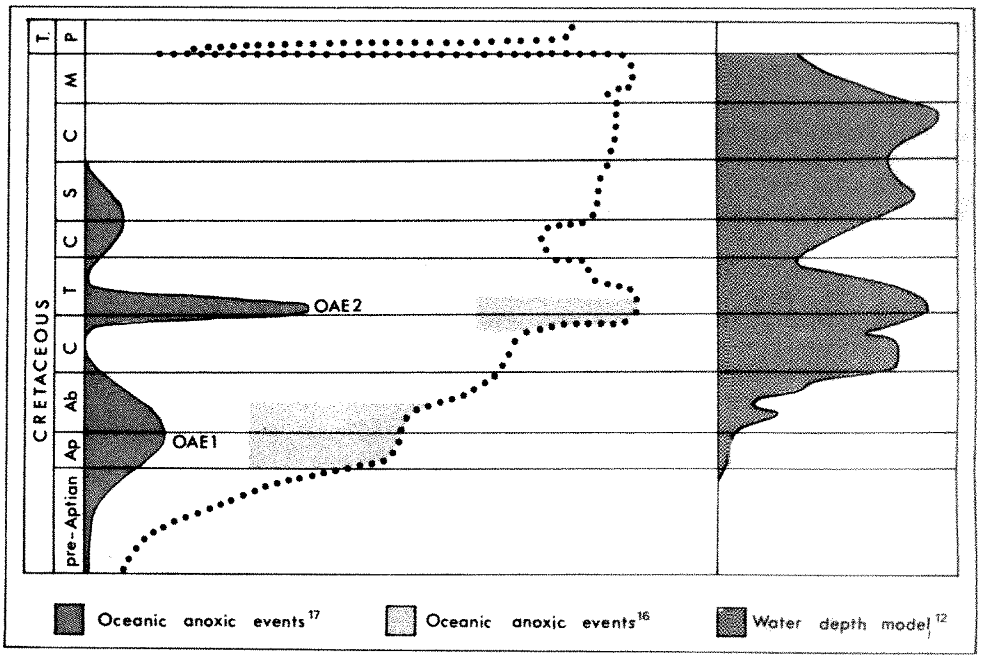

Fig. 2 Depth stratification model compared with the transgression/regression model of Hancock[12] and Cretaceous anoxic events[17,18].

Jenkyns[17] (together with the modifications proposed by Arthur and Schlanger[18] and Jenkyns[19]). These anoxic events coincide with the levels of maximum faunal change (for example, the late Cenomanian–early Turonian boundary, the Aptian–Albian interval, and the Coniacian–Santonian interval). The 'envelope' is also similar, in broad outline, to many published transgression/regression models[11,12], especially that figured by Schlanger and Jenkyns[17]; the present curve is produced simply by matching foraminiferal test morphology against a Recent water depth scale[6].

This close similarity suggests that the evolution of the planktonic Foraminiferida may be a function of increasing water depth on or near the shelf, which is, after all, where productivity is at its highest. This would be particularly true if a rising sea level was actively eroding its shorelines, thereby providing a vital nutrient source (Fig. 4 of ref. 19). This argument cannot, however, be applied to the Miocene–Pliocene interval where the same evolutionary patterns have been produced by a falling sea level. The same problem exists if one applies a temperature model; rising temperatures in the mid–late Cretaceous, and generally falling temperatures in the Miocene–Pliocene. Perhaps one should consider the stability of the stratification of the water column as the control. The oceanic anoxic events[17–19] imply a certain degree of stagnation of the water column, probably created by overproduction of phytoplankton in the surface waters, and a lack of O_2-rich waters being introduced into the ocean basins from cold polar sources. In such a situation the oceans probably become very sluggish and highly stratified. Such a stratification of the water column immediately implies a host of physical/chemical constraints[20] including temperature. If the plankton in the water column were stimulated into high productivity by a rising sea level over the extensive Cretaceous shelf seas, there is the possibility that the associated O_2-depletion of the water could have contributed to the localized (and in some cases quite widespread) stagnation of the ocean floor (and the expanded shelf areas at times of high sea level) in a highly stratified situation.

During three main intervals of time (mid-late Cretaceous, Palaeogene and Neogene) the planktonic Foraminiferida apparently adapted (or were forced to adapt) to the status quo, and when the stratification was disturbed (by the terminal Cretaceous Event[21], and the late Oligocene Event) they were then obliged to repeat their evolution as a direct response to the new situation.

This response has provided the successive appearance of the morphological features reported in Fig. 1 and the concomitant palaeotemperature values recorded by Douglas and Savin[7]. These various attempts to occupy the same levels in the water column have produced some remarkable examples of homeomorphy. Perhaps the best is the repeated evolution of the deeper-water plano-convex forms, with the successive appearance of the completely unrelated *Praeglobotruncana helvetica* (Bolli), *Dicarinella concavata* (Brotzen), *Globotruncana gansseri* Bolli, *G. gagnebini* Tilev, *Morozovella caucasica* (Glaessner), and *Truncorotalia truncatulinoides* (d'Orbigny). A not so extreme form of this morphotype (*Globotruncana stuartiformis* Dalbiez) was assigned to deeper levels in the water column on the basis of isotopic determinations by Douglas and Savin[7].

While the proposed model (Fig. 1) is clearly for further discussion and research it does highlight many problems of foraminiferal classification. Can Masters[16] be supported in his attempts to rejuvenate the use of *Globigerina* for Cretaceous species, when some workers in the Cenozoic feel unjustified in using that name back beyond the Neogene? It would also seem to indicate that in many places in the Cretaceous we are not using a phylogenetic classification, although the desirability/undesirability of such an approach is not being promoted by this account.

The recent work on isotopes/palaeotemperatures[7] has suggested a depth stratification model for planktonic Foraminiferida as far back as the Albian, and this is supported here. Also, if one could establish a direct relationship between eustatic changes (and their associated transgressions and regressions), phytoplankton productivity, evolution, and the production of anoxic sediments at selected levels in the geological record (particularly in the Cretaceous) then this would provide an interesting avenue of palaeo-oceanographic research.

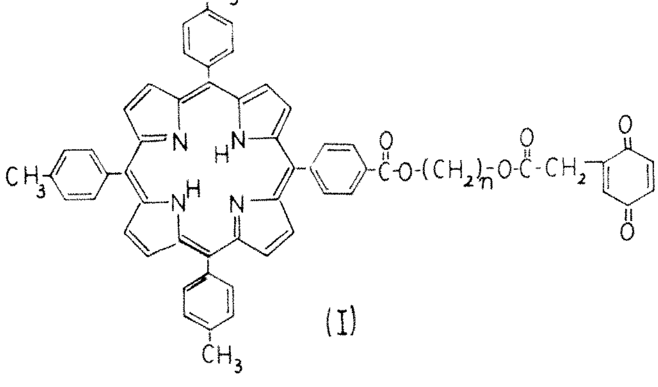
Intramolecular photochemical electron transfer in a linked porphyrin–quinone molecule as a model for the primary step of photosynthesis

Te-Fu Ho, Alan R. McIntosh & James R. Bolton

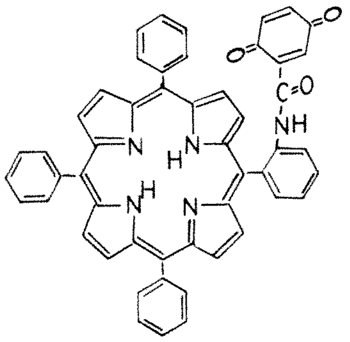
Photochemistry Unit, Department of Chemistry,
University of Western Ontario, London, Ontario, Canada N6A 5B7

The primary photochemical process in algal and green-plant photosynthesis is a one-electron transfer reaction from a chlorophyll donor species to an electron-acceptor molecule, with the electron transfer taking place across the thylakoid membrane probably within a special reaction-centre protein[1]. A similar process takes place in bacterial photosynthesis. We have mimicked this reaction through the synthesis described here using the method of Kong and Loach[2], of a single molecule (P–Q) (I) containing a porphyrin (P) linked to a quinone (Q) by a hydrocarbon chain. When illuminated with visible light an intramolecular electron transfer occurs from the porphyrin to the quinone creating the biradical $\mathrm{P}^{+\cdot}$–$\mathrm{Q}^{-\cdot}$ which can be detected by electron paramagnetic resonance (EPR) spectroscopy. In certain conditions the electron transfer is reversible.



(I)

There has been considerable interest in constructing various models to mimic the *in vivo* photochemical system. These have ranged from models of the primary donor and intermediate electron-acceptor complexes[3-5], monolayer assemblies[7-10], vesicles[11,12], intramolecular exciplex complexes[13-18] to chlorophyl–quinone electron transfer in solution[19]. The P–Q compounds with $n = 2$ and 3 were previously synthesized by Kong and Loach[2]. They reported that the benzoquinone oxidation state quenches the fluorescence of the attached porphyrin in dioxane and petroleum ether with a very low fluorescence yield in the latter solvent. Tabushi *et al.*[20] reported that in (II) fluorescence was considerably quenched compared to that of the unlinked porphyrin. They have attributed the fluorescence quenching to electron transfer but presented no direct evidence for such a mechanism.



(II)

In the synthesis of P–Q (I with $n = 3$) we followed the method of Kong and Loach[2] except that we started with the more stable 2,5-dimethoxylphenylacetic acid. The purity of the final compound was assessed by NMR and mass spectra which were consistent with (I) and by obtaining a single spot on thin layer chromatography using two separate solvents on silica gel. We also found that the fluorescence of P–Q ($n = 3$) in methanol at room temperature is quenched to an extent of 90% compared with that of the free porphyrin; however, this observation alone does not prove that photochemical electron transfer has taken place. More direct evidence can be obtained from EPR measurements. Both steady-state and transient EPR measurements were carried out for concentrations of P–Q between 10^{-4} and 10^{-3} M in a frozen methanol plus 2% chloroform solution between 12 and 165K. The P–Q UV–visible optical spectrum obeys Beer's law for concentrations up to 5×10^{-4} M. Above that there are some changes in the spectrum which could be due to dimerization. However, all measurements were carried out down to 10^{-4} M with little or no change in behaviour. For $T < 150$K, photolysis with a 200 mW 647 nm Spectra Physics Krypton cw laser beam or with a Phase-R 620 nm pulsed dye laser generated an irreversible light-induced EPR signal. The spectrum (Fig. 1*a*) was found to be nearly invariant for temperatures below ~150K. The *g* factor and the lineshape are similar to those of the unlinked porphyrin $\mathrm{P}^{+\cdot}$ (Fig. 1*c*). However, on subtracting the $\mathrm{P}^{+\cdot}$ spectrum from that of Fig. 1*a* (to the extent of one-half of the latter's integrated intensity), the difference spectrum of Fig. 1*e* is obtained, which is neither that of $\mathrm{P}^{+\cdot}$ (Fig. 1*c*) nor the unlinked quinone $\mathrm{Q}^{-\cdot}$ (Fig. 1*d*). We have performed several control experiments in which the unlinked components P and Q were photolysed in methanol at low temperatures. When the concentration of Q is 1,000 times that of P, we observe irreversible intermolecular electron transfer, as shown in the EPR spectrum of Fig. 1*b*. When the spectrum of $\mathrm{P}^{+\cdot}$ is subtracted from Fig. 1*b* in the same manner as before, the difference spectrum of Fig. 1*f* is generated. This spectrum is similar to that of the unlinked $\mathrm{Q}^{-\cdot}$ (see Fig. 1*d*) allowing for some spin exchange broadening effects. However, when P and Q are mixed at the same low concentration, the quantum efficiency of production of the EPR photolysis spectrum is much less than that generated by photolysis of the same concentration (2×10^{-3} M) of the P–Q complex as shown in Fig. 2. Both meso-tetratolylporphyrin in chloroform/methanol and meso-tetra(4-carboxyphenyl)porphyrin in methanol were used, and nearly the same low yield of radicals was obtained.

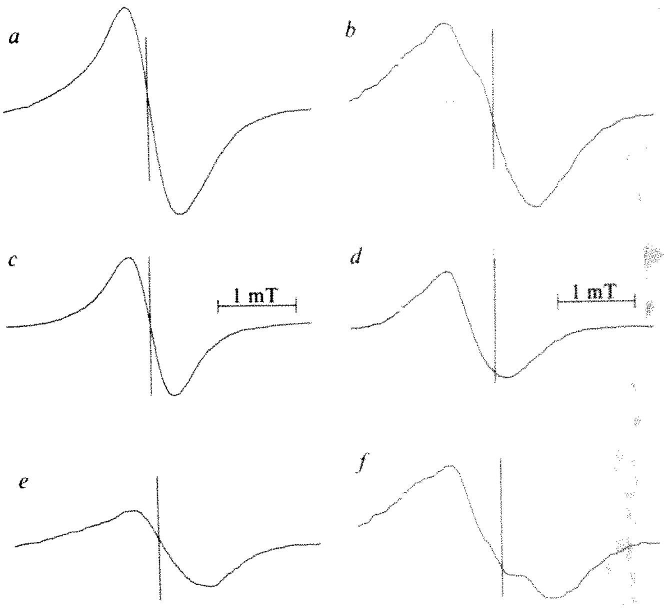


Fig. 1 Typical irreversible EPR spectra observed after the 200 mW 647 nm Krypton cw laser photolysis (except for *c* and *d*) of linked and non-linked P and Q compounds in methanol observed at 100K with EPR detection conditions of 0.2 mT modulation amplitude at 100 kHz and 1 mW microwave power at ~9.0 GHz. The vertical line in each case indicates the P^{+} *g* factor: *a*, photolysis spectrum observed from the linked compound P–Q at 2×10^{-3} M concentration; *b*, photolysis spectrum observed from 10^{-4} M meso-tetra(4-carboxyphenyl)porphyrin with 10^{-1} M benzoquinone; *c*, meso-tetratolylporphyrin radical cation (obtained by iodine oxidation) at half of the integrated amplitude or concentration of part *a*; *d*, spectrum of semireduced quinone (obtained by the air oxidation of 2,5-dihydroxyphenylacetic acid) at half of the integrated amplitude or concentration of part *a*; *e*, difference spectrum of *a* (P–Q) minus *c* (P^{+}) which removes the theoretical 50% contribution of P^{+} from the PQ photolysis spectrum; *f*, difference spectrum of *b* (P^{+} and Q^{-}) minus *c* (P^{+}) which removes the theoretical 50% contribution of P^{+} from the separated component spectrum.

On the basis of these steady-state EPR measurements, we conclude that the irradiation of P–Q results in an initial intramolecular electron transfer with high yield; however, there is also probably a low-yield contribution to the spectrum resulting from some electron transfer into the solvent or intermolecular transfer to the quinone moiety of another P–Q molecule.

As a further test of our intramolecular electron transfer hypothesis, we carried out flash-photolysis experiments with EPR detection[21] as the temperature was raised from 90 to ~160K (about 15° below the melting point of methanol). A large irreversible EPR signal was generated by photolysis at about 140K, as shown in Fig. 2. However, as the temperature approached 160K, the EPR kinetics became almost totally reversible, as shown in Fig. 3. The reversibility at 160K was very strong as the recorder pen of the Varian E-12 100 kHz EPR spectrometer jumped with each ~1 mJ flash of the red-filtered Photochemical Research Associates Model 610A Pulsed Light Source. The magnetic field profile of the EPR transients matched very well to the spectrum shown in Fig. 1*a*. Note that no reversible EPR signal could be observed by photolysis of solutions of the mixed unlinked components P and Q in conditions identical to those in Fig. 3 at 160K.

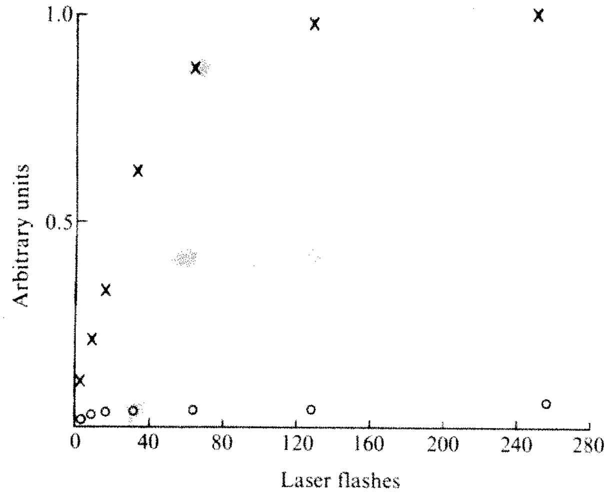

Fig. 2 Amplitude of the $g = 2.0$ EPR photolysis spectra induced by 620 nm photolysis at 140K in methanol followed by rapid cooling to 100K (where the spectra were measured as in Fig. 1) plotted as a function of the number of pulsed dye laser flashes with ~20 mJ per flash and a flashing rate of 1 Hz: for 2×10^{-3} M P–Q (×), and for meso-tetra(4-carboxyphenyl)porphyrin and benzoquinone each at 2×10^{-3} M (○).

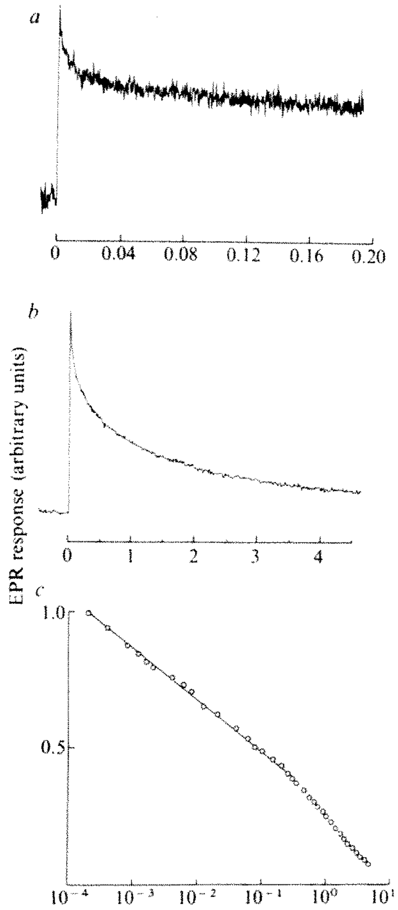

Fig. 3 Typical flash induced reversible EPR kinetics observed at 160K at the first derivative low field maximum of the spectrum of Fig. 1*a* for 2×10^{-3} M P–Q in methanol. The pulsed xenon light source was filtered by a Corning CS-262 filter with ~1 mJ per flash and the flashing rate was 0.1 Hz with 256 flashes accumulated in each kinetic trace and with EPR detection conditions of 0.5 mT modulation amplitude at 100 kHz and 5 mW microwave power at ~9.0 GHz: *a*, time domain of 200 ms; *b*, time domain of 5 s; *c*, logarithmic time domain up to 5 s.

Note that the observed electron-transfer kinetics (see Fig. 3) are approximately logarithmic in time over nearly four orders of magnitude, as shown in Fig. 3*c*. Ke *et al.*[22] have carried out a quantitative analysis of the charge recombination in photosystem I of green plants at low temperatures, and have shown that log *t* kinetics can be observed for an intramolecular electron-transfer process. They showed that the log *t* kinetics can be explained by assuming a rectangular distribution function for the distances separating the reacting species, or for some other parameter, such as the activation energy, for which the rate constant is an exponential function. On the basis of the restricted temperature domain for the observations of electron-transfer reversibility in the present work, we assume that we are observing a rectangular distribution in activation energies rather than a distribution of donor–acceptor distances leading to a temperature-independent electron tunnelling expression. Thus, at ~15° below the melting point of methanol, we assume that there is a range of activation energies for the electron to return to the primary donor arising from the relative motion of the donor and acceptor ends of P–Q at this temperature. This range of activation energies could arise from the various conformations of the hydrocarbon chain linking the quinone acceptor to the porphyrin donor.

We have used the route of Kong and Loach[2] to synthesize a donor–acceptor-molecule which, in certain conditions, exhibits reversible photochemical intramolecular electron transfer. Similar photochemical reactivity for P–Q has been observed at room temperature in acetronitrile (J.L.Y. Kong and P. A. Loach, personal communication). This system is an excellent model for the primary photochemical electron-transfer process in reaction centres of photosynthesis as both the confinement of donor and acceptor together and reversible photochemical electron transfer have been duplicated. This well-characterized model system should give us considerable insight into the mechanism of the *in vivo* reaction. We are continuing these studies with a view to stabilize the charge separation reaction and to study the effect of distance and molecular structure on the kinetics and mechanism of the intramolecular electron-transfer process.

This research was supported by a Strategic Grant in Energy from the Natural Sciences and Engineering Research Council of Canada. We thank Professor P. A. Loach for helpful discussions. This is publication no. 242 of the Photochemistry Unit.

Note added in proof: It has come to our attention that Dalton and Milgrom[23] have prepared porphyrins with attached quinones. However, they only report substantial fluorescence quenching.

Inhibition of photosynthesis in *Arabidopsis* mutants lacking leaf glutamate synthase activity

C. R. Somerville & W. L. Ogren*

Department of Agronomy, University of Illinois, Urbana, Illinois 61801

The CO_2 released in photorespiration is believed to result from a complex mitochondrial reaction in which glycine is converted to equimolar amounts of CO_2, NH_3 and the C-1 group of N^5,N^{10}-methylene-tetrahydrofolate[1-3]. Because photorespiratory CO_2 production may amount to 80 μmol per h per g fresh weight[4,5] the stoichiometry of the decarboxylation reaction indicates that NH_3 release from glycine exceeds primary NO_3^- reduction[6,7]. Leaf cells must therefore be capable of rapid NH_3 re-assimilation in photorespiratory conditions. It has been suggested[8] that NH_3 could be refixed directly into glutamate by mitochondrial glutamate dehydrogenase (GDH), utilizing the NADH generated during glycine decarboxylation[1,9,10]. This seems unlikely[11,12] because of the high K_m for NH_3 exhibited by GDH *in vitro*. An alternative suggestion[11,12], that photorespiratory NH_3 could be re-assimilated into glutamate by the sequential action of cytoplasmic glutamine synthetase (GS) and the chloroplast enzyme glutamate synthase (GOGAT)[13,14], is supported by circumstantial evidence from *in vitro* studies[12,15]. Here we provide direct evidence for such a pathway, based on the results of experiments with mutants of *Arabidopsis thaliana* (L.) Heynh which are deficient in leaf GOGAT activity.

These mutants are inviable in atmospheric conditions that permit photorespiration, but are fully viable and phenotypically indistinguishable from the wild type when maintained in an atmosphere that suppresses photorespiration[5] (1% CO_2 in air). This conditional lethal phenotype, shared by several other mutants with defects in photorespiratory carbon metabolism[16,17], provided the basis for the isolation of the mutants[16].

Leaf extracts of wild-type *Arabidopsis* contained levels of ferredoxin-dependent GOGAT activity (Table 1) comparable to that observed in other species[11,18]. NADH or NADPH (0.2 mM) were relatively ineffective as electron donors, supporting about 4% of the activity obtained with ferredoxin in otherwise identical assay conditions (results not presented). Leaf extracts of the mutant lines CS30, CS103 and CS113 contained less than 5% of the wild-type level of ferredoxin-dependent GOGAT activity (Table 1). Mixing of mutant and wild-type extracts resulted in additive activity, suggesting that the low activity of mutant extracts was not due to the presence of an inhibitor. The presence of normal levels of ribulose bisphosphate (RuBP) carboxylase activity in all extracts indicates that recovery of chloroplast enzymes was similar in each case. Extracts of the mutants also contained normal levels of activity for GDH, GS and several enzymes related to photorespiration (results not presented). Thus, the mutants seem to be specifically defective in the synthesis of functional leaf GOGAT.

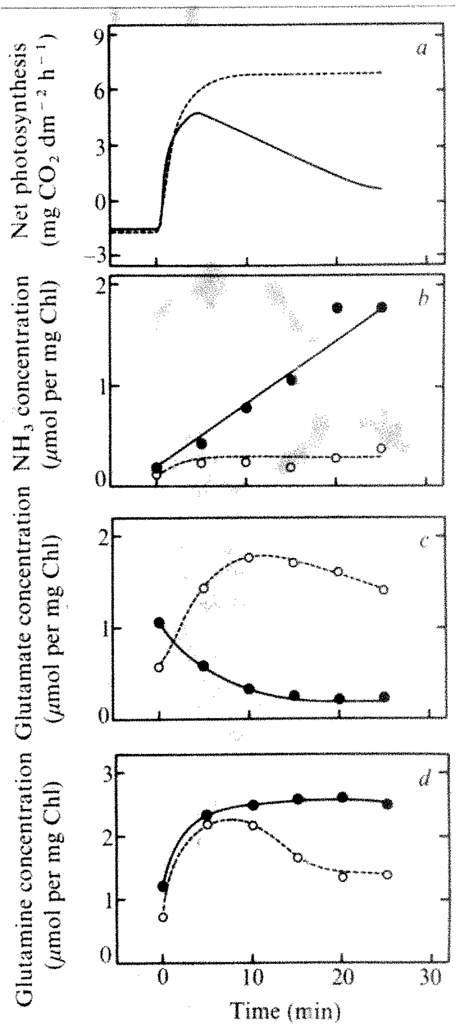

Fig. 1 Changes in *a*, photosynthesis rate and levels of *b*, NH_3; *c*, glutamate; and *d*, glutamine during illumination of wild-type and mutant *Arabidopsis* in photorespiratory conditions. Plants were grown in a 1% CO_2 atmosphere[16] on an artificial medium irrigated with a solution containing 2.5 mM KH_2PO_4 (pH 6.5), 5 mM KNO_3, 2 mM $Ca(NO_3)_2$, 2 mM $MgSO_4$ and micronutrients. The plants were placed in darkness in standard atmospheric conditions several hours before use to allow equilibration of metabolite pools. The plants were then placed in a photosynthesis chamber at 25 °C and continuously flushed with a gas stream (357 μl l^{-1} CO_2, 50% O_2, balance N_2) which exited through an infrared gas analyser. At time zero, the plants were illuminated at 300 μeinsteins m^{-2} s^{-1}. At the indicated intervals, plants were removed from the chamber and the leaf material ground in 2 ml chloroform/methanol/water (5:12:1). An additional 1.5 ml of chloroform and 1 ml of water was added, and the phases separated by centrifugation. Chlorophyll was determined on an aliquot of the organic phase. NH_3 was assayed in an aliquot of the aqueous phase by a colorimetric procedure[21]. Amino acid concentrations were determined with a Beckman (Model-119CL) amino acid analyser. Mutant and wild-type averaged 1.8 mg chlorophyll per g fresh weight. The response of the *gluS* mutant strain CS113 is indicated by the solid lines and symbols (●) and that of the wild type by broken lines and open symbols (○). Chl, chlorophyll.

A single nuclear mutation seems to be responsible for the enzyme deficiency and the conditional lethal phenotype. Reciprocal F_1 hybrids from crosses of wild-type and mutant lines showed the wild-type phenotype and had about 50% of wild-type GOGAT activity (Table 1). The mutant phenotype, scored as the onset of chlorosis after 4 days exposure to standard atmospheric conditions[15,16], segregated 3:1 (wild type:mutant) in the F_2 progeny resulting from crosses of wild-type × mutant. F_1 hybrids, obtained by crossing the mutants in all possible combinations, showed the mutant phenotype and were deficient in GOGAT activity (see for example CS103 × CS113, Table 1). The lack of complementation is evidence that the mutants carry defective alleles of the same gene, which we have designated *gluS*. Co-segregation of the mutant phenotype and enzyme deficiency was tested by first scoring the F_2 progeny from a wild-type × CS113 cross for the mutant phenotype at the rosette stage. The plants were revived by transfer to a CO_2-enriched environment for 2 weeks, then 64

randomly chosen plants were assayed individually for GOGAT. We observed an absolute correspondence between low enzyme activity and mutant phenotype.

The photosynthetic characteristics of the *gluS* mutants are similar to those of *Arabidopsis* mutants deficient in phosphoglycolate phosphatase[16] and serine–glyoxylate aminotransferase[17]. In atmospheric conditions that limit the oxygenation of RuBP[5] (1% CO_2 and 21% O_2 or 350 µl l^{-1} CO_2 and 2% O_2), photosynthesis (carbon dioxide fixation) continued indefinitely at wild-type rates (results not presented). However, in photorespiratory conditions (357 µl l^{-1} CO_2, 50% O_2, balance N_2), the photosynthesis rate of the mutants was initially similar to the wild type but rapidly declined to about 7% of that rate (Fig. 1*a*). The inhibition was reversible, for if the mutants were subsequently shifted to atmospheric conditions which suppressed photorespiration, photosynthesis was fully restored within about 30 min. Photosynthesis was also restored, irrespective of atmospheric conditions, by placing the plants in darkness for a similar period.

The inhibition of photosynthesis and reduced viability of the mutants in standard atmospheric conditions may be attributed to the accumulation of high levels of NH_3 during illumination in photorespiratory conditions (Fig. 2*b*). During 25 min of illumination in 357 µl l^{-1} CO_2, 50% O_2, balance N_2, free NH_3 in mutant CS113 increased 20-fold to a final intracellular concentration of about 3 mM. In the same conditions the concentration of NH_3 in the wild type remained below about 0.4 mM. The high concentration of NH_3 in the mutants would be expected to cause the observed inhibition of photosynthetic CO_2 fixation by uncoupling photophosphorylation[19]. In conditions of high CO_2 or low O_2, carbon flow through the photorespiratory pathway is negligible[5] so that little NH_3 is released from glycine. Photosynthesis and growth of the *gluS* mutants are therefore unimpaired in conditions which prevent photorespiration.

The accumulation of NH_3 in the *gluS* mutant in photorespiratory conditions is attributed to the virtual disappearance of free glutamate in leaf tissue (Fig. 1*c*), and thus the lack of an amino acceptor for re-assimilation of NH_3 by GS. The reduction in glutamate corresponds roughly to the increase in glutamine (Fig. 1*d*) as NH_3 is initially refixed by GS. The glutamine pool in the mutant then stabilizes because further synthesis is prevented by the lack of glutamate, and the GOGAT deficiency prevents conversion of glutamine to glutamate. The observation that NH_3 is not rapidly refixed into glutamate verifies the suggested[11] low *in vivo* activity of GDH in an assimilatory direction and confirms the importance of the GS/GOGAT pathway in the re-assimilation of photorespiratory NH_3[11,12].

Table 1 Glutamate synthase activity in extracts of wild-type and mutant lines of *Arabidopsis*

Strain	Glutamate synthase activity*	RuBP carboxylase activity*
Wild type	5.3	30.4
CS30	0.2	29.7
CS103	0.2	29.7
CS113	0.1	30.7
F_1 (W1 × CS113)	2.8	31.1
F_1 (CS103 × CS113)	0.3	31.5
Mixture†	2.8	30.0

Extracts were prepared by grinding leaf material in 50 mM KH_2PO_4 (*p*H 7.2), 12.5 mM *β*-mercaptoethanol, 0.5 mM EDTA and 0.5 mM EGTA. The extracts were centrifuged (30,000*g* for 15 min), passed through a column of Sephadex G-75, and dialysed against the same buffer for 12 h. Glutamate synthase activity was determined by measuring the formation of ^{14}C-glutamate from labelled 2-oxoglutarate. The complete 500 µl assay mixture[18] contained: 25 µmol KH_2PO_4 (*p*H 7.2), 6.2 µmol *β*-mercaptoethanol, 0.25 µmol EDTA, 0.25 µmol EGTA, 5 µmol aminooxyacetate, 1 µmol L-glutamine, 1 µmol ^{14}C-oxoglutarate (0.5 µCi µmol^{-1}), 50 µg spinach ferredoxin (Sigma), 0.8 mg $Na_2S_2O_4$, 0.8 mg $NaHCO_3$ and 60–70 µg of extract protein. The reaction was initiated by the addition of the dithionite and bicarbonate and terminated after 10 min at 24 °C by the addition of 60 µl of 3% H_2O_2. Product formation was measured by liquid scintillation counting following fractionation of the labelled compounds by ion exchange chromatography. Control reactions, lacking reductant, produced 1% of the d.p.m. obtained in the complete reaction mixture. RuBP carboxylase activity was measured as described previously[16]. Protein was determined by a dye binding assay[20].

*Enzyme activity is expressed as µmoles of product per h per mg protein.

†Equal volumes of wild-type and mutant (CS113) extract were mixed immediately before assay.

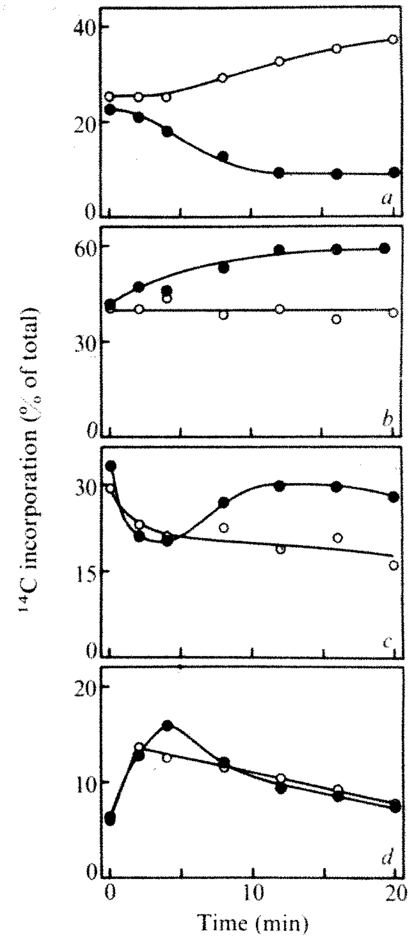

Fig. 2 Products of $^{14}CO_2$ assimilation by wild-type and mutant *Arabidopsis*. Intact plants were placed in a photosynthesis chamber and flushed with a humidified gas stream containing 350 µl l^{-1} CO_2, 21% O_2, balance N_2. At time zero the plants were illuminated (300 µeinsteins m^{-2} s^{-1}). At the indicated intervals the system was closed and $^{14}CO_2$ introduced. After 2 min the plants were quickly (3–5 s) removed to liquid nitrogen. The labelled products were extracted and separated as described previously[16]. The CO_2 concentration in the chamber remained between 300 and 350 µl l^{-1} during the period of incorporation. *a*, Basic fraction (amino acids); *b*, acid-1 fraction (organic acids and sugar monophosphates); *c*, combined acid-2 and acid-3 fractions (mostly sugar diphosphates); *d*, neutral fraction (sugars). The response of the mutant strain CS113 is indicated by solid symbols and that of the wild type by open symbols.

The low intracellular concentration of glutamate caused a plethora of secondary metabolic aberrations evident from the pattern of $^{14}CO_2$ incorporation into the products of photosynthesis (Fig. 2). In this experiment, plants were allowed to photosynthesize in standard atmospheric conditions for various periods, then given a short (2 min) pulse of $^{14}CO_2$ and the photosynthetic products were analysed. During the first few minutes, the labelling pattern of mutant and wild type were essentially indistinguishable. However, after several minutes of photosynthesis, the proportion of label in the amino acid fraction of the mutant dropped considerably (Fig. 2*a*). This is attributed to reduced availability of glutamate as an amino donor for the synthesis of glycine from glyoxylate. As a result, the intracellular concentration of serine declined to about one-fifth of the wild-type level (data not presented) as serine was utilized, by way of serine–glyoxylate aminotransferase, for glycine synthesis.

The central role of glutamate in cellular metabolism precludes a succinct description of the manifold effects resulting from glutamate depletion. In this respect it is not surprising that the mutants are inviable in normal atmospheric conditions. More surprising, perhaps, is the normal growth of the mutants in non-photorespiratory conditions. This implies that the plant does not require leaf GOGAT activity for NH_3 assimilation from primary nitrate reduction. Rather, the sole requisite function of leaf GOGAT seems to be the re-assimilation of photorespiratory NH_3.

We thank R. H. Hageman for growth chamber facilities, J. M. Widholm for amino acid analyses, and M. E. Hageman for technical assistance. This research was supported in part by grant No. 5901-0410-9-0341-0 from the USDA Competitive Research Grants Office.

Regulation of wound ethylene synthesis in plants

Thomas Boller* & Hans Kende†‡

*Botanisches Institut der Universität Basel, 4056 Basel, Switzerland
†Institut für Allgemeine Botanik, Eidgenössische Technische Hochschule, 8092 Zürich, Switzerland

Ethylene is produced by plants at specific stages of their life cycle and is involved in the regulation of many developmental processes, such as fruit ripening, flower fading, leaf abscission, growth in aquatic plants and initiation of flowering in bromeliads[1,2]. Ethylene is also formed when plants are subjected to stress by, for example, wounding, noxious chemicals, drought or waterlogging[1–3]. In both cases the biosynthetic pathway begins with methionine[1–5]. It proceeds to ethylene by way of *S*-adenosylmethionine (SAM) and 1-aminocyclopropane-1-carboxylic acid (ACC), a recently discovered intermediate[6,7], in ripening fruit[7,8] and auxin-treated pea stem sections[9,10]. We now report that wound-induced ethylene synthesis also proceeds by way of ACC and that it is regulated at the level of the ACC-forming enzyme (ACC synthase). Wounding of pericarp tissue of tomato fruit (*Lycopersicon esculentum* Mill.) results in rapid enhancement of the activity of ACC synthase and, consequently, in a greatly increased rate of ACC synthesis.

Cut tomato fruit evolves large amounts of wound ethylene[11–13]. We found that disks excised from the pericarp of green tomatoes produced relatively little ethylene in response to isolation (Table 1), but when each disk was further cut into 12 sectors (wounding), there was a substantial increase in ethylene production. In the same tissue, production of ACC increased even more rapidly as a result of wounding (Table 1). Aminoethoxyvinylglycine (AVG) is a potent inhibitor of ethylene biosynthesis[2] and of ACC synthase from tomato fruit[8]. When sectors of pericarp were incubated on 0.1 mM AVG after wounding, ethylene production was inhibited 89% after the first hour (2.07 nmol per g per h in control compared with 0.23 nmol per g per h in AVG-treated sectors).

In further experiments, we determined the activity of ACC synthase at short intervals after wounding of pericarp tissue and correlated the results with the time course of ACC accumulation and ethylene production. The activity of ACC synthase, as determined *in vitro*, was low in freshly cut sectors, tripled within 20 min and increased 10-fold within 40 min (Fig. 1), remaining fairly constant thereafter. The amount of ACC in the tissue increased approximately linearly after a lag of about 20 min; thus, the accumulation rate of ACC *in vivo* essentially paralleled the activity of ACC synthase *in vitro* (Fig. 1). The activity of ACC synthase was only about 20% of that expected from the rate of *in vivo* ACC synthesis, and we have been unable to discover where the loss occurred. Finally, the rate of ethylene formation, calculated from the total formed after wounding, increased after a lag of 30 min for at least 100 min and was proportional to the amount of ACC in the tissue.

Table 1 Effect of wounding on ethylene and ACC production

		Ethylene		ACC	
Incubation time (h)	Treatment	nmol per g	nmol per g per h	nmol per g	nmol per g per h
0		—	—	1.27	—
1	Intact	0.12	0.12	3.81	2.54
1	Wounded	0.72	0.72	8.73	7.46
2	Intact	0.25	0.13	3.77	—
2	Wounded	3.04	2.32	18.40	9.67

Disks of 11.5 mm diameter were cut from the pericarp of glasshouse-grown green tomato fruit (cv. Linda) and trimmed to 3 mm by removing extra tissue that formerly faced the inside of the fruit. They were incubated in pairs, epidermis facing upwards, on moist filter paper in 25-ml serum vials sealed with rubber stoppers at 28 °C. Disks were wounded by cutting each into 12 equal sectors. Ethylene was determined by gas chromatography[15]. ACC was extracted with ice-cold ethanol (4 ml for two disks), and insoluble residue was removed by centrifugation. The supernatant was taken to dryness and the residue was redissolved in 1 ml water. Of this, 0.1 ml was tested in the ACC assay of Lizada and Yang[16], based on the liberation of ethylene from ACC in alkaline solution containing Hg^{2+} and NaOCl. We had verified that all material in the crude ethanolic extract which released ethylene in the ACC assay of Lizada and Yang co-chromatographed with authentic ACC on cellulose thin-layer plates (solvent 2 of Boller *et al.*[8]).

The tissue already had the capacity to liberate ethylene from ACC during the lag phase, as reflected by the high rate of ethylene production in freshly cut sectors incubated on 10 mM ACC (Fig. 2). The rate of ethylene production during the first 10 min after cutting was 0.66 nmol per g per h and increased to a steady rate of about 2 nmol per g per h within 80 min. The maximum rate of ethylene formation was reached faster in tissue on 10 mM ACC than in that on 1 mM ACC. Attainment of the maximum rate of conversion of ACC to ethylene was probably delayed because of the time required to take up ACC into the pericarp sectors. The maximum rate of ACC-dependent ethylene formation might have been limited by

saturation of an ACC uptake system and/or by saturation of the ethylene-forming system.

Ethylene synthesis after wounding, as in other situations, is inhibited by cycloheximide[5,14]. When sectors of pericarp were incubated on cycloheximide (25 µg ml^{-1}) for 2 h, the tissue produced 86% less ethylene and contained 84% less ACC and 96% less ACC synthase activity than untreated sectors.

These results indicate that ethylene is produced from ACC in tomato pericarp tissue in response to wounding. Such ethylene formation seems to be induced through rapid enhancement of ACC synthase activity. Because cycloheximide inhibits the development of this enzyme activity, it is likely, though not proven, that ACC synthase is newly formed rather than activated when the tissue is wounded. The last step in ethylene formation—conversion of ACC to ethylene—does not seem to be regulated in wounded tissue. This follows from two kinds of experiments. First, wounded pericarp disks already had the capacity to convert added ACC to ethylene during the lag phase of wound-induced ethylene synthesis. Second, when no ACC was added, the rate of ethylene formation was proportional to the level of endogenous ACC throughout the experiment. This also indicates that the system converting ACC to ethylene is not saturated at the concentrations of ACC reached in the wounded tissue.

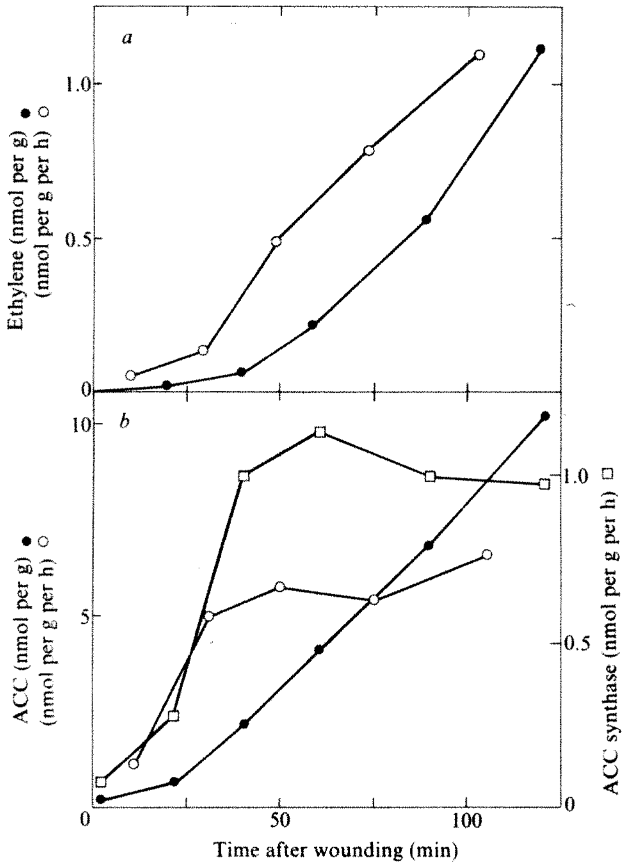

Fig. 1 Ethylene evolution, ACC content and ACC synthase activity in wounded pericarp disks from green tomato fruit. *a*, Ethylene production. From each of two freshly harvested tomato fruits (cv. Moneymaker), seven disks were cut. Each was wounded immediately by cutting into 12 equal sectors. Pairs of wounded disks, one from each fruit, were incubated for different times on moist filter paper in sealed 25-ml serum vials. After incubation, ethylene was determined[1,5], and the tissue was frozen in liquid N_2. Data are mean values from three identically incubated samples. The rate of ethylene production was calculated for each time interval of the experiment. *b*, ACC content and activity of ACC synthase. The frozen sectors from *a* (six disks, 1.8 g fresh weight total) were combined, pulverized in liquid N_2 with pestle and mortar and extracted in 3 ml 0.1 M K-HEPES buffer, *p*H 8, containing 4 mM dithiothreitol (DTT) and 0.4 µM pyridoxal phosphate. After centrifugation (10 min at 10,000*g*), two 0.1-ml samples of supernatant solution were used directly for ACC determination[16]. The rate of increase in ACC content was derived for each time interval of the experiment. The true rates of ACC formation were probably 10% higher if all ethylene formed was derived from ACC. Centrifuged extract (2 ml) was desalted on a column of Sephadex G-50 (2 × 6 cm) with 2 mM K-HEPES buffer, *p*H 8, containing 0.1 mM DTT and 0.2 µM pyridoxal phosphate as eluting buffer, and the eluted protein was used to determine ACC synthase activity with 50 µM SAM as substrate[8]. Enzymatically formed ACC was determined according to Lizada and Yang[16].

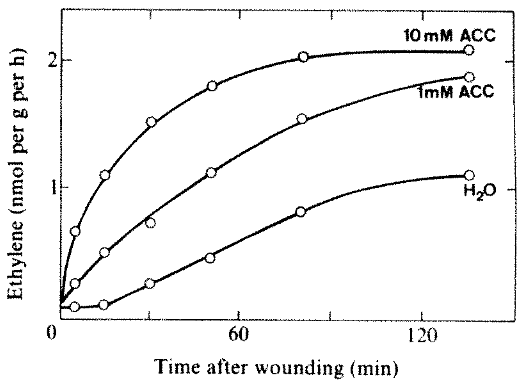

Fig. 2 Rate of ethylene formation in wounded pericarp incubated on ACC. Freshly cut disks of pericarp from a single tomato (cv. Linda) were cut into 12 sectors each, and the sectors from two disks were incubated in sealed 25-ml serum vials on filter paper wetted with water or 1 mM or 10 mM solutions of ACC. Ethylene was determined by gas chromatography[15] after 10, 20, 40, 60, 100 and 170 min. From these data, the mean rate of ethylene formation was calculated for each time interval. Control vials containing ACC solutions without tissue produced less than 2 pmol h^{-1} ethylene.

The regulation of wound ethylene synthesis in tomato pericarp resembles that of ethylene synthesis in senescing tomatoes. In the latter case, the activity of ACC synthase and the concentration of ACC increase during maturation of the fruit, when ethylene formation is initiated[8]. Similarly, auxin at high concentrations seems to induce ethylene synthesis in etiolated pea epicotyls by enhancing ACC synthase activity[9]. It remains to be seen whether developmental, stress and hormonal stimuli all regulate the activity of ACC synthase through the same mechanism or whether different modes of control are exerted to modulate the activity of this important enzyme in ethylene synthesis.

Heterozygosity at enzyme loci and morphological variation

Paul Handford*

Rockefeller University, New York City 10021

*Present address: Zoology Department, University of Western Ontario, London, Canada N6A 5B7

Two recent reports[1,2] have concerned the relationship between genic heterozygosity, as indicated by electrophoretically detected enzyme loci, and an individual's tendency to depart from the mean on a variety of morphological traits. Using different methods to assess differences in morphological variances between homozygote and heterozygote classes, both conclude that homozygotes show a significantly higher level of morphological variation. These conclusions are important in that they seem to extend the phenomenon from studies on manipulated stocks of organisms[3] to variation in natural populations. As Eanes[2] points out, it is necessary to determine the generality of this result. Both these studies[1,2] consider poikilotherm animals (a fish and an insect), so it would be particularly interesting to look for the relationship in homoiotherms. As a contribution to this end, I present here the results (Table 1) of an analysis of variation in the Rufous-collared sparrow, *Zonotrichia capensis*[4]. I found no difference in levels of variation either between the homozygote and heterozygote classes or between classes of individuals heterozygous at different numbers of loci. My results thus suggest a difference between homoiotherms and poikilotherms in this phenomenon.

My data concern variation at four enzyme loci (mannose-6-phosphate dehydrogenase, M6PI; 6-phosphogluconate dehydrogenase, 6-PGD; glucose-6-phosphate dehydrogenase, G6PD and α-glycerophosphate dehydrogenase, α-GPD) and in 11 metrical characters (tarsus, tail length and three bill, four toe and two wing measures). As the sexes differ significantly on several variables they are considered separately.

There are some difficulties in comparing levels of variation among population samples or subsamples. These and some possible solutions are reviewed by Van Valen[5]. In the univariate case, one customarily compares sample variances. Additional variables may justifiably be considered independently, provided there is low correlation between them. This is the approach adopted by Eanes[2], considering variation in two wing characters in the butterfly *Danaus plexippus*. It is unwise, however, to test the null hypothesis, σ^2 homozygotes $= \sigma^2$ heterozygotes, by use of an F-test. The F-distribution is rather sensitive to deviations from normality of the measured distributions, which can give spuriously high values of F. The simplest way to test such a null hypothesis is that given by Levene[6]. One constructs a new variable $y_i = |x_i - \bar{x}|$ for each case i and tests the samples for differences in y by means of a t-test.

In most circumstances it is probably best to consider variation in several characters collectively, by some multivariate method, rather than separately, as even small degrees of correlation between variables introduce potential bias through, in effect, making the same test several times. This is particularly relevant when using the sign test[7] to assess a hypothesis. Mitton[1] has used two techniques for extracting a single measure of variability from his seven meristic characters: computing the mean coefficient of variation, c.v., and the determinant of the variance–covariance matrices, $|\Sigma|$. These are compared among the homozygote and heterozygote classes, and the results tested by the sign test. In fact, matrices may be tested for homogeneity of dispersion, and a probability ascribed[8], but one should note some undesirable properties of $|\Sigma|$ as a statistic of multivariate variability. If even one of the characters used in computing $|\Sigma|$ has a very low variance, then $|\Sigma|$ becomes very small regardless of variation in other characters. Small differences in such very small numbers will have large effects on the ratios between them, and so interpretation of these ratios becomes difficult and potentially misleading. Similarly, any degree of correlation between variables, which is almost inevitable when using more than three or four variables, reduces $|\Sigma|$ to very small values. Table 1 shows the results of applying a multivariate test for matrix homogeneity. Three of five tests among males are significant, but probably spurious given the very tiny values of $|\Sigma|$ (of the order of 10^{-20}). Van Valen[5] also discusses the use of principal components in this kind of analysis. This approach eliminates the problem of correlated variables, but exaggerates the problem of low variance in one or more variables, as the last principal components to be extracted

Table 1 Comparison of variability in morphological characters among genetic subgroups in samples of Rufous-collared sparrows, *Zonotrichia capensis*

Matrix homogeneity, P	—		0.000†		—		—		0.585 NS	

Heterozygosity is the number of loci, of four, at which an individual is heterozygous. In males, Low = 0–1 loci; in females, Low = 0 loci. Different criteria were used to make sample sizes comparable. Σs^2 is the simple sum of all character variances within given subgroups. Hom/Het is the ratio $\Sigma s^2_{\text{hom}}/\Sigma s^2_{\text{het}}$; significance level tested by Levene's method (see text). Matrix homogeneity is the P level given by a multivariate test for the homogeneity of the two variance–covariance matrices. Where no value is given, as in the females, this is because the test could not be carried out due to matrix singularity caused by there being more morphological variables than cases in the heterozygote class. NS, Not significant. All analyses performed on ln-transformed measurements.

0028–0836/80/290261–02$01.00

usually account for a very small fraction of the total variance in the sample. There are no objective methods available appropriate to the present purpose, for setting a level for exclusion of these later components, and in any case this loses information.

By analogy with the univariate case, Van Valen recommends the use of total sample variance for j variables, $\Sigma_j s_j^2$. This eliminates problems of correlation and low variances by making them irrelevant. If the variables are log-transformed, scale effects are eliminated as is the need for some multivariate c.v. Differences in Σs^2 may again be tested for significance by an extension of Levene's test: $y_i = (\Sigma_j (x_{ij} - \bar{x}_j)^2)^{\frac{1}{2}}$, again using a t-test for differences in $\bar{y}$. The results of such an analysis of my data fail to show significantly different levels of variation either between the homozygote and heterozygote classes considered separately, or between classes of individuals heterozygous at different numbers of loci. Because the studies of Mitton[1] and Eanes[2] use other methods of analysis, it is not possible to make a close comparison between their results and mine. However, some points are worth mentioning. First, the absence of a significant result in this single sample from one species does not, of course, demonstrate the absence of the effect. What it does is raise the possibility of a difference between homoiotherms and poikilotherms in this regard, one which is consistent with other considerations about development and adaptation, as indicated below. It has been widely suggested that development of homoiotherms is more resilient to environmental insult than that of poikilotherms and invertebrates, and that their growth rates and final size are more determinate[9]. Again, genetic enzyme polymorphism among vertebrates as a whole is lower than among invertebrates, and homoiotherms are slightly, though non-significantly, less variable than are poikilotherm vertebrates[10]. This perhaps reflects different tactics of adaptation among very different kinds of organisms, and suggests the possibility that heterozygosity and polymorphism may have quite different significance in organisms with widely different organization and ecological situations[11]. This specifically suggests a relationship between levels of genic heterozygosity, body size and mobility which is consistent with predictions from Levins' theory of adaptive strategies in relation to environmental grain[12]. Thus, vertebrates which are typically larger and more mobile, so experiencing the environment in a more fine-grained fashion, exhibit lower levels of genic polymorphism. There are other studies considering variability and heterozygosity (at the population level), but these also consider variation in poikilotherms and invertebrates[13,14]. Clearly, there is a need for investigation of variation in a wider range of taxa, particularly the higher vertebrates, before we can make generalizations about the relationship between genic heterozygosity and morphological variability.

Vitamin D_3 metabolites and PTH synergistically stimulate bone formation of chick embryonic femur *in vitro*

Bone remodelling depends on a balance between formation and resorption. Little is known of the biological factors involved in bone formation, whereas there is much evidence that physiological factors, such as parathyroid hormone (PTH) and active metabolites of vitamin D_3, influence resorption. Cells responsible for osteogenesis and osteoclasis occur in close proximity, suggesting that both might be controlled by the same physiological factors in the micro-environment of the body fluid. To clarify the factors stimulating bone formation or accelerating osteogenic cell activity, we have examined the effects of vitamin D_3 metabolites and PTH on bone formation *in vitro*. We report here that combinations of those metabolites especially 1α,25-$(OH)_2D_3$ and 24R,25-$(OH)_2D_3$, directly stimulate calcification on bone synergistically with PTH.

We used the culture system described before[1,2]. Femora of 9-day-old chick embryos were obtained by removing adherent soft tissues under a dissecting microscope. Each femur was transferred to a roller tube containing 1.5 ml of medium. To allow for differences between embryos, the bones from one side of an embryo were cultivated in control medium and those from the opposite side of the same embryo in experimental medium. Basal medium was a mixture of BGJb-HW2 (ref. 3) and 11-day-old chick embryo extract (CEE), (9:1). PTH ($1\ \mathrm{U\,ml^{-1}}$), 1α,25-$(OH)_2D_3$ (0.02 and $2.0\ \mathrm{ng\,ml^{-1}}$), 24R,25-$(OH)_2D_3$ (0.5 and $50.0\ \mathrm{ng\,ml^{-1}}$) and 25-OH-$D_3$ ($2.5\ \mathrm{ng\,ml^{-1}}$) were added to the mixture, singly or in combination, to examine their effect on calcification. Roller tubes were incubated at 37 °C for 6 days, rotating 10 times per hour in a roller drum which held them at an angle of 5°. The medium was replaced every other day. At the end of cultivation, the calcium of most pair-mate bones was determined and

Values represent mean ± s.e.m. The amount of calcium deposited in the femur was determined by OPCP method[15]. Control femur was cultivated in the basal medium plus PTH.

*The ratio of calcium levels in treated femora to pair-mate control bones.

†$P < 0.005$.

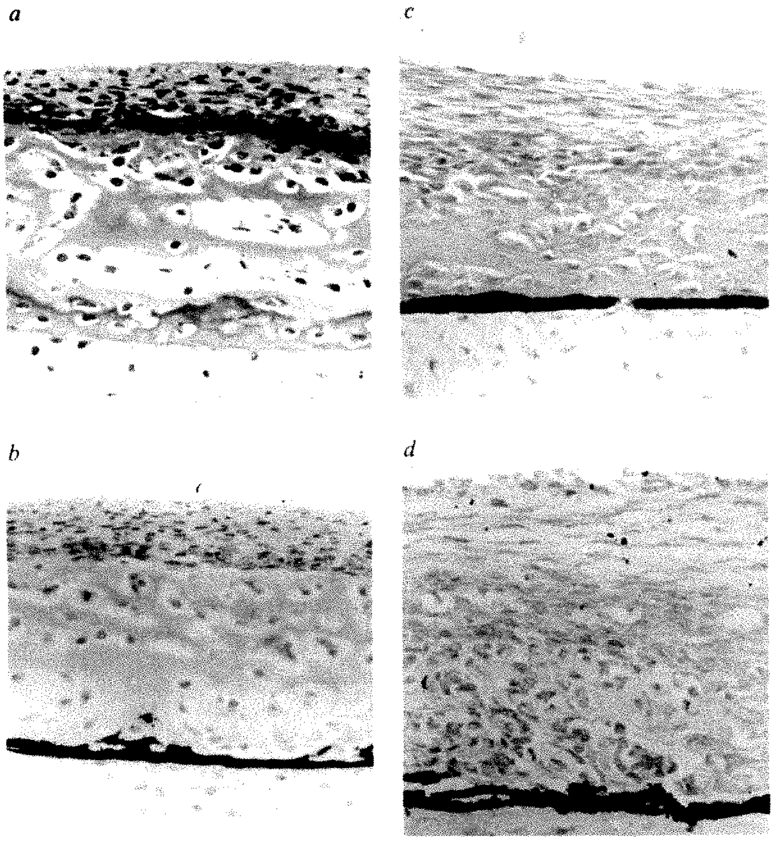

Fig. 1 Diaphyses of the femora from 9-day chick embryos after 6 days cultivation. *a*, Bone cultured in the medium CEE:BGJb-HW2 (1:9) (haematoxylin and eosin stain); *b*, the same specimen as in *a* (von Kossa's stain); *c*, bone cultured in medium containing the three metabolites of vitamin D_3 (von Kossa's stain); *d*, bone cultured in medium containing PTH (von Kossa's stain); *e*, bone cultured in medium containing PTH and the three metabolites of vitamin D_3 (haemotoxylin and eosin stain); *f*, the same specimen as in *e* (von Kossa's stain. All ×400.

histological development of residual pairs was examined microscopically with haematoxylin–eosin and von Kossa's stain.

Femora cultured in basal medium or in medium with vitamin D_3 metabolite(s) formed only osteoid tissue with no calcification (Fig. 1*a*–*c*). In medium containing PTH alone, mineralization scarcely occurred (Fig. 1*d*), although the bone elongated significantly[4]. In medium plus PTH and three kinds of vitamin D_3 metabolites, however, the diaphyseal cortex of the bone became heavily calcified (Fig. 1*e*, *f*).

The amount of calcium deposited in the femur treated with all three vitamin D_3 metabolites in the presence of PTH was 2.07 times greater than that in control bone treated with PTH alone. Similarly, combined treatment with 1α,25-$(OH)_2D_3$ and 24R,25-$(OH)_2D_3$ in the presence of PTH gave a value of 2.04 for that calcification ratio. When combined with 25-OH-D_3 in the presence of PTH, however, neither 1α-25-$(OH)_2D_3$ nor 24R,25-$(OH)_2D_3$ stimulated calcium deposition, the calcification ratio being 1.05 and 1.15 (Table 1). Moreover, no single treatment with 1α,25-$(OH)_2D_3$ or 24R,25-$(OH)_2D_3$ in the presence of PTH affected calcification, even at high concentrations (Table 1). 1α,25-$(OH)_2D_3$, when combined with 24R,25-$(OH)_2D_3$, could be replaced by the synthetic vitamin D_3 analogue 1α,24R-$(OH)_2D_3$ (ratio 1.93), although the synthetic vitamin alone with added PTH did not enhance calcification (ratio 1.03). Bone growth in medium plus PTH alone was 1.04 times that in medium alone, and in medium plus three kinds of vitamin D_3 metabolite the ratio was 1.17 (Table 2). Treatment with any one of these vitamin D_3 metabolites alone did not affect calcification.

Many observations made *in vivo* have suggested that vitamin D_3 metabolites could be involved in bone mineralization[5]. Our results show that these metabolites, especially the combination of 1α,25-$(OH)_2D_3$ and 24R,25-$(OH)_2D_3$, stimulate bone formation under the synergistic influence of PTH. These can activate bone resorption[6,7], and so our result suggested that bone could be remodelled successfully by simultaneous activation of both osteoclastic and osteogenic processes.

1α,25-$(OH)_2D_3$ is the most active metabolite of vitamin D_3 for many biological processes[8], and we have now demonstrated that 24R,25-$(OH)_2D_3$ is important for ossification, with mineralization proceeding only in the presence of both metabolites. This supports *in vivo* studies which suggested that 24R,25-$(OH)_2D_3$ may be active in bone

Table 2 Calcium level of 9-day-old chick embryonic femur after 6 days cultivation using basal medium as control

†PTH concentration was 1 unit ml^{-1}.

formation[9,10], possibly in combination with 1α,25-$(OH)_2D_3$ (ref. 11).

The role of PTH in bone formation, however, has been controversial, with some studies suggesting that it inhibits bone collagen synthesis[12], and other evidence indicating that it increases bone formation[13,14]. Our results demonstrate that PTH is essential for the calcification of bone. We are now studying the role of CEE and the dose–response relationship of PTH and vitamin D_3 metabolites in stimulating bone formation *in vitro*.

Leukotriene B, a potent chemokinetic and aggregating substance released from polymorphonuclear leukocytes

A. W. Ford-Hutchinson, M. A. Bray, M. V. Doig, M. E. Shipley & M. J. H. Smith

Biochemical Pharmacology Research Unit, Department of Chemical Pathology, King's College Hospital Medical School, Denmark Hill, London SE5 8RX, UK.

Arachidonic acid is metabolised either by cyclooxygenases to produce prostaglandins and thromboxanes or by lipoxygenases to produce mono-, di- and trihydroxyeicosatetraenoic acids (HETEs). Polymorphonuclear leukocytes (PMNs) release HETEs, including mono- and dihydroxy fatty acids, when exposed to stimuli such as the calcium ionophore A23187 (refs 1, 2). The mono-HETEs are assumed to be of particular importance with respect to effects on leukocyte function because they have been shown to possess both chemotactic and chemokinetic activities towards PMNs and eosinophils[3,4]. However, we have now shown that the chemokinetic and aggregating activities released from rat and human PMNs exposed to ionophore A23187 (ref. 5) are not due to the release of mono-HETEs but to that of 5,12-di-HETE (leukotriene B). This compound is active over the concentration range 10 pg ml^{-1} to 5 ng ml^{-1}.

Rat peritoneal or human peripheral PMNs, when exposed to ionophore A23187, release substances into the surrounding media which cause the aggregation and chemokinesis of other PMN suspensions[5]. The release of the activities was prevented by drugs known to inhibit lipoxygenase pathways of arachidonic acid (AA) metabolism.

The aggregating and chemokinetic activities released following exposure of human PMNs to ionophore A23187 were extracted into diethyl ether after acidification of the media. Both activities could be recovered from a silicic acid column following elution with ethyl acetate and >95% of the biological activity was recovered in a single UV absorbent peak following HPLC (see Fig. 1). Identical results were obtained with rat PMNs. This peak had a retention time identical to that previously reported for leukotriene B (5, 12-dihydroxy 6,8,10,14-eicosatetraenoic acid)[1]. Ultraviolet spectra were obtained for the methyl ester of the compound which showed three major bands ($\varepsilon_{\mathrm{mx}}^{\mathrm{MeOH}}$ 262±2, 271±2 and 282±2 nm), indicating the presence of three conjugated double bonds[6]. Gas–liquid chromatographic analysis of the active fraction showed a major peak with a C value of 23.6. The mass spectrum of this compound is shown in Fig. 2 and the substance was identified as leukotriene B by comparison with the spectra previously reported for this compound[7].

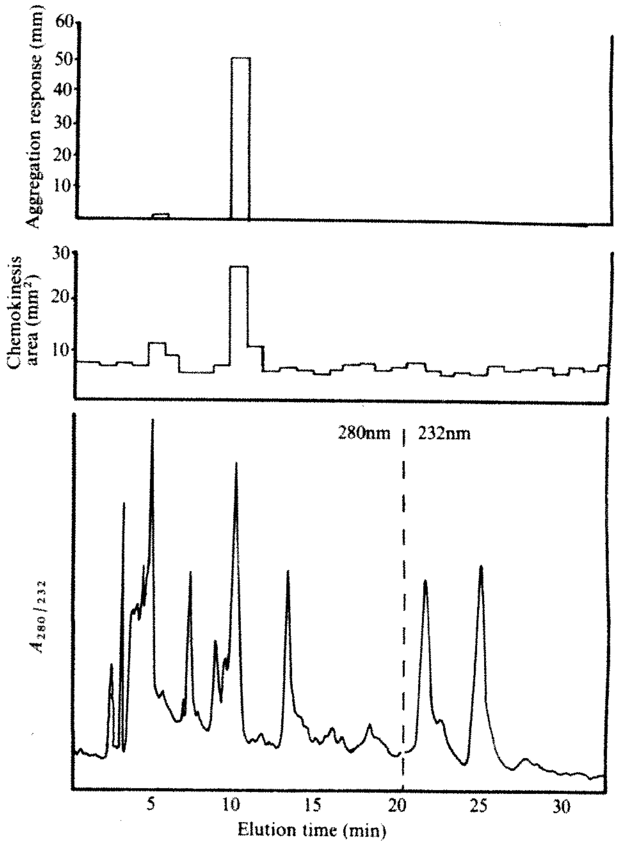

Fig. 1 Separation by HPLC of lipoxygenase products released by human PMNs exposed to 10 μM ionophore A23187 for 4 min as previously described[5]. The reaction was terminated by the addition of 1.5 vol. methanol, the cells were removed by centrifugation and the supernatant was acidified to *p*H 3.5 and extracted twice with diethyl ether. The ether extracts were washed once with water and dried under vacuum. The residue was dissolved in diethyl ether/hexane (20:80) and applied to a silicic acid column equilibrated with the same solvent[1]. The column was subsequently eluted with ethyl acetate, the ethyl acetate was removed under vacuum and the residue dissolved in 50 μl methanol for application to a reverse phase HPLC column (4.6 × 250 mm packed with Spherisorb 5ODS eluted at a flow rate of 1 ml min^{-1} with a mixture of methanol/water (75:25, v/v) plus acetic acid (0.01%)[1]. HPLC columns were calibrated with a mixture of dimethylphthalate, di-*n*-butylphthalate and pyrene using as a solvent methanol/water (85:15, v/v). The elution times for 15-, 12- and 5-HETE were 24, 26.5 and 31.5 min, respectively. HPLC fractions were dried under vacuum and resuspended in medium for assay as below. Chemokinetic activity towards human PMNs was assayed in an agarose microdroplet assay[11], the results being expressed as the increase in the area of migration when compared with that of cells in the presence of medium alone. Aggregation of rat PMNs was assessed by nephelometry in a Payton aggregometer, the results being expressed as the change in transmittance as measured (in mm) on the recorder[12].

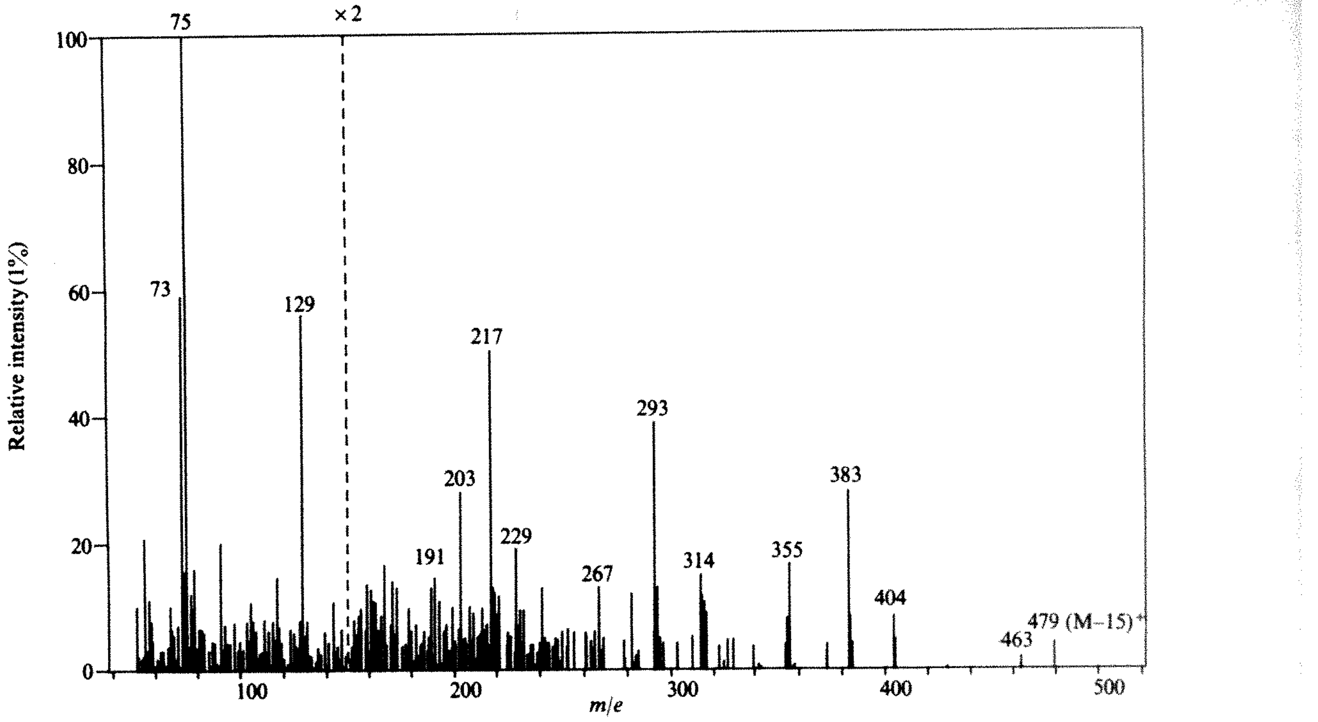

Fig. 2 Mass spectrum of the trimethylsilyl derivative of the methylester of leukotriene B obtained from rat peritoneal PMNs after incubation with A23187. The active fraction obtained from the HPLC column was methylated with diazomethane and further derivatized to the trimethylsilyl ether with bis (trimethylsilyl) trifluoroacetamide. The sample was chromatographed on a 20 m SE54 WCOT column coupled to a VG Micromass 16F mass spectrometer. Spectra were put on to a data system in the following conditions; electron energy 70 eV, trap current 180 μA and source temperature 240 °C. Peaks at *m/e* 281 and 355 represent bleed peaks from the column.

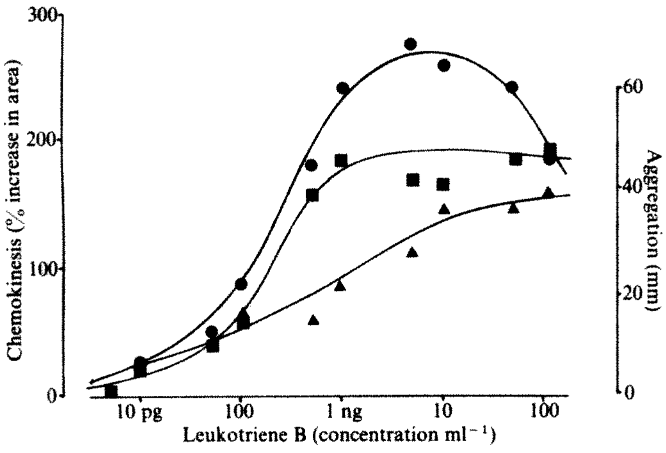

Fig. 3 The effects of leukotriene B on the chemokinesis of human PMNs (●) and the aggregation of rat (■) and human (▲) PMNs. Leukotriene B was prepared from 10^9 rat peritoneal PMNs incubated with calcium ionophore A23187 and was purified by ether extraction, silicic acid chromatography and HPLC and tested in aggregation and chemokinesis assays as described in Fig. 1 legend. The concentration of leukotriene B was determined using an $\varepsilon_{281}^{\mathrm{MeOH}}$ of 39,500 (ref. 6), 9 μg being recovered from 10^9 cells. Each point represents two separate experiments carried out on separate days ($n = 8$–16, standard errors were always $< 10\%$ of the mean).

Figure 3 shows the effects of leukotriene B on the chemokinesis of human PMNs and the aggregation of rat and human PMNs. Dose-related effects were seen over the range 10 pg ml^{-1} to 5 ng ml^{-1}, ED$_{50}$ values for human PMN chemokinesis, human PMN aggregation and rat PMN aggregation being 250, 560 and 170 pg ml^{-1}, respectively.

These results show that leukotriene B exhibits comparable activity on a molar basis to that observed for the complement peptide C5a and the synthetic peptide fMet-Leu-Phe. Furthermore, leukotriene B seems to be 100–1,000 times more active as a chemokinetic agent than the mono-HETEs[3,8] and in the present experiments no aggregating or chemokinetic activity was recovered in the fractions where the mono-HETEs would be expected to elute.

Release of lipoxygenase products, including leukotriene B, may be a common feature of exposure of PMNs to a variety of inflammatory stimuli[2,4]. Such release may be associated with the O_2 uptake, O_2^- production and stimulation of hexose monophosphate shunt activity that occur following exposure to such stimuli[9] and may also be involved in PMN degranulation[10]. The much greater potency of leukotriene B, compared with that reported for the mono-HETEs, suggests that the latter compounds are of less biological significance. It will be of some interest to study the role of leukotriene B *in vivo* with respect to the accumulation of inflammatory cells at sites of inflammatory and allergic reactions.

We thank the Arthritis and Rheumatism Council (M.A.B.), the Science Research Council (M.V.D.) and Lilly Research Ltd for financial support.

†Department of Microbiology and Immunology, Wright State University, School of Medicine, Dayton, Ohio 45435

It is becoming increasingly apparent that interferon exerts a major role in cellular regulatory processes. Besides its well known antiviral properties[1], interferon has been shown to affect cell surface antigen expression[2,3], lymphoid cell function[4,5], as well as cellular protein synthesis[6,7] and growth[8-11]. To date, however, there is little information available on the mechanism of interferon production *in vivo* except in response to a variety of exogenously administered viral and nonviral systemic inducers. We report here the detection of a pregnancy-associated elevation of interferon, or an interferon-like component, in selected reproductive tissues of mice.

Ten-week-old virgin NIH Swiss mice, a random-bred strain, were killed at specific times after mating. Female mice were examined daily and mating was indicated by the appearance of a copulation plug and was referenced as day 1 of gestation. Mice were maintained on a 12 h light cycle at a temperature of 24 °C. Lab chow and water were available *ad libitum*. At autopsy the uteri were aseptically excised, carefully trimmed and the conceptuses removed. The conceptuses of individual mice were then pooled and after the 10-day stage dissected into placental and embryonic/fetal components. Earlier conceptuses (7-day stage) from individual mice were also pooled but were not dissected further. Immediately after removal, a 20% (w/v) homogenate of each specimen was prepared in phosphate-buffered saline (*p*H 7.2) and clarified for 30 min at 2,500*g*. Following storage at −76 °C the samples were defrosted and the level of antiviral activity was determined by the 50% plaque reduction (PR_{50}) method as described previously[12]; see legend to Fig. 1. The titre of antiviral activity is expressed as the reciprocal of the highest dilution that inhibited plaque formation by 50%. One unit of antiviral activity is equivalent to 0.5 NIH (G002-904-511) reference units.

Preliminary studies showed the presence of an antiviral activity in mouse placental extracts. Biological and biophysical characterization of this activity as an interferon was determined by its protection of L-cell cultures against the cytopathic effects (CPE) of MM virus and is summarized in Table 1. The antiviral activity was sensitive to treatment with trypsin, actinomycin D, and heat and was neutralized by anti-interferon γ globulin. Also, it was not inactivated by low *p*H treatment (at *p*H 2) and was not removed by high speed centrifugation. By these criteria, the placental component exhibits the properties of virally induced, Type 1, interferon[13,14]. It seems highly unlikely that the inhibition of CPE resulted from a nonspecific mechanism, such as an interference of virus attachment to the target L-cells by the tissue extracts, as the antiviral activity of the placental component requires a transcriptional event (sensitive to actinomycin D) and furthermore, is neutralized by specific anti-interferon γ globulin.

The interferon levels of uterine, placental and fetal tissues at various stages of gestation are shown in Fig. 1. As may be noted, interferon was detected in most uterine samples between 10–15 days of gestation; however, specimens taken before and after this interval of pregnancy, as well as from virgin mice ($n = 3$, data not shown), had no detectible titre (< 10 units ml^{-1}). This transient appearance of interferon in the gravid uterus developed abruptly and was highest at the 13-day stage (300 units ml^{-1}). By comparison, interferon was found in all placental samples examined, and its level increased significantly during pregnancy. This increase was most dramatic between 10- and 13-day stages (8-fold) but continued until the 17-day stage. Subsequently, the interferon level generally plateaued at approximately 2,000 units ml^{-1} until term. In other data not shown, the mean interferon level of 7-day old conceptuses from three individual mice was found to be essentially the same as 10-day placentas (110 as compared to 120 units ml^{-1}) and approximately 3-fold greater than 10-day fetuses (33 units ml^{-1}; right panel). Note that no fetal specimen had an interferon level greater than 80 units ml^{-1} and further, that interferon-positive fetal samples were clustered around the 10-day stage, a stage at which contamination by extra-embryonic tissues is difficult to avoid. After this stage only one out of 6 fetal samples had a detectable interferon level.

These results clearly demonstrate a progressive increase in the level of interferon in the mouse placenta during gestation. Significant levels were detected in this organ as early as 10 days after mating, and most likely, the interferon detected in the 7-day conceptus was largely of placental origin. In contrast, little if any interferon was found in embryonic/fetal tissues. This observation is consistent with earlier reports that the placenta forms an effective barrier limiting migration of interferon into fetal circulation[15,16]. Although a decrease in the efficacy of the placental barrier to interferon migration has been reported in the pregnant rat near term[17], we have found no evidence of transplacental transfer of interferon into mouse fetuses in late gestation. This discrepancy may be attributed either to species differences or to the stage of gestation as we have not examined fetuses beyond the 18-day stage. The presence of an interferon antagonist in mouse embryos[18] may also contribute to the apparently low levels of interferon in the embryo.

The significance of the transitory appearance of interferon in the uterus is more difficult to interpret. Although the level of interferon seems to be sufficiently elevated to indicate an active production or an accumulation process, we have not ruled out the possibility that uterine contamination by placental material

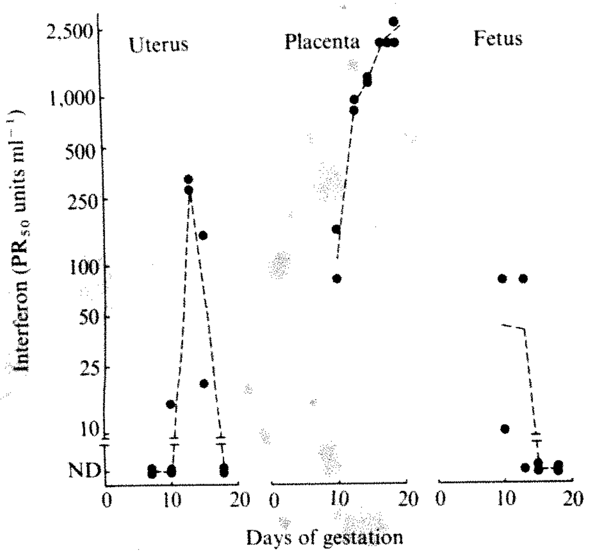

Fig. 1 Interferon levels of uterine, placental, and fetal tissues from NIH Swiss mice at various stages of gestation. For assay, twofold dilutions of each sample were made in Dulbecco's minimal essential medium supplemented with 10% fetal calf serum. Each dilution was added to duplicate monolayer cultures of L929 cells. After 18 h at 37 °C, the cultures were washed and challenged with approximately 100 plaque forming units (p.f.u.) of encephalomyocarditis virus (strain MM) and incubated for 48 h. The cultures were then stained and the plaques counted. Each point represents the antiviral activity of the tissue from an individual pregnant mouse.

is the source of the observed interferon. However, of the three explanations, the last seems least probable since a contamination of major proportion (>33%) would be necessary to account for uterine interferon level at the 13-day stage (300 units ml^{-1}). On the other hand, the production or accumulation of interferon in the gravid uterus, specifically between 10 and 15 days of gestation, would suggest stringent regulation.

The inductive event(s) of interferon production in the pregnant mouse and the mechanism of its concentration in the placenta are not known; however, studies in progress indicate that the maximum level of placental interferon in mice is under genetic control. We have not so far detected interferon in the serum (<10 units ml^{-1}) of either virgin or pregnant NIH Swiss mice. Whereas this may be interpreted as evidence favouring the *de novo* synthesis of interferon by the placenta, it does not preclude the possibility that this organ possesses an extraordinary capacity to concentrate interferon from maternal systemic pools. In the latter situation, induction by chronic parasitic infections in the mouse population could provide such a source of interferon. In our experiments, however, we have also examined tissues from specific pathogen-free NIH Swiss mice and in all cases, placental interferon levels of barrier-maintained mice were similar to mice housed in our conventional facility.

The demonstration that interferon accumulates in mouse placenta is interesting from several points of view. The placenta is an organ which occupies the intermediate zone between the maternal and fetal organisms. It is an organ of protective, endocrine, and immunological functions and is considered intricately involved in fetal acceptance[19]. Although a role for interferon in any of these events is conjectural, this class of glycoproteins exhibit numerous biological properties that are compatible with those of successful gestation. In addition to its viral prophylactic activity, interferon influences a variety of other physiological processes ranging from cell surface and growth control to immunoregulation. In this regard it is particularly noteworthy that prolongation of graft survival across H-2 barriers results with systemic interferon inducers[20,21], as well as with the direct administration of interferon[21–23]. Likewise, cell-mediated immunity in both graft-versus-host[24] and delayed-type hypersensitivity[25,26] reactions was reduced by interferon treatment. These results and the findings that interferon also inhibits DNA synthesis induced in mouse lymphocytes *in vitro* by mitogens and allogeneic cells[27–29] suggest a possible involvement of interferon in the immunoregulation of fetal acceptance. As we have also detected an antiviral activity in a human term placenta, the presence of interferon in this organ may not be unique to the murine species.

Detection of a cell-surface antigen correlated with organ-specific metastasis

P. J. Shearman, W. M. Gallatin & B. M. Longenecker

Department of Immunology, University of Alberta, Edmonton, Alberta, Canada T6G 2H7

Despite the fact that tumour cells with the potential for metastasis may circulate randomly, many demonstrate a preference for specific organs. Recently, several investigators have selected variant tumour cell lines with enhanced capacity to metastasize to specific organs, mainly using the spontaneously originating B16 melanoma cell line of the mouse and tumour variants with enhanced capacity to metastasize to the lungs[1], brain[2] and liver[3]. We previously reported[4,5] the derivation of a liver-specific metastatic variant of a Marek's disease (MD) virus-transformed, non-producer[4,6] lymphoma cell line. MD is a naturally occurring, herpes virus-induced, T-cell lymphoma of chickens which bears pathological and aetiological similarities to Burkitt's lymphoma in man. This makes MD a useful model for study[7]. One similarity is the pattern of metastasis in which both lymphomas induce a high incidence of ovarian and liver lesions[8,9]. We now report the existence of a cell-surface antigen, detectable by a monoclonal antibody, correlated with organ-specific metastasis.

To quantify liver-specific metastasis in our system, we inject tumour cells intravenously into day 11 chick embryos and enumerate metastatic liver foci which form during 6 days of further incubation[4]. MDCC-AL2, a cell line which has been selected for liver-specific metastasis, forms many more embryonic liver foci than MDCC-RP1 or MDCC-AL1, lines not selected for organ-specific metastasis, or MDCC-AL3, selected for metastasis to the ovary[4]. Following the same *in ovo* procedure, cell lines which have been selected for increased virulence (RP1 < AL1 < AL2 < AL3) form increasingly more tumour foci on the chorioallantoic membrane (CAM) of the chick embryo. As these embryo assays are sensitive and convenient, we used them in inhibition assays to attempt to detect specific cell-surface antigens expressed on our liver-metastasizing, variant cell line, AL2.

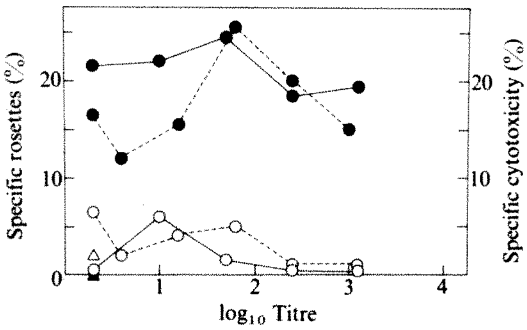

Fig. 1 Indirect rosettes (solid lines) were formed by incubating dilutions of hybridoma 1.20 culture supernatant with MDCC-AL2 cells (●) or MDCC-AL3 cells (○) for 60 min at 4 °C. After three washes in culture medium, chicken red blood cells with rabbit anti-mouse immunoglobulin antiserum (Cappel) coupled to their surfaces by a modified 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (Sigma) technique were added at a 10:1 red cell-to-target cell ratio and incubated for 180 min at 4 °C. Specific rosettes were calculated by subtracting background rosettes formed without culture supernatant. Complement-mediated cytotoxicity (broken lines) was accomplished by incubating RP1 (▲), AL1 (△), AL2 (●) or AL3 (○) cells with dilutions of hybridoma 1.20 culture supernatant and guinea pig complement for 45 min at 37 °C. The cells were washed once in culture medium and cytotoxicity determined by dye exclusion. Specific cytotoxicity (broken lines) was calculated by subtracting cytotoxicity due to complement alone. In both assays, each point represents the average of two determinations.

For the generation of anti-tumour cell hybridomas, five CBA/J mice were injected intravenously with 10^8 AL2 cells. Three days later the spleen cells from the mice were pooled and fused with 315.43 myeloma cells as described previously[10]. Hybrid clones exhibiting positive direct or indirect agglutination activity in their culture supernatants against AL2 cells were picked and grown for further analysis. Sixteen clones proved to be stable and antibody-producers. Of these, nine clones seemed to detect chicken major histocompatibility complex (MHC, B locus) antigens. Only one clone produced antibody which reacted with all types of chicken cells tested, normal and malignant, and was considered to be anti-chicken panspecific. One clone produced antibody reacting with all lymphocytes tested regardless of MHC type. Four clones produced antibody which reacted with RP1, AL1, AL2, AL3 and another MD-derived lymphoma cell line, MDCC-MSB1, but which did not react with normal lymphocytes or erythrocytes. One clone, 1.20, produced antibody which reacted specifically with AL2 cells (Fig. 1) and showed little or no reactivity against chicken red or white blood cells of various genotypes, or tumour cells of the other MD-tumour cell lines.

To test whether the 1.20 antigen might be associated with specific liver metastasis, we measured the capacity of 1.20 antibody to inhibit liver foci induced by AL2 cells in the *in ovo* assay[4]. It was found that preincubation of AL2 cells with 1.20 monoclonal antibodies (Table 1) specifically blocks the ability of AL2 cells to colonize the embryonic liver without affecting the ability of the same cells to produce CAM foci. In contrast, CH-4 monoclonal antibodies which detect a chicken MHC antigen[10] not found on AL2 cells, or 1.24 monoclonal antibodies which detect a public MHC antigen common to all MDCC-RP1-derived cell lines tested, inhibited neither CAM nor liver foci. To test another monoclonal antibody binding to AL2 cells, the capacity of 1.20 antibodies to inhibit liver foci was compared with that of 1.5 monoclonal antibodies, similar in specificity to 1.24 antibodies. This test (Table 2) was done with or without the prior complement-mediated killing of AL2 cells. Hybridoma 1.20 but not 1.5 monoclonal antibodies significantly inhibited the development of liver foci in the presence of complement. It is noteworthy that 1.5 monoclonal antibodies, which directly agglutinate the AL2 cells, caused a significant enhancement in the number of CAM foci induced by AL2 cells, suggesting that large emboli of tumour cells might be nonspecifically trapped in the CAM. In the same conditions, however, 1.5 monoclonal antibodies did not cause a significant enhancement in liver foci; this is consistent with our previous observations[4] which suggest that homing of AL2 cells to the embryonic liver is a specific process and not simply a nonspecific trapping of emboli of tumour cells. The fact that 1.5 monoclonal antibodies caused a slight, but not significant, reduction in the number of liver foci suggests that at least a few of the liver focus-forming cells may have been trapped within cell aggregates. As different classes of mouse antibody may affect the homing of metastatic tumour cells differentially, we have standardized the class of antibody used. All the monoclonal antibodies used in our studies are IgM (unpublished data). This is in keeping with our previous observations[10] which show that the mouse preferentially responds to chicken MHC antigens with antibodies of the IgM class in the same conditions with which the hybridomas were produced for the present study.

Two different *in vitro* assays, indirect rosette formation and complement-mediated cytotoxicity, were used to verify the specificity of 1.20-derived monoclonal antibodies. Both of these assays showed that approximately 20% of AL2 cells have detectable cell-surface antigen (Fig. 1). AL3 cells demonstrated a small but significant number of 1.20 antigen-positive cells.

To determine if the frequency of 1.20 antigen expression in a cell line correlates with the degree of liver metastasis exhibited by the cell line, we derived limiting dilution clones of metastatic variants AL2 and AL3. Six clones were isolated from AL2 and four from AL3. All 10 clones are non-producers for virus, tested as for the parent cell lines (data not

Table 1 Specific inhibition of liver metastasis by monoclonal antibody

Monoclonal antibody added	CAM foci	Liver foci
None	60 ± 17 (8)	63 ± 11 (8)
CH-4	59 ± 16 (8)	78 ± 21 (5)
1.20	61 ± 11 (7)	32 ± 10 (9)
1.24	68 ± 17 (10)	56 ± 6 (8)

Assays for chorioallantoic membrane (CAM) and embryonic liver foci were performed as described previously[4]. For CAM foci, 1×10^3 MDCC-AL2 cells were injected intravenously per embryo, and for liver foci, 3×10^4 AL2 cells were used. Before injection, cells were left untreated or preincubated for 30 min with ascites antibodies from hybridomas CH-4, 1.20 or 1.24 at a final dilution of 1:100. Results are expressed as means ± s.d. with number of embryos per group in parentheses. Statistically significant differences were obtained in comparing results in liver foci for 1.20 with controls ($P < 0.001$); 1.20 with CH-4 ($P < 0.01$) and 1.20 with 1.24 ($P < 0.001$).

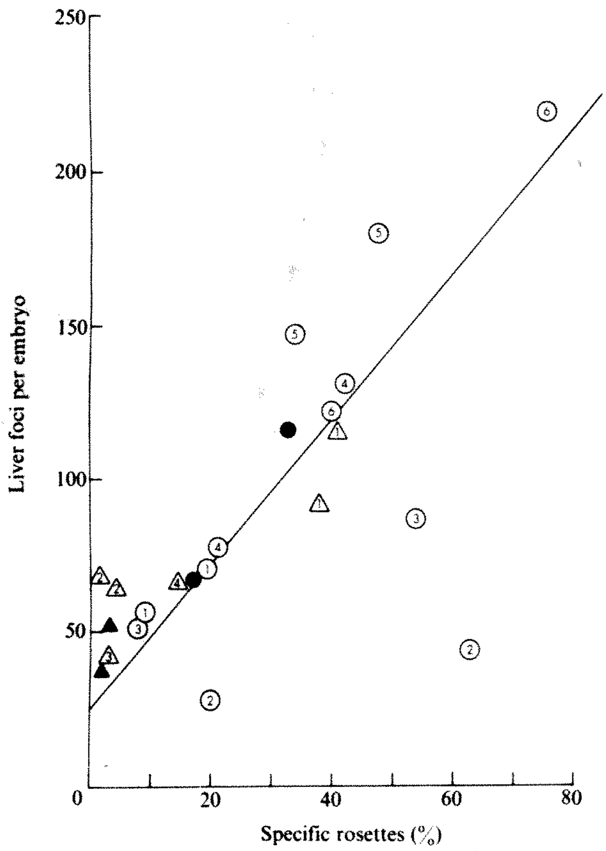

Fig. 2 The cell lines MDCC-AL2 (●) plus six limiting dilution clones (numbers in circle) and MDCC-AL3 (▲) plus four clones (numbers in triangles) were tested for 1.20 antigen frequency by the indirect rosette assay and for liver metastatic ability by the liver focus-forming assay[4] on two occasions. Indirect rosettes were formed as described in Fig. 1 using a 1.20 antibody dilution of 1:100. A cell dose of 3×10^5 cells per embryo was used in the liver focus-forming assay. Paired values of 1.20 antigen frequency and average number of liver foci per embryo are plotted for each cell line and clone. These values demonstrate a correlation coefficient of 0.70 ($P < 0.001$).

Table 2 Specific inhibition of liver metastasis by monoclonal antibody plus complement

Monoclonal antibody added	CAM foci	Liver foci
None	70 ± 51 (5)	88 ± 14 (6)
C′	60 ± 38 (7)	75 ± 11 (6)
1.20	115 ± 33 (7)	62 ± 23 (7)
1.20 + C′	93 ± 15 (7)	34 ± 12 (8)
1.5	184 ± 58 (7)	76 ± 11 (8)
1.5 + C′	86 ± 29 (6)	63 ± 9 (8)

Assays for CAM and embryonic liver foci were performed as described previously[4]. Before injection, AL2 cells were incubated for 45 min at 37 °C with the culture supernatants (full strength) from hybridomas 1.20 or 1.5 in the presence or absence of guinea pig complement (C′). The cells were washed and the cell concentrations were readjusted so that 1×10^3 viable AL2 cells were injected per embryo for CAM foci and 1×10^5 viable AL2 cells were injected per embryo for embryonic liver foci. 1.20 plus complement killed ~20% of AL2 cells and 1.5 plus complement killed ~40% of AL2 cells at the concentrations used. Results are expressed as means ± s.d. with number of embryos per group in parentheses. Statistically significant differences were obtained in comparing results in CAM foci for control or 1.5+C′ with 1.5 alone ($P < 0.01$); also for results in liver foci for C′ or 1.5+C′ with 1.20+C′ ($P < 0.001$); 1.20 and 1.20+C′ ($P < 0.02$); Control and 1.20 ($P < 0.03$).

shown)[4,6,11]. According to the work of Fidler and co-workers[12], these clones should vary in their metastatic ability and possibly their antigenic profile. We tested each clone as well as the parent cell lines on two occasions for both indirect rosette-forming cells and liver focus-forming ability. Cell line AL2 and its clones ranged from 8 to 75% in frequency of 1.20 antigen-positive cells. AL3 and its clones ranged from 1 to 41%. For the liver focus assay, we injected a relatively large number of cells to allow maximal precision of the assay. The paired observations are plotted in Fig. 2 and show that the number of liver foci formed by a clone is directly proportional to the number of 1.20 antigen-positive cells in that clone ($r = 0.70$, $P < 0.001$). Clone AL3.1 demonstrates a high frequency of 1.20 antigen-positive cells and showed high liver metastatic ability on both occasions. In contrast, all the other AL3-derived clones have a low value for each of these parameters as does the uncloned parental line AL3. Note that there is some day-to-day variation in 1.20 antigen expression and liver focus-forming ability, although successive assays correlate very highly. Thus, although correlated and possibly associated in a functional sense, the parameters of antigen expression and metastasis may vary in the strength of the correlation between them for a given clone. This is not unexpected as metastasis is a complex series of events only one of which involves specific organ recognition. Kerbel[13] has reported that random cloning produces unstable metastatic variants in contrast to the work of Fidler[12]. Stable metastatic variants were produced only after treatment with mutagens and lectins[13]. In our studies, we have found a strong and relatively stable correlation between 1.20 antigen expression and liver metastasis. This strengthens the argument in conjunction with the 1.20 antibody-mediated inhibition of liver metastases that the 1.20 antigen is involved in determining liver-specific metastasis.

Thus, we have described the existence of a cell-surface antigen, detectable by a monoclonal antibody which is correlated with specific liver metastasis of a lymphoma cell line. Cell populations with a low capacity to form liver foci have a low expression of the 1.20 antigen specificity and cell populations with a high capacity to form liver foci have a high level of 1.20 antigen expression. Monoclonal antibodies directed against the 1.20 antigen inhibit specific liver metastasis by AL2 cells but do not inhibit CAM lesions, which is a measure of the invasiveness of the cell line[4]. Our working hypothesis is that the 1.20 antigen has a functional role in the interaction of a blood-borne, metastasizing tumour cell with the target organ, the liver. The metastatic process is a complex series of events[12] and our results with clone AL3.1 have shown that 1.20 antigen expression is a necessary but not a sufficient condition in the determination of successful liver metastases.

T-cell hybridoma bearing heavy chain variable region determinants producing (T,G)-A--L-specific helper factor

Zelig Eshhar, Ron N. Apte, Ilana Löwy, Yinon Ben-Neriah, David Givol & Edna Mozes

Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Thymus-derived lymphocytes (T cells) exert their regulatory effect (help or suppression) on the antibody production by B cells either by direct cell to cell interaction or by soluble mediators or factors[1,2]. The low frequency of specific T cells, the heterogeneity of their responses and their relatively short life span have hampered the molecular characterization of the antigen recognition unit of T cells, and its structure is largely unknown. The lymphocyte hybridization technique, which has been found very useful for the production of B-cell hybridomas secreting specific monoclonal antibodies[3], has also been used for the generation of homogeneous and stable T-cell hybridomas with unlimited growth potential[4,5]. So far the only specific effector function demonstrated in the established T hybridomas is the property to generate a factor(s) which suppresses antibody responses[6-8]. We now describe the establishment of hybrid lines which exhibit characteristic T-cell markers. One of the hybridomas (denoted R-9) releases into the culture supernatant factor(s) with helper activity specific to the synthetic polypeptide (T,G)-A--L and bears surface determinants of the immunoglobulin heavy chain variable region (V_H). Such hybrid cell lines are of great value for studies on the nature of the T-cell receptor.

Cell fusion was carried out essentially as described previously[9], using 41% polyethylene glycol 1500 (PEG) as fusing agent (Table 1). The AKR/J thymoma line BW5147, which lacks the enzyme hypoxanthine guanine phosphoribosyl transferase (derived by Dr R. Hyman), was fused with an enriched population of activated T cells. Activation of T cells to (T,G)-A--L was carried out by the transfer of thymocytes from C3H.SW ($H-2^b$) mice into irradiated (750 R) syngeneic recipients together with 10 μg of (T,G)-A--L (ref. 10). One week after transfer and 24 h before hybridization, 'educated' T cells from the spleens of the recipient mice were cultured on monolayers of (T,G)-A--L-bearing splenic adherent cells. This procedure augments the helper activity of (T,G)-A--L educated cells (R.N.A. and E.M., unpublished). After hybridization, cell suspensions were distributed into 24-well culture plates (Costar) and selected for 3 weeks in medium containing hypoxanthine, aminopterin and thymidine (HAT). Hybrid populations were grown in Dulbecco's modified Eagle's medium (DMEM) containing 15% horse serum (DMEM-HS). One month after fusion, 21 individual hybridoma cultures had been established.

The hybrids were screened for the presence of T-cell surface markers, immunoglobulin constant and variable (V_H and V_L) determinants[11] and (T,G)-A--L-specific biological activity. Most of the hybrid lines expressed the Thy 1.1 and Thy 1.2 alleles (originated from the parental BW5147 and C3H.SW lymphocytes, respectively). None of the hybridomas reacted with anti-V_L or anti-Ig antibodies, whereas 5 out of the 21 lines reacted with anti-V_H antibodies. Three of the V_H-positive hybrid lines—R-9, R-11 and R-17—affected the antibody response to (T,G)-A--L. R-11 demonstrated suppressive activity which will be described elsewhere. Here we present the characteristics of the R-9 hybrid line which exhibits antigen-specific helper activity.

Detailed analysis of the surface antigens (double immunofluorescence staining) and karyotype of R-9 hybridoma are shown in Table 1. The hybrid nature is indicated by the average chromosome number (65), which is higher than diploid (40), and by the expression of the H-2 and Thy-1 alloantigens of both parental strains on R-9 cells. Cytotoxicity assays using anti-Lyt reagents and rabbit complement resulted in 40% lysis of the R-9 cells with anti-Lyt-1.1, whereas no lysis was observed following treatment with anti-Lyt-2.1. Hybrids were not analysed for the Lyt-3.2 marker. The presence of immunoglobulin variable-region determinants was detected by using the $F(ab')_2$ of specifically purified rabbit antibodies against isolated V_H and V_L fragments derived from M-315 myeloma protein[11]. Most of the R-9 cells did express V_H determinants whereas neither BW5147 cells nor R-19 (another hybrid line derived from the same fusion) reacted with anti-V_H antibodies. The distribution of stained cells was further analysed by the fluorescence-activated cell sorter (FACS-II) as depicted in Fig. 1. Whereas R-9 cells were labelled with anti-V_H antibodies in a manner which suggests a homogeneous population of the stained cells, they failed to react with either anti-V_L or anti-Ig antibodies. Computer analysis of the relative cell number stained with anti-V_H indicated that 70–85% of R-9 cells were positively labelled. BW5147 cells were not stained by either anti-V_H or anti-V_L antibodies (Fig. 1).

The antigen-specific activity of the hybrid lines was evaluated by their ability to produce a factor(s) with helper activity in the (T,G)-A--L-specific antibody response. Supernatants from 48–72-h cultures (containing $1-2 \times 10^6$ hybrid cells per ml) were injected together with (T,G)-A--L and 2×10^7 primed B cells into irradiated syngeneic recipients. Mice were bled 10–14 days later and (T,G)-A--L-specific antibodies in their sera were determined as shown in Table 2. Supernatants from R-9 and R-17 hybridomas induced anti-(T,G)-A--L responses when transferred together with T-cell-depleted primed spleen cells and (T,G)-A--L. Such activity was not manifested by supernatants of BW5147 cells and 19 other hybridomas of which R-19 is a representative. The degree of help provided by the active supernatants was not as high as with the T cells in the unfractionated primed spleen cells, but it was comparable to that of 5×10^6 (T,G)-A--L-activated T

Table 1 Cell-surface markers and karyotype analysis of T hybridomas

Antisera or antibodies	BW5147	R-9	R-19
		% Stained cells	
Anti-Thy 1.1 (1:100)	>95	>95	>95
Anti-Thy 1.2 (1:100)	<5	>90	85

Anti-$V_L(\lambda)$ (0.3 mg ml^{-1})	<5	<10	<5
Anti-$V_L(\kappa)$ (0.3 mg ml^{-1})	<5	<5	<5
Karyotype*	41(40–45)	65(60–72)	65(59–75)

Fusion was carried out by the addition of 41% PEG 1500 in serum-free DMEM to a cell pellet of 36×10^6 enriched activated T cells from C3H.SW mice ($H-2^b$, Thy 1.2, Lyt 1.1, Lyt 2.1, Lyt 3.2) and 10×10^6 AKR/J BW5147 thymoma. After 2 min at 37 °C, PEG was gradually diluted with serum-free DMEM and after centrifugation the cells were suspended in DMEM-HS to a concentration of 10^5 viable BW cells per ml. Aliquots (1 ml) were distributed into each well of 24-well culture plates. Medium containing HAT was added the next day and cultures were fed each third day with fresh HAT medium. The % of stained cells was analysed by indirect immunofluorescence using fluorescein-conjugated (FITC) rabbit antibodies against mouse IgG (Miles-Yeda) that were intensively absorbed with mouse T-cell lines and thymocytes for the detection of the murine alloantisera. FITC coupled to $F(ab')_2$ of goat anti-rabbit IgG was used for the detection of the rabbit antibodies against the murine variable region (V_H and V_L) and whole immunoglobulins (Ig). Anti-Thy 1.2 and anti-Thy 1.1 are monoclonal antibodies. Anti-$H-2^k$ antiserum was obtained by the immunization of C3H.SW mice with C3H/DiSn lymphocytes and for the production of anti-$H-2^b$ antiserum C3H/DiSn lymphocytes and for the production of anti-

*Chromosome number was detected 8 months after fusion. In each determination 10 mitotic cells were counted. The range of chromosome number is given in parentheses.

2×10^7 (T,G)-A--L-primed B cells + supernatant of line R-9‡	4,164	4,619	4,380
2×10^7 (T,G)-A--L-primed B cells + R-9 eluate from a (T,G)-A--L–Sepharose column§	15,393	NT	NT
	Antibody response to ovalbumin (c.p.m.)		
2×10^7 Ovalbumin-primed spleen cells	11,257	9,843	
2×10^7 Ovalbumin-primed B cells*	4,521	2,523	
2×10^7 Ovalbumin-primed B cells + supernatant of line R-9	4,346	1,820	
2×10^7 Ovalbumin-primed B cells + supernatant of BW5147	4,054	NT	
2×10^7 Ovalbumin-primed B cells + supernatant of line R-17	7,008	NT	

Cells and supernatants were transferred into 750-R irradiated C3H SW recipient mice together with 10 µg of (T,G)-A--L or 100 µg of ovalbumin. Antibody responses in antisera of mice bled 12–14 days after transfer were measured by plate radioimmunoassay; 0.05 mg ml^{-1} of either (T,G)-A--L or ovalbumin diluted in phosphate-buffered saline PBS were used to coat the wells of flexible plates. Antigen-coated plates were incubated with aliquots of 1:20 dilution of pooled sera (5–10 mice per group). The plates were then incubated with ^{125}I-labelled goat anti-mouse Fab. Results are expressed as mean c.p.m. of triplicate wells. NT, Not tested.

*Anti-Thy 1.2 and complement-treated primed spleen cells.

†Educated T cells obtained from spleens of irradiated recipients 1 week after transfer of 10^8 thymocytes and immunization with 10 µg (T,G)-A--L in complete Freund's adjuvant.

‡Supernatants (1 ml) of hybridoma cultures grown to a concentration of $1-2\times10^6$ cells per ml were injected into each recipient mouse together with B cells and antigen.

§R-9 supernatant was passed through a (T,G)-A--L–Sepharose column. Elution was with 0.1 M NH_4OH. The dialysed eluate was injected at a twofold concentration of the original supernatant.

cells (Table 2). The antigen specificity of the help provided by the factor was analysed in a parallel system using ovalbumin-primed splenic lymphocytes. As shown in the lower section of Table 2, R-9 supernatants which contain helper factor for (T,G)-A--L failed to reconstitute the anti-ovalbumin response in recipients of ovalbumin-primed B lymphocytes. However, R-17 supernatants functioned as non-antigen-specific mediators and provided help both to (T,G)-A--L and ovalbumin responses.

A further confirmation for the (T,G)-A--L specificity of R-9 supernatants is provided by the high efficiency of an eluate of a (T,G)-A--L–Sepharose column in replacing T cells in antibody production to (T,G)-A--L. As shown in Table 2 the antibody levels produced in recipients of (T,G)-A--L-primed B cells reconstituted with such an eluate (at a twofold concentration of the original supernatant) are comparable to those observed in recipients of primed spleen cells.

To determine whether the antigen-specific factor carries V_H determinants, as shown for R-9 hybrid cells, the above eluate of a (T,G)-A--L column was applied to immunoadsorbents made of anti-V_H and of anti-mouse immunoglobulin. The effluents and the 0.1 M NH_4OH eluates of these columns were analysed for their helper activity in an *in vitro* antibody production system[12] which enabled us to assay small doses of the factor. In this system nitro-iodophenyl (NIP)–ovalbumin primed spleen cells served as a source of hapten-specific B cells. The ability of the different R-9 fractions to provide help to these cells in the presence of NIP–(T,G)-A--L was determined by measuring the NIP-specific plaque forming cell (PFC) responses (Table 3). As shown in Table 3, the eluate of a (T,G)-A--L–Sepharose column provided (T,G)-A--L-specific helper activity; this was also shown *in vivo* in the transfer experiments (Table 2). In addition, as demonstrated in Table 3, the activity of the (T,G)-A--L–Sepharose eluate was removed by an anti-V_H–Sepharose column and could be eluted from this immunoadsorbent with 0.1 M NH_4OH. On the other hand, the helper activity could not be retained in an eluate of a guinea-pig anti-mouse immunoglobulin immunoadsorbent. Thus, the (T,G)-A--L-specific helper factor of R-9 hybridoma possesses the same V_H determinants as the cell line itself.

The R-9 hybrid line has expressed V_H determinants and produced active helper factors for 15 months since its establishment. This line could be cryopreserved and fully retained its properties. R-9 cells have been further cloned on soft agar. All 45 clones analysed reacted with the anti-V_H antibodies. Preliminary screening revealed helper activity in about 50% of the clones.

Antigen-specific helper and suppressor T cells and their products have been reported to possess determinants encoded by the I region of the major histocompatibility complex[13–18] and variable-region gene products[19–23]. We have previously described the generation and partial characterization of a helper T-cell factor specific for the synthetic polypeptide (T,G)-A--L[10,24]. The helper T-cell-replacing factor could be absorbed to immobilized antigen, anti-I-A antibodies and anti-idiotypes against (T,G)-A--L-specific antibodies[13,14,22]. Similarly, factors with suppressor activity have been shown to possess both I-J and idiotypic determinants[16,17,23]. More general reagents of potential reactivity against the T-cell receptor are the anti-V-region antibodies directed against the common framework-related determinants (V_H)[11]. Such anti-V_H antibodies effectively interfered with T-cell activities[25] and reacted with some T-cell products[26]. In accordance, we report here the establishment of an immunoglobulin-negative V_H-positive T-cell hybrid line producing a (T,G)-A--L-specific helper factor which bears V_H determinants.

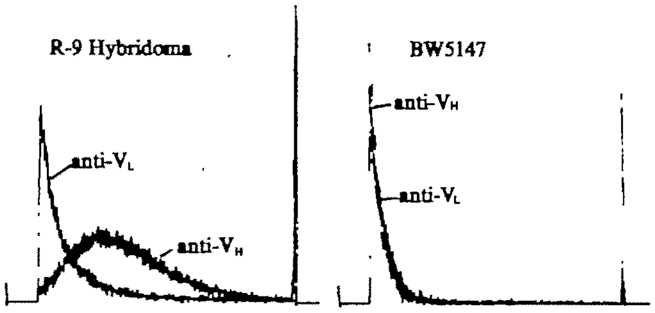

Fig. 1 Immunofluorescence profile of R-9 hybridoma and its parental BW5147 thymoma labelled with either anti-V_H or anti-$V_L(\lambda)$ purified rabbit $F(ab')_2$ antibody fragments. Fluorescein conjugated $F(ab')_2$ of goat anti-rabbit IgG was used for staining. Abscissa, fluorescence intensity; ordinate, relative cell number.

Table 3 (T,G)-A--L-specific helper factor of R-9 hybrid line possesses V_H determinants

NIP-OVA primed spleen cells cultured with:	NIP specific PFC per 10^6 viable cells*			
	NIP-(T,G)-A--L		NIP-FGG	
	Expt 1	Expt 2	Expt 1	Expt 2
—	279±43	81±23	175±24	66±28
(T,G)-A--L-primed spleen cells	1,333±76	500±33	375±25	47± 8
Eluate from (T,G)-A--L–Sepharose†	1,045±57	487±23	213±31	111±17
Effluent from anti-mouse Ig–Sepharose	416±36	388±71	196±33	103±38
Eluate from anti-mouse Ig–Sepharose‡	230±13	102±31	114±45	46±26
Effluent from anti-V_H–Sepharose	175±20	62±32	151±19	48±17
Eluate from anti-V_H–Sepharose‡	621±58	413±34	108±24	73±27

NIP–Ovalbumin primed spleen cells were cultured in microtitre plates (10^6 per well) together with either (T,G)-A--L-primed spleen cells (2.5×10^5 per well) or the different effluents and eluates (final concentration 25%). Either NIP-(T,G)-A--L or NIP-FGG (fowl γ-globulin) (1 μg) was added to each well. Culture conditions were as described elsewhere[12].

*Indirect plaque forming cells (PFC) were determined using NIP-sheep red blood cell indicator cells. Results are expressed as the mean number of quadruplicates tested ± s.e. NIP–Ovalbumin primed spleen cells cultured in the presence of homologous antigen gave 1,794 PFC and 678 PFC whereas the background without antigen was 68 PFC and 50 PFC in Expts 1 and 2 respectively.

†R-9 eluted from (T,G)-A--L–Sepharose column (as described in Table 2 legend). This affinity-purified fraction was further passed through the rabbit anti-V_H and guinea pig anti-mouse IgG–Sepharose columns.

‡Elution was with 0.1 M NH_4OH.

Experiments are under way to characterize the products of R-9, the first T-cell hybridoma which is a constitutive producer of (T,G)-A--L-specific helper factor and bears surface variable-region determinants. The information obtained may clarify the nature of the molecular association between MHC-coded determinants and immunoglobulin variable-region gene products in the T-cell recognition unit.

We thank Ms Heidy Zinger and Ms Tova Waks for technical assistance, Dr Patrick de Baetselier for analysing the hybridomas in the FACS, and Drs R. Hyman, A. Peled and A. Rothstein for BW5147 thymoma, anti-Lyt 2.1 antibodies, and anti-Thy 1.2 and 1.1 antibodies, respectively. This research was supported in part by a grant from the National Council for Research and Development, Israel, and the DKFZ, Heidelberg, FRG. Z.E. is an incumbent of the Recanati Career Development Chair in Cancer Research. R.N.A. is a recipient of the Wolf Michaels postdoctoral fellowship.

Small subunit of I–A subregion antigens determines the allospecificity recognized by a monoclonal antibody

Jack Silver, Susan L. Swain* & Jeffrey J. Hubert

The Department of Cellular and Developmental Immunology, Scripps Clinic and Research Foundation, 10666 North Torrey Pines Road, La Jolla, California 92037

*Department of Biology, University of California San Diego, La Jolla, California 92037

The murine major histocompatibility complex (MHC) codes for three groups of identifiable cell-surface proteins, the K, D molecules, the I–A subregion antigens and the I–E subregion antigens. All three groups of molecules display a high degree of serologically detectable polymorphism[1] and consist of two noncovalently associated polypeptides[2–8]. Amino acid sequence and peptide comparisons among allotypes of K, D and I–E molecules reveals that one polypeptide is relatively constant, whereas the other is highly variable[9–13]. Thus, it is likely that only one of the two polypeptides, the variable component, determines the antigenic specificities recognized by alloantisera. In contrast to the K, D and I–E molecules, both subunits of I–A molecules display substantial structural differences when comparisons among allotypes are made[4,14–16]. Therefore, we have investigated whether one or both subunits of I–A molecules determine their alloantigenic specificities. Our results, presented here, indicate that only one of the two subunits determines a particular allospecificity recognized by a monoclonal antibody.

I–A molecules radiolabelled with ^{3}H-phenylalanine were isolated from B10.A(5R) mice by indirect immunoprecipitation with (B10.A × A)F_1 anti-B10.A(5R) antisera[14] (Fig. 1*b*). I–A molecules were isolated from B10.A(4R) and [B10.A(4R) × B10.A(5R)]F_1 mice with monoclonal antibody 10-2.16 (Fig. 1*a*,*c*), which is unreactive with B10.A(5R) mice and putatively directed against the public antigenic specificity Ia.17 based on its pattern of reactivity (Table 1 and ref. 17). The larger (A_α) and small (A_β) chains were purified by SDS-polyacrylamide gel

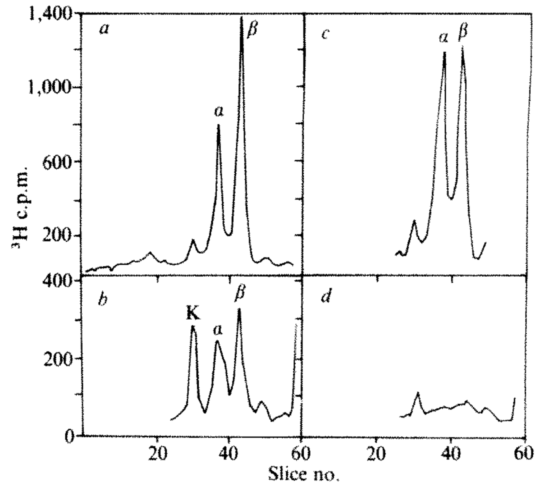

Fig. 1 SDS-PAGE profiles of I–A antigens immunoprecipitated from B10.A(4R) (*a*), B10.A(5R) (*b*) and [B10.A(4R) × B10.A(5R)]F_1 (*c*) mice. I–A antigens consist of two polypeptide chains designated α (molecular weight 37,000) and β (MW 28,000). The antiserum used to immunoprecipitate I–A antigens from B10.A(5R) mice is multispecific and also precipitates the H–2K molecule (MW 45,000). *d* Illustrates the inability of monoclonal antibody 10-2.16 to precipitate any I–A molecules from B10.A(5R) mice.

Table 1 Cytotoxic activity of reagent from 10-2.16

Spleen from:	I–A	I–E/C	Reciprocal titre
B10.BR	k	k	160
B10.D2	d	d	<10
B10.A	k	k/d	160
B10.A(4R)	k	b	160
B10	b	b	<10
B10.G	q	q	<10
B10.S	s	s	320
PL/J	u	u	160
B10.LPRIII	r	r	160
B10.M	f	f	160
B10.A(5R)	b	k/d	<10

Monoclonal antibody used to precipitate I–A subregion antigens from B10.A(4R) and [B10.A(4R) × B10.A(5R)]F_1 mice was produced by collecting and concentrating supernatants from cultures of hybridoma 10-2.16. This hybridoma was originally produced by fusing splenocytes from a CWB mouse immunized with C3H cells with the NS-1 myeloma. Cytotoxic activity was measured as described previously[32]. The resultant monoclonal antibody only lyses cells which possess the I–$A^{k,s,f,r,u}$ subregion, and is putatively directed against the antigenic specificity Ia.17 based on this pattern of reactivity[17].

electrophoresis (PAGE)[18] and tryptic peptide maps were obtained as described elsewhere[19–21]. A_α chains isolated from B10.A(4R) and B10.A(5R) mice (designated A_α^k and A_α^b, respectively) are distinguishable by their tryptic peptide maps (Fig. 2*a*), as are the A_β chains isolated from B10.A(4R) and B10.A(5R) mice (designated A_β^k and A_β^b, respectively) (Fig. 3*a*). Peptide mapping of the A_α and A_β chains immunoprecipitated from [B10.A(4R) × B10.A(5R)]F_1 mice with monoclonal antibody 10-2.16 directed against the I–A molecule of the B10.A(4R) parent (I-A^k) reveals that they consist solely of the A_β^k chain (Fig. 3*b*) and a mixture of A_α^k and A_α^b chains (Fig. 2*b*). The absence of an A_β^b chain in the immunoprecipitate is not due to the inability of these F_1 mice to express the A_β^b chain; antiserum directed against I–A^b antigens precipitates the A_β^b chain from F_1 mice.

We conclude from these results that the allospecificity Ia.17 recognized by monoclonal antibody 10-2.16 is determined by the β chain according to the following rationale: when a monoclonal reagent specific for I–A from parent 1 is used to precipitate I–A molecules from an F_1 offspring, several results are possible. If the specificity is determined only by the α chain, the α chain from parent 1 but not from parent 2 would be found in the F_1 precipitate. Conversely, if only the β chain determines the specificity, the β chain of parent 1 but not of parent 2 would be found. Finally, if both chains are responsible, both α and β chains from parent 1 and none from parent 2 would be found. Because the antibody displays specificity for the A_β^k chain and none for the α chains, we conclude that the β chain determines the antigenic specificity recognized by the monoclonal antibody. The observation that both α chains are found in the F_1 indicates that both α chains can freely associate with the A_β^k chain. Immunoprecipitation of both α chains cannot be due to their recognition by the monoclonal antibody, because then the monoclonal antibody would be expected to react with and precipitate I–A molecules from B10.A(5R) mice, which it does not (Table 1 and Fig. 1). However, we cannot rule out the possibility that the antigenic determinant recognized by monoclonal antibody 10-2.16 actually resides on the α chain and is generated when either A_α^k or A_α^b associate with the specific A_β^k chain.

Thus, only one of the two subunits of I–A subregion antigens, the β chain, has a crucial role in determining the antigenic determinant recognized by the monoclonal antibody. This, combined with studies that attribute the molecular polymorphism of the murine I–E subregion and K, D gene products, and their respective human analogues the HLA-DR[19–21] and HLA-A,B,C[22,23] antigens, to one of two subunits, makes it tempting to propose that only one chain, the β chain, is generally responsible for the alloantigenic specificities of I–A antigens. To substantiate this hypothesis, reagents against several other I–A specificities must be tested.

Assignment of the alloantigenic specificities of I–A molecules to one subunit has important functional implications. Genetic[24] and serological[25] studies suggest that T-cell recognition of allotype-specific I–A molecules on B cells and macrophages is a prerequisite for the development of optimal immune responses. If T cells perceive I–A antigens with a specificity similar to antibody, it is also possible that only the β chain determines allotype-specific recognition of I–A molecules by T cells. The free association of both α components with the A_β^k component may be interpreted to mean that both α components have a common effector function and may be substituted for one another.

In contrast to the proposal that the β subunit alone determines I–A antigenic specificities, the findings of Fatham *et al.*[26] may be construed to suggest that some antigenic specificities perceived by T cells are due to unique combinations of α and β chains. These authors found that some cell-surface antigenic determinants controlled by the MHC and recognized by T cells in mixed lymphocyte culture (MLC) reactions, are unique to F_1 animals and absent from both parental types. Although some of these specificities may be attributed to complementation of two MHC genes required for the expression of I–E molecules, as has been demonstrated by several investigators[27,28], others cannot be explained on this basis. The observation that α and β chains from an F_1 animal are capable of associating in a random manner introduces the possibility of generating antigenic specificities unique to the F_1 offspring and absent from both types, and may explain the findings of Fathman *et al.* If α and β chains can reassociate in a random fashion, F_1 animals should have four distinct sets of I–A complexes, two that are unique to the F_1 and not found on either parental types and one from each parental type. From a functional viewpoint, if I–A molecules are perceived by T cells in both MLC reactions and T–B or T–macrophage cell interactions in a similar fashion, an F_1

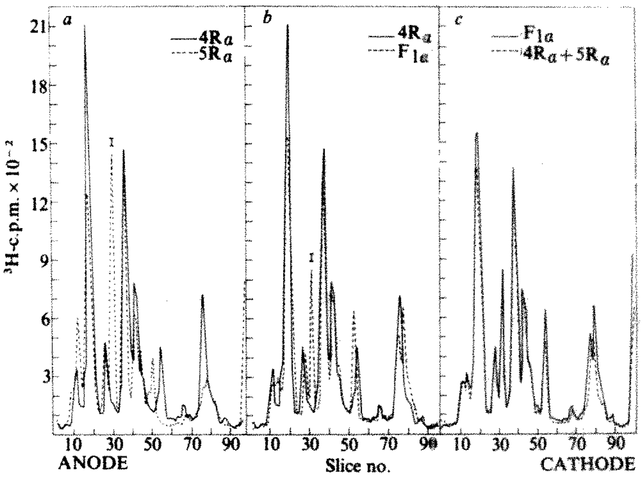

Fig. 2 Comparative tryptic peptide maps of the A_α chains immunoprecipitated from B10.A(4R), B10.A(5R) and [B10.A(4R) × B10.A(5R)]F_1 mice. The A_α chain isolated from B10.A(5R) mice (designated A_α^b) displays a peptide peak (I) that is absent from the A_α chain isolated from B10.A(4R) mice (designated A_α^k) (*a*). The peptide map of the A_α chain isolated from [B10.A(4R) × B10.A(5R)]F_1 mice displays peak I, which is unique to the A_α^b chain (*b*). Furthermore, this peptide map is virtually identical to that derived from a mixture of the A_α^b and A_α^k chains (*c*). Positional differences (1–2 gel slices) of peptides and the apparent 'splitting' of the peak near slice 80 (*c*) are due to minor variations in gel slicing.

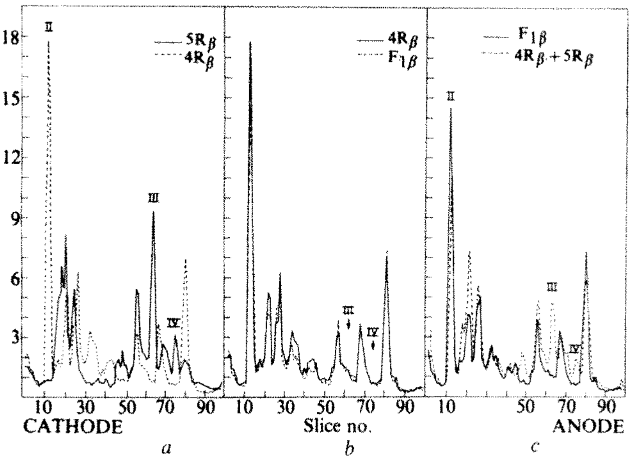

Fig. 3 Comparative tryptic peptide maps of the A_β chains immunoprecipitated from B10.A(4R), B10.A(5R) and [B10.A(4R) × B10.A(5R)]F_1 mice. The A_β chain isolated from B10.A(5R) mice (designated A_β^b) displays several unique peptides (III and IV); the A_β chain isolated from B10.A(4R) mice (designated A_β^k) also has one unique peptide (II) (*a*). The peptide maps of A_β chains isolated from [B10.A(4R) × B10.A(5R)]F_1 and B10.A(4R) mice are virtually identical (*b*). Clearly, the A_β chain isolated from [B10.A(4R) × B10.A(5R)]F_1 mice does not comprise a mixture of A_β^b and A_β^k chains, as its peptide map is different from that derived from the mixed A_β^b and A_β^k chains (*c*).

animal might be expected to possess some T cells that are capable of interacting with B cells and macrophages only from F_1 animals and not from either parental type. Although experiments by others clearly demonstrate that cells of F_1 animals can interact with cells of either parental type[29–31], functional studies designed specifically to determine the possibility of F_1 specific interactions have not been performed. It is important to discover whether such unique F_1 determinants frequently have an important role or are only found in rare cases.

The analytical method used in the present studies provides a general means of determining which chain confers the unique allospecificity on any complex consisting of multiple subunits, provided that both subunits from both parents are distinguishable and that monoclonal antibody or an operationally monospecific alloantiserum directed against the allospecificities is available. Furthermore, this method does not require retention of alloantigenicity after separation of noncovalently associated subunits to determine which subunit carries the allospecificities. Additional studies with several monoclonal antibodies directed against I-A^k and other allospecificities will enable us to assess definitively the relative contributions of the A_α and A_β polypeptides to the alloantigenicity of I-A subregion antigens.

It has recently been demonstrated[1] that in rats induced to overeat by being fed a varied and palatable diet (the 'cafeteria diet') there is a marked increase in heat production which serves to reduce, or prevent, the development of obesity. This diet-induced thermogenesis is associated with increases in sympathetic activity, and with changes in brown adipose tissue. Following cafeteria feeding, brown adipose tissue hypertrophies and exhibits increased lipolysis and an apparently greater thermogenesis in response to noradrenaline. These metabolic changes resemble those seen during non-shivering thermogenesis in cold-adapted rats, and it was proposed[1] that non-shivering thermogenesis and diet-induced thermogenesis have a similar metabolic origin which depends on the unique capacity of brown adipose tissue for thermogenesis. During non-shivering thermogenesis heat is produced in brown adipose tissue through a proton conductance pathway across the inner mitochondrial membrane that dissipates the proton gradient generated by respiration[2]. The activity of the proton conductance pathway can be modulated by purine nucleotides, and changes in the pathway seem to be related to the level of purine nucleotide binding to brown adipose tissue mitochondria. We now report results which indicate that the proton conductance pathway is augmented in cafeteria-fed rats, and suggest that it operates to dissipate their excess energy intake through diet-induced thermogenesis.

In the first experiments, the activity of mitochondrial enzymes and the effect of purine nucleotides on mitochondrial respiration were determined with brown adipose tissue of normal and cafeteria-fed animals. Groups of adult, male Sprague–Dawley rats (Charles River) were maintained on either the conventional stock diet (PRD, Christopher Hill Group) or the cafeteria diet (see refs 1, 3 for details) for up to

0028–0836/80/290274–03$01.00

20 days in a room maintained at 24 °C. As in previous studies[1], the cafeteria-fed rats overate and exhibited increased metabolic rates and an increased thermogenic response to injected doses of noradrenaline. After 10–20 days the rats were killed and the interscapular brown adipose tissue was removed and homogenized, and the total protein content and cytochrome oxidase (EC 1.9.3.1.) activity were measured. Mitochondria prepared from homogenates were also assayed for protein, and for cytochrome oxidase and α-glycerophosphate dehydrogenase (EC 1.1.1.99.5.) activity. Details of the methods used and the results obtained are shown in Table 1.

Cafeteria feeding resulted in a near doubling of interscapular brown adipose tissue (BAT) mass and total protein content. There were also large increases in the total activity of the two mitochondrial respiratory enzymes, related to a twofold increase in mitochondrial protein content of the brown adipose tissue of cafeteria-fed rats. The enzyme changes were not due to increases in specific activity (that is, activity per mg mitochondrial protein) nor to differences in the recovery of mitochondria, and indicate that the oxidative capacity of this brown adipose tissue depot increases substantially during overfeeding.

These changes resemble those seen in cold-adapted animals[4–6] where high rates of mitochondrial respiration in brown adipose tissue result from a combination of increased oxidative capacity and reduced respiratory control[2]. Respiratory control can be partially restored by incubating mitochondria in the presence of albumin but significant improvements require the further addition of purine nucleotides[7]. In the present study, respiratory rates of brown adipose tissue mitochondria from cafeteria-fed rats were 30% greater than those from control animals, even when incubated with albumin to avoid differences due to any uncoupling effect of endogenous fatty acids (Table 2). However, the addition of GDP (Sigma) resulted in a marked 'tightening' of respiratory control such that respiratory rates were decreased in both groups and the differences between them were abolished. This effect of GDP could be overcome by adding the uncoupling agent carbonyl cyanide *p*-trifluoromethoxyphenylhydrazone (FCCP, Sigma). These results indicate that brown adipose tissue mitochondria from cafeteria rats are more 'loosely coupled' than those from control rats.

Table 1 Mitochondrial enzyme activities in interscapular brown adipose tissue from control and cafteria-fed rats

	Control	Cafeteria
Weight of animals (g)	196.5 ± 3.3	190.7 ± 2.5 NS
Interscapular brown adipose tissue mass (mg)	275 ± 10	538 ± 18*
Total brown adipose tissue protein (mg)	32.4 ± 2.4	58.7 ± 4.0*
Total cytochrome oxidase activity (μmol cytochrome *c* oxidized per min per mg tissue)	19.8 ± 3.3	44.2 ± 7.1†
Mitochondrial cytochrome oxidase activity (μmol cytochrome *c* oxidized per min per total mitochondrial preparation)	5.1 ± 0.7	11.8 ± 1.5†
α-Glycerophosphate dehydrogenase activity (μmol O_2 consumed per min per total mitochondrial preparation)	0.58 ± 0.03	1.62 ± 0.19*

The animals used were aged approximately 6 weeks. Protein content of tissue homogenates and mitochondrial preparations was determined using a protein dye reagent kit with a bovine serum albumin standard (Bio-Rad). Mitochondria were prepared using the isolation procedure described by Slinde *et al.*[16]. Cytochrome oxidase activity was determined spectrophotometrically using a modification of the assay described by Yonetani and Ray[17] and α-glycerophosphate dehydrogenase activity was assayed polarographically[18]. The specific activities of the two enzymes (that is, activity per mg mitochondrial protein) were not different in the two groups but the amount of mitochondrial protein isolated was different—3.5 ± 0.3 and 7.1 ± 0.4 mg in control and cafeteria-fed groups, respectively ($P < 0.001$). Comparison of cytochrome oxidase activities in whole tissue homogenates and mitochondrial preparations indicates that the fractional yield of mitochondria was identical in both groups. Results are mean values ± s.e.m., $n = 8$. NS, Not significant ($P > 0.05$).

*$P < 0.001$; †$P < 0.01$, compared with control values.

Table 2 Respiration of mitochondria from brown adipose tissue of control and cafeteria-fed rats
